This book comprises the abstracts of the presentations for the platform and poster sessions of the 33<sup>rd</sup> Annual Meeting in North America of the Society of Environmental Toxicology and Chemistry (SETAC), conducted at the Long Beach Convention & Entertainment Center in Long Beach, California, 11–15 November 2012. The abstracts are reproduced as accepted by the Scientific Program Committee and appear in numerical order. In each abstract, the presenting author's name is underlined.

The author index cross-references the corresponding abstract numbers. Affiliation, session and keyword indices are also included.

## A Professional Society for Environmental Scientists and Engineers and Related Disciplines Concerned with Environmental Quality

The Society of Environmental Toxicology and Chemistry (SETAC), with offices in North America and Europe, is a nonprofit, professional society established to provide a forum for individuals and institutions engaged in the study of environmental problems, management and regulation of natural resources, education, research and development, and manufacturing and distribution.

Specific goals of the society are:

- Promote research, education, and training in the environmental sciences
- Promote the systematic application of all relevant scientific disciplines to the evaluation of chemical hazards
- Participate in the scientific interpretation of issues concerned with hazard assessment and risk analysis
- Support the development of ecologically acceptable practices and principles
- Provide a forum (meetings and publications) for communication among professionals in government, business, academia, and other segments of society involved in the use, protection, and management of our environment

These goals are pursued through the conduct of numerous activities, which include:

- Conduct meetings with study and workshop sessions, platform and poster presentations, and achievement and merit awards
- Publish scientific journals, a newsletter, and special technical publications
- Provide funds for education and training through the SETAC Scholarship/Fellowship Program
- Organize and sponsor chapters and branches to provide a forum for the presentation of scientific data and for the interchange and study of information about local and regional concerns
- Provide advice and counsel to technical and nontechnical persons through a number of standing and ad hoc committees

SETAC membership currently comprises more than 6000 individuals from government, academia, business, and nongovernmental organizations with backgrounds in chemistry, toxicology, biology, ecology, atmospheric sciences, health sciences, earth sciences, environmental engineering, hazard and risk assessment, and life cycle assessment.

If you have training in these or related disciplines and are engaged in the study, use, or management of environmental resources, SETAC can fulfill your professional affiliation needs.

All members receive the SETAC Globe newsletter highlighting environmental topics and SETAC activities, reduced fees for meetings, and discounts on SETAC books. All members receive online access to monthly issues of *Environmental Toxicology and Chemistry* (ET&C) and quarterly issues of *Integrated Environmental Assessment and Management* (IEAM), the peer-reviewed journals of the Society. Members may hold office and, with the Emeritus Members, constitute the voting membership.

If you desire further information, contact the Pensacola Office if you are in Latin America, Asia/Pacific, or North America or the Brussels Office if you are in Europe or Africa.

**1 Biodegradation of MC252 Oil in Marsh Sediments** R. Atlas, University of Louisville / Dept. of Biology; S. Faith, Battelle; L. Cook, Exponent; K. Murray, Exponent; K. Cerrito, Exponent, Inc.; P.D. Boehm, Exponent, Inc. / Environmental & EcoScience Group. Biodegradation of MC252 oil in marsh sediments that had varying degrees of oiling was examined at 27 sites along the Louisiana coast. Surface samples (0-2 cm) were collected in Fall 2010 and sediment cores were collected at varying distances from the shorelines in Fall 2011. The sediment cores were sectioned and aliquots at different depths were taken for chemical and microbiological (molecular) analyses. Microbial analyses using PhyloChip showed significant differences between *Spartina*, mixed mainland, and mangrove plant habitats regardless of the degree of oiling. Oil penetrated below 4 cm at eight sites with penetration to >8 cm in three cores. Compared to the oil released at the wellhead, the oil in the shoreline sediments was highly degraded as evidenced by the extensive loss (>90%) of alkanes and polycyclic aromatic hydrocarbons in the majority of the MC252 oiled sediment samples. Changes in C17/pristane, C18/phytane, C2phenanthrene/C2dibenzothiophene, C3phenanthrene/C3dibenzothiophene, total polycyclic aromatics to hopane, and total heavy polycyclic aromatics (4-6 rings) to hopane in samples having sufficient oil for analysis, showed evidence for extensive biodegradation as well as other weathering processes that had affected the oil as it moved to shore. In the cores collected in Fall 2011 there were additional losses of PAH and further changes in the ratios of alkylated phenanthrenes to alkylated dibenzothiophenes compared to surface shoreline samples that had been collected in 2010 at some of the sites, indicating that biodegradation was continuing in the sediments. Molecular analyses performed with GeoChip and high-throughput whole metagenomic sequencing indicated increased abundances of genes involved in alkane, aromatic, and cycloparaffinic hydrocarbons within oiled samples when stratified by vegetation type.

**2 Bioavailability of PAH in Fresh and Naturally/Artificially Weathered Deepwater Horizon Oil** D. Shea, North Carolina State University / Department of Biology; K. O'Neal, W. Thorsen, P. Lazaro, X. Kong, X. Xia, North Carolina State University. On 20 April 2010, the *Deepwater Horizon* offshore drilling rig in the Gulf of Mexico exploded after a blowout and sank two days later, causing the largest offshore oil spill in U.S. history. One of the ecological and human health issues associated with this spill is the potential for exposure to and accumulation of polycyclic aromatic hydrocarbons (PAH) and other oil components in the food chain and how the use of dispersants may have influenced the bioavailability of PAHs. We will update our preliminary assessment of PAH bioavailability presented at the SETAC Gulf Oil Spill Focused Topic Meeting in April 2011 with final data and conclusions of our field and laboratory experiments. We investigated the bioavailability of PAH in fresh and weathered crude to zooplankton, bivalves, and crustaceans and also tested the ability of passive sampling devices (PSDs) and standard water sampling to predict PAH bioavailability. We found that bioavailability of PAH decreased significantly with the degree of weathering and this effect was most pronounced with lower molecular weight PAH. Use of dispersant increased the bioavailability of fresh crude oil in a manner that appears to be related to the surface area-to-volume ratio of the oil droplets. Various PSD designs were tested and some were subject to a very high bias that was dependent on the presence of oil droplets or films in the water and the ability of the oil to make sustained contact with the PSD sorptive phase. Standard whole and filtered water sampling also was subject to a very high bias and like most PSD designs this bias was highly variable and dependent on the presence oil droplets and films. The potential for this bias was clearly indicated by enrichment of highly water insoluble PAH and hopanes in the sampling media. Our results provide an excellent, though incomplete, basis for determining the bioavailability of PAH as a function of weathering and the appropriateness and potential pitfalls of various sampling technologies to estimate PAH exposure and bioavailability following this oil spill, with clear lessons to be learned for monitoring future oil spills.

**3 A Comprehensive Marine Toxicity Program to Address the Potential Toxicity of Petroleum Hydrocarbons from the DWH Incident in the Gulf of Mexico** G.M. Rand, Florida International University / Ecotoxicology & Risk Assessment; P.R. Gardinali, Florida International University / Department of Chemistry & Biochemistry and SERC; B.A. Stubblefield, Oregon State University, Oregon State University / Environmental and Molecular Toxicology; M. Huddleston, ENTRIX; B.S. Echols, Virginia Tech / Department of Biological Sciences, Florida International University / Southeast Environmental Research Center; M.T. BenKinney, Exponent; O.X.

Pelz, BP / Gulf Coast Restoration Organization, BP Gulf Coast Restoration Organization / GCRO, BP / GCRO. The recent crude oil released into the Gulf of Mexico (or Deepwater Horizon Oil incident) has raised important questions relating to complex mixtures, like petroleum hydrocarbons, the exposure scenarios that are produced in water after their release and how they are assessed to determine their potential toxicity. The existing literature is limited and not consistent with respect to petroleum hydrocarbon toxicity methodology, making it difficult to compare results from different investigators. This presentation provides an overview of a comprehensive marine toxicology program designed to provide a robust empirical toxicity database to: 1) apply directly to the assessment of the potential acute and chronic effects to Gulf of Mexico biota as a result of exposures to different oil types (crude, weathered, dispersed, etc.); 2) validate existing toxicity exposure media, general methods and water systems to provide replicable data; 3) assess the potential effects of oil droplets; and the 4) potential occurrence of UV-enhanced toxicity. A multi-species trophic level testing approach is used with ecologically and economically important native test organisms as well as standard test ---organisms. The presentation will emphasize the importance of methods validation to ensure the reproducibility of results and the comparability of results from different tests. Therefore, data sets will be presented on exposure methods [types of exposures (static vs flow-through systems) and WAF preparations (oil: water ratios, high vs low energy mixing, natural vs synthetic saltwater)], and test conditions (sealed vs open test chambers).

**4 Acute toxicity and cardiac impairment of Deepwater Horizon oil on two pelagic fish species native to the Gulf of Mexico** A. Esbaugh, University of Miami, RSMAS / Rosenstiel School of Marine and Atmospheric Science, University of Texas – Austin, Marine Science Institute; E. Mager, J. Stieglitz, R. Hoenig, University of Miami – RSMAS; J. Incardona, N. Scholtz, Northwest Fisheries Science Center; D. Benetti, M. Grosell, University of Miami – RSMAS. Brood stock for two common Gulf of Mexico pelagic species, Mahi (*Coryphaena hippurus*) and Cobia (*Rachycentron canadum*), were collected off the Atlantic coast of Florida and housed at the University of Miami experimental hatchery. Both species performed natural spontaneous spawning events in captivity that yielded high quality fertilized embryos for toxicity testing. Acute toxicity to dissolved PAHs resulting from Deep Water Horizon oil was examined using a 96 h static exposure set-up, with 1 L volumes and 20 organisms per replicate. Mahi tests were performed on a matrix of oil preparations that included three different oil samples (source, artificially weathered source, and naturally weathered slick oil collected from the Gulf of Mexico) and two different preparation methods (high energy and chemically enhanced water accommodated fractions). A dispersant only test was also performed. Cobia tests on high energy preparations (slick and weathered source) were performed for the purposes of cross species comparison. LC50s for cobia and mahi and relative sensitivity will be reported. Additionally, the relative potency of high energy preparations versus chemically enhanced preparations, and of weathered oil versus source oil will be discussed, as will the results of dispersant only tests. Additional tests were performed on Mahi to investigate sub-lethal cardiac impairment (cardiac edema) at 48 h, which is a well characterized impact of PAH exposure. EC50s based on the presence of edema will also be reported and compared to LC50 data generated using the same preparations.

**5 Assessment of the chemistry and acute toxicity of fresh and weathered MC252 oils: The toxic unit approach** J. McGrath, HDR Inc; L. Faksness, B. Hansen, D. Altin, T. Nordtug, SINTEF; O. Pelz, British Petroleum; D. Di Toro, University of Delaware. WAFs prepared from oils are comprised of the water-soluble components of oil and, as such, they are mixtures of different chemicals. The chemicals of concern for toxicity assessment are typically limited to the monocyclic aromatic hydrocarbons (MAHs) and the polycyclic aromatic hydrocarbons (PAHs) which are structurally classified as Type I narcotics. The target lipid model (TLM) of narcotic toxicity demonstrates that the acute toxicities of these chemicals vary and are correlated with  $K_{OW}$  such that LC50 decreases with increasing  $K_{OW}$ . As a result, it is necessary to use the concentrations of individual chemicals, and not just the total hydrocarbon concentration (e.g., total PAH  $\mu\text{g/L}$ ), to estimate hydrocarbon toxicity. To understand the impact of weathering on oil toxicity, the toxicity of a solution at the water solubility of each component needs to be examined. For each chemical, the maximum toxicity or maximum toxic unit (TU) is equal to its water solubility divided by its water effect concentration

(e.g., LC50). Using the relationship of the solubility of oil components to log  $K_{OW}$ , it is demonstrated that chemicals with a lower log  $K_{OW}$  have a greater maximum toxicity than the chemicals with higher log  $K_{OW}$ . Weathering preferentially removes these chemicals with the lower log  $K_{OW}$  (and higher maximum toxicity) as compared to the chemicals with the higher log  $K_{OW}$  (but lower toxicity). As such, weathering decreases the toxicity. The TLM and TU approaches were applied to toxicity and chemistry data from fresh (i.e., neat) and weathered MC252 oils. The weathered oils included artificially and naturally weathered samples. The artificially weathered oil samples were generated by heating fresh oil to 150 to 300°C. The naturally weathered samples were collected in the Gulf after the Deepwater Horizon accident. In the exposures using 100% WAFs, the observed biological responses of *Acartia tonsa* (e.g., mortality) and *Skeletonema costatum* (e.g., reduced growth rate) decrease as the samples increase in weathering, demonstrating that weathering decreases toxicity. The computed TUs also decrease in the 100% WAF for the more weathered samples which is in agreement with the observed biological responses. The use of TUs allows for a correct interpretation of the observed toxicity and the effect of weathering.

**6 Genomic footprint of the Deepwater Horizon oil spill in resident killifish in the laboratory and field** A. Whitehead, University of California Davis; W. Pilcher, Louisiana State University / Department of Biological Sciences; G. Mayer, Texas Tech University / Institute for Environmental and Human Health; B.D. Dubansky, Louisiana State University / Department of Biological Sciences, Louisiana State University / graduate student; F. Galvez, Louisiana State University / Dept. of Biological Sciences. Gulf killifish (*Fundulus grandis*) are the most abundant vertebrate in coastal marsh ecological communities. Large populations of killifish inhabit Gulf-exposed marsh habitats that are at high risk of contamination from oil spilled in the Gulf of Mexico; indeed much habitat was oiled following the Deepwater Horizon oil spill. For these reasons, these killifish are strategic models for assessing contaminating oil impacts on Gulf coast marshes. We conducted a field study spanning the first four months following the oil spill and one year later, integrated with controlled laboratory exposures to experimentally-weathered oil, to characterize oil spill impacts on the coastal marsh by integrating genomic and physiological indicators of biological effects. In field studies genome expression within livers and gills of resident fish was tracked across space (contaminated and reference sites) and time (pre-oil, during oil, and after oil exposure). Genome expression was most distinct at our only field site out of six that was clearly impacted by oil, and at the peak of oil contamination documented by satellite imagery and analytical chemistry, showing a clear genomic footprint of oil exposure. Divergence in genome expression that coincides with contaminating oil is consistent with genome responses that are predictive of exposure to hydrocarbon-like chemicals and suggestive of physiological and reproductive impairment, and coincide with significant impacts on tissue morphology. Transcriptional responses following exposures to experimentally-weathered oil in the laboratory were predictive of the responses observed in the field, and coincided with damage to the DNA molecule. These studies highlight mechanisms of exposure and effects in a relevant resident species.

**7 Impacts of Deepwater Horizon oil on pelagic fish from the Gulf of Mexico – an overview of testing efforts and results** M. Grosell, RSMAS, University of Miami; A. Esbaugh, University of Miami, RSMAS / Rosenstiel School of Marine and Atmospheric Science, University of Texas – Austin, Marine Science Institute / Post-Doctoral Fellow; E. Mager, University of Miami / Rosenstiel School of Marine and Atmospheric Science / Division of Marine Biology & Fisheries; J. Stieglitz, University of Miami; R. Hoenig, D. Benetti, University of Miami / Rosenstiel School of Marine and Atmospheric Sciences; A. Roberts, University of North Texas; J. Incardona, NOAA Fisheries / Env. Conservation Division; N. Scholz, NOAA Fisheries – Northwest Fisheries Science Center. Yellowfin tuna (*Thunnus albacares*), Mahi (*Coryphaena hippurus*) and Cobia (*Rachycentron canadum*), were exposed to oils collected from the Gulf of Mexico following the Deep Water Horizon (DWH) spill in 2010. Brood stock of these three species were captured and maintained at RSMAS, University of Miami (Cobia and Mahi) or at the IATTC Achotines Laboratory, Panama (Yellowfin tuna). All brood-stock spawned spontaneously allowing for exposure of embryos beginning a few hours post fertilization. Standard toxicity tests were performed indoor under controlled light and temperature conditions on all three species. For Mahi, different oils and approaches for preparing Water Accommodated Fractions (WAFs) exhibited different potency with 48-96 hour LC50s in

terms of total polyaromatic hydrocarbons (PAHs). Natural light enhanced DWH oil toxicity to Mahi embryos and larvae suggesting that toxicity data obtained under laboratory conditions may underestimate DWH impacts on early life stages of pelagic Gulf of Mexico fish species. Mortality in young larval Yellowfin tuna and Mahi was preceded by impaired cardiac development and cardiac function, as evident from edema, shortly after hatch and at very low exposure concentrations. In addition to the observed impacts on early life stages, brief (24 hour) exposures of young juvenile Mahi (30-40 days of age) resulted in significantly impaired swimming performance. The effects levels as well as the overall, order of sensitivity to DWH oils among the three test species will be reported.

**8 Acute effects of fresh and weathered MC252 crude oil and dispersants on mollusc and echinoderm larvae** C. Langdon, Oregon State University / Coastal Oregon Marine Experiment Station; S.M. Pargee, Oregon State University; B.A. Stubblefield, Oregon State University, Oregon State University / Environmental and Molecular Toxicology. Following the Deepwater Horizon accident, a series of acute assays were carried out in which developing embryos of bivalve (Pacific oyster, *Crassostrea gigas*; Kumamoto oyster, *Crassostrea sikamea*, Gallo mussel *Mytilus galloprovincialis*) and echinoderm species (sand dollar, *Dendraster excentricus*; purple sea urchin, *Strongylocentrotus purpurata*) were exposed to samples of fresh and field-collected weathered Mississippi Canyon 252 oil. Labs tests used the water-accommodated fractions (WAF) of weathered (CTC) and fresh (Q4000 and MASS) oil samples (prepared at 1:1000 oil to water ratio), chemically-enhanced WAF (CEWAF) where Corexit 9500 was added at a 1:20 dispersant to oil ratio (based on the suppliers recommended application rate), and dispersant alone. Exposure to WAFs of fresh crude oil resulted in EC10 values (based on larval development) of 15 to 59% WAF for fresh oils. Naturally weathered CTC oil was substantially less toxic for the tested species, with EC10 values >25 or >100% for all but one of the seven studies. Under the conditions of the tests, the addition of dispersant increased toxicity in the tests of all three oil. The EC10 values for Corexit 9500 with all species in tests that met USEPA and ASTM criteria ranged from 8 to 13% (expressed as % dilutions of WAF with added dispersant). Oils with dispersant added showed similar responses to those with Corexit 9500 alone; EC10 values ranged from 0.4 to >25% WAF for Q4000/Corexit 9500 mixtures and from 7 to 13% WAF for CTC/Corexit 9500 mixtures. Observed responses were evaluated based on oil component concentrations (polynuclear aromatic hydrocarbons, saturated hydrocarbon compounds, and volatile compounds) as well as dispersant “marker” components, i.e., di-octyl-sulfosuccinate (DOSS) and dipropylene glycol n-butyl ether (DPnB). Hydrocarbon concentrations causing responses in laboratory tests will be compared with concentrations measured in “field-collected” samples at the time of the accident. Examination of the available data suggests that exposures evaluated in the laboratory toxicity tests include the most highly contaminated conditions observed in the Gulf of Mexico during the DWH incident.

**9 Spatio-temporal trends of organophosphate flame retardants in Great Lakes herring gulls, as well as Lake trout and their convergent aquatic food webs** R.J. Letcher, Carleton University / Department of Chemistry, Environment Canada / Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Ecotoxicology and Wildlife Health Division, Science and Technology Branch / Environment Canada; D. Chen, Carleton University / Chemistry, Ecotoxicology and Wildlife Health Division, Wildlife and Landscape Directorate, Science and Technology Branch, Environment Canada, National Wildlife Research Centre, Carleton University, Ottawa, ON, Canada / Department of Chemistry, Carleton University / Department of Chemistry; S. Backus, D. McGoldrick, Water Quality Monitoring and Surveillance Division, Science and Technology Branch / Environment Canada; L.T. Gauthier, Ecotoxicology and Wildlife Health Division, Science and Technology Branch / Environment Canada. From the early 1960s to present day, organophosphate (triesters) flame retardants (OPFRs) have been produced in high volumes and widely used in plastics, foams, textiles and furniture. With the phase-out of flame retardants such as polybrominated diphenyl ethers (PBDEs), the usage of certain OPFRs has increased (e.g., tris(1,3-dichloro-2-propyl) phosphate (TDCPP) and tris(1-chloro-2-propyl) phosphate (TCP)). In the present study, 15 non-halogenated, chlorinated or brominated OPFRs were analyzed for in egg pools (2010) of herring gulls from 5 colonial sites in the Great Lakes (Chantry Is. (Lake Huron), Fighting Is. (Lake Erie), Agawa Rock (Lake Superior), Toronto Harbour (Lake Ontario) and Gull Is. (Lake Michigan)),

and retrospectively over a 20 year period from 1990-2010. Of the 15 OPFRs analyzed for, TCP and tris(2-chloroethyl) phosphate (TCEP) were found in 2010 samples at concentrations ranging from 5.4 to 30.1 and 1.1 to 7.9 ng/g lipid weight (lw), respectively. For tris(2-butoxyethyl) phosphate (TBEP) and triphenyl phosphate (TPP), the concentrations ranged from n.d. to 39 ng/g and 2.1 to 8.2 ng/g lw, respectively. Spatial trends were not obvious regarding the concentrations of these OPFRs among colony sites. For TCP, TCEP, TPP and TBEP, retrospective temporal trends revealed changes to be highly variable. Eggs from the Chantry Is. had no detectable levels prior to 1998. TPP was only quantifiable in eggs from Chantry Is. and Gull Is. taken in 2008 and 2010. TBEP was quantifiable in eggs from almost every year going back to 1990; however, levels appeared to be increasing for Gull Is. and Agawa Rock up to 55 and 30 ng/g lw, respectively, in 2010. TCEP levels also appeared to be increasing for Agawa Rock and Toronto Harbour egg pools with levels of 30 to 40 ng/g lw in 2008-2010. Comparing the sum-concentrations of these four OPFRs, there were general increases for all sites over the 20 year period. Our results demonstrated that several OPFRs bioaccumulate via the diet (aquatic- and/or terrestrial-based) in gulls and are transferred to their eggs, have been in eggs (e.g. TBEP) for at least 20 years, and are present in eggs at sites throughout the Great Lakes basin. We also present data on 2010-collected Lake trout from western Lakes Erie and Ontario, a purely aquatic top predator, and examine the comparative fate and possible biomagnification of e.g., TBEP, in gulls and trout from their convergent prey species including alewife and rainbow smelt.

**10 In ovo effects of TCP and TDCP on lethality, development, thyroid hormone levels and mRNA expression in chicken embryos** A. Farhat, University of Ottawa; D. Crump, S. Chiu, K.L. Williams, R.J. Letcher, L.T. Gautier, S.W. Kennedy, Environment Canada / National Wildlife Research Centre. Tris(1-chloro-2-propyl) phosphate (TCP) and tris(1,3-dichloro-2-propyl) phosphate (TDCP) are high production volume organophosphate flame retardants used primarily in rigid and flexible polyurethane foams. They have been detected in the environment and biota, including wild avian species, but there has been little effort in measuring their toxicological and molecular effects in birds. Egg injection studies were conducted to determine the effects of TCP and TDCP on pipping success, development, thyroid hormone (TH) levels, and hepatic messenger RNA (mRNA) expression levels of genes associated with xenobiotic metabolism and the TH pathway in domestic chicken embryos. Neither compound reduced pipping success; however, TCP exposure significantly delayed pipping time by 13 and 17 hours at the two highest doses (10,000 and 50,000 ng TCP/g egg), respectively, and reduced tarsus length at 50,000 ng/g. TDCP exposure caused a dose-dependent decrease in head plus bill length, and significant decreases in embryo mass and gall bladder size at 50,000 ng/g. Free plasma T4 levels for TCP-exposed embryos did not change; however, a significant decrease in plasma T4 levels was observed in embryos exposed to 10 000 ng TDCP/g. Neither compound affected free plasma T3 levels or total T4 content in thyroid glands. There was a dose-dependent increase in type I deiodinase mRNA expression following TCP exposure, whereas liver fatty-acid binding protein and cytochrome P450 (CYP) 3A37 mRNA levels were induced only at the 50,000 ng/g dose. CYP3A37 and CYP2H1 mRNA levels were induced in liver tissue of embryos exposed to TDCP. THs play a crucial role in initiating hatching of precocial birds; however, the delay in pipping and decreased growth of TCP-exposed embryos was not accompanied by changes in TH levels. The effects of TDCP on growth, gall bladder development and plasma T4 levels highlight a phenotypic response to exposure. Further research on TCP- and TDCP-mediated effects in birds is warranted in order to understand their mechanisms of toxicity and better assess the health effects associated with exposure for the purpose of risk assessment.

**11 Early Embryogenesis is Susceptible to Developmental TDCP Exposure** S.P. McGee, University of South Carolina / Environmental Health Sciences; E.M. Cooper, Duke University / NSOE; H.M. Stapleton, Duke University / Nicholas School of the Environment; D.C. Volz, University of South Carolina / Department of Environmental Health Sciences. Chlorinated phosphate esters (CPEs) are widely used as additive flame retardants for low-density polyurethane foams, and have frequently been detected at elevated levels within environmental media. The objectives of this study were to begin investigating the potential developmental toxicity of four CPEs commonly used in polyurethane foam – tris(1,3-dichloro-2-propyl) phosphate (TDCP), tris(2-chloroethyl) phosphate (TCEP),

tris(1-chloro-2-propyl) phosphate (TCP), and 2,2-bis(chloromethyl) propane-1,3-diyl-tetrakis(2-chloroethyl) bis(phosphate) (V6). Using zebrafish as an animal model, we first demonstrated that (1) static exposure from 5.25 to 96 hpf to TCEP, TCP, or V6 concentrations as high as 50  $\mu$ M resulted in no significant effects on embryonic development or survival; (2) static exposure from 5.25 to 96 hpf to concentrations of 8  $\mu$ M TDCP and above resulted in a significant increase in mortality ( $LC_{50}$  = 8.5  $\mu$ M) compared to vehicle controls; (3) relative to exposures initiated at 5.25 hpf, TDCP exposures initiated at the start of cleavage (0.75 hpf) or restricted to cleavage alone – 0.75 hpf (2-cell) to 2 hpf (64-cell) – resulted in a significant decrease in the concentration required to induce a similar magnitude of toxicity; and (4) embryos surviving static TDCP exposure exhibited a range of abnormal phenotypes that were first visible at initiation of the hatching period (48 hpf). Following characterization of TDCP toxicity, we showed that TDCP uptake and BDCP formation were not associated with enhanced toxicity following exposures that included the cleavage period of development. Moreover, TDCP exposure did not result in obvious impacts on cell cycle, overall embryo size, or cell morphology during cleavage, suggesting that TDCP mediates toxicity at the sub-cellular- or genomic-level during this stage of embryogenesis. Finally, as TDCP-specific genotoxicity assays have largely been negative *in vivo* and zygotic genome remethylation is a key biological event during cleavage, we investigated whether TDCP altered the status of genomic DNA (gDNA) methylation, and showed that normal gDNA methylation at the end of cleavage (2 hpf) was absent in TDCP-treated embryos. Overall, our findings suggest that the cleavage period is susceptible to TDCP-induced delays in remethylation of the zygotic genome, a mechanism that may be associated with enhanced developmental toxicity following initiation of TDCP exposure at the start of cleavage.

**12 The Flame Retardant  $\beta$ -1,2-Dibromo-4-(1,2-dibromoethyl)cyclohexane ( $\beta$ -TBECH): Fate, Fertility and Reproduction in American Kestrels (*Falco sparverius*)** K. Fernie, Environment Canada / Ecotoxicology and Wildlife Health, Wildlife and Landscape Science Directorate, Science and Technology Branch; S.C. Martenson, McGill University / Avian Science and Conservation Centre; L. Graham, University of Guelph / Department of Animal and Poultry Science; S. Kimmons, McGill University; G. Tomy, Department of Fisheries & Oceans Canada; V.P. Palace, Department of Fisheries & Oceans Canada, Stantec Consultants; I. Ritchie, McGill University; L. Gauthier, Environment Canada; R.J. Letcher, Carleton University / Department of Chemistry, Environment Canada / Science and Technology Branch, Ecotoxicology and Wildlife Health Division. Breeding pairs of captive American kestrels (*Falco sparverius*) were exposed via diet during reproduction to an environmentally relevant concentration of  $\beta$ -1,2-dibromo-4-(1,2-dibromoethyl)cyclohexane ( $\beta$ -TBECH). The  $\beta$ -TBECH isomer was injected into the food source at a daily dosing concentration of 0.239 ng/g kestrel/day (22 pairs); control birds were exposed via diet to the safflower oil vehicle only (24 pairs). The males from eight pairs in each group were exposed for four weeks and sacrificed for testicular analysis; the remaining pairs completed their breeding cycle, with exposure ceasing at the end of incubation (82 days).  $\alpha$ - and  $\beta$ -TBECH appeared to be rapidly metabolized and/or eliminated from fat, liver and plasma samples; both isomers and potential hydroxylated metabolites of  $\beta$ -TBECH (plasma) were undetected. Notwithstanding, compared to controls, pairs exposed to  $\beta$ -TBECH laid fewer eggs ( $p = 0.019$ ) that were lighter (successful eggs:  $p = 0.009$ ). Exposed pairs also demonstrated poorer egg fertility ( $p = 0.035$ ) although testis mass and the number of seminiferous tubules containing final spermatids were similar among males. Reductions in egg production and fertility resulted in decreased hatching success ( $p = 0.023$ ). The  $\beta$ -TBECH-exposed pairs also produced fewer males overall ( $p = 0.009$ ), which may have been related to the increased estradiols maternally deposited in the first egg ( $p = 0.039$ ). These findings demonstrate that  $\beta$ -TBECH may be detrimental for breeding in wild birds receiving similar exposure levels.

**13 In Vitro Screening, and use of an Animal Model, the Zebra Finch, to Identify Possible Endocrine Disrupting Effects of TBECH** H. Currier, Simon Fraser University / Biological Sciences; L.I. Wong, Simon Fraser University / Department of Biological Sciences; J. Elliott, Environment Canada / Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada / Wildlife Toxicology, Environment Canada / Canadian Wildlife Service; T. Beischlag, Simon Fraser University / Health Sciences; T. Williams, Simon Fraser / Biology. Many brominated flame retardants (BFRs) can be classified as endocrine disrupting compounds.

Various toxicological effects in both humans and animals have been reported. TBECH (1,2- dibromo-4-(1, 2-dibromoethyl) cyclohexane), has recently been detected in the environment and biota, but very little is known of its environmental impacts. To identify whether or not TBECH has any endocrine disrupting capabilities, it was run through an *in vitro* screening process that included real-time PCR techniques in two different cell lines (human ECC-1 endometrial carcinoma, and human LNCaP prostate cancer cells). We were interested in whether or not TBECH affected the expression of human hormone receptor-regulated target genes. Cells were treated with environmentally comparable levels of TBECH alone and in combination with the respective steroid hormones to determine if the compound acts as an agonist, antagonist, or amplifies the effects of the hormones. We investigated the effects of the TBECH diastereomers ( $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\delta$ ) on mRNA and protein accumulation of the prostate-specific antigen (PSA) and prostate-specific membrane antigen (PSMA) and AR protein levels in the human prostate cancer cell line, LNCaP. TBECH  $\gamma/\delta$  was shown to relieve R-1881-induced repression of PSMA expression. However, TBECH  $\alpha/\beta$  alone significantly increased mRNA accumulation of PSMA while TBECH  $\gamma/\delta$  in combination with R1881 further repressed PSMA mRNA accumulation. At the protein level, all four TBECH diastereomers at both 1  $\mu$ M and 10  $\mu$ M relieved repression of PSMA expression induced by R1881, which was inconsistent with our mRNA accumulation results. Furthermore, we found that TBECH  $\gamma/\delta$  induces protein accumulation of AR similar to R1881. To look at how these results might affect growth and development in an animal model, TBECH was then tested in zebra finches. Finch embryos were exposed to TBECH via *in ovo* dosing procedures, and their growth and development was measured to fledging. No significant effects on growth or survival of offspring were observed, however analysis of tissue samples at various growth stages suggests that TBECH may be metabolized too quickly to cause long-term effects. Collectively, these results demonstrate that these chemicals may not have the same properties as classic agonists of the AR but may affect AR levels by up-regulation.

**14 PBDE Metabolites Disrupt the Thyroid System and Impair Development in Embryonic Zebrafish (*Danio rerio*)** L.J. Macaulay, L.V. Dishaw, W. Dong, H.M. Stapleton, Duke University / Nicholas School of the Environment. Polybrominated diphenyl ether (PBDE) flame retardants are biotransformed by mammals into hydroxylated PBDEs (OH-BDEs). These metabolites are known to have thyroid disrupting effects, such as competitive binding to thyroid transporter proteins and nuclear receptors, likely due to their strong structural resemblance to endogenous thyroid hormones. Previous studies have demonstrated that OH-BDEs have significant acute toxicity in zebrafish embryos; however the modes of action are unclear. In addition, our laboratory has demonstrated that OH-BDEs inhibit thyroid deiodinase and sulfotransferase activity. To follow-up on these studies, we examined the effects of several OH-BDE congeners in embryonic zebrafish. Zebrafish embryos were exposed to either aqueous 6-OH-BDE-47, 5-OH-BDE-47, 3-OH-BDE-47, or BDE-47 from 4 hours post fertilization (hpf) to 5 days post fertilization (dpf) at concentrations ranging from 1 nM-10  $\mu$ M. Embryos or larvae were evaluated daily for lethality, abnormality, and hatching success. Whole mount *in situ* hybridization was performed on embryos exposed to 100 nM 6-OH-BDE-47 to examine mRNA expression of Deiodinase (DI) I and II. Exposure to  $\geq 1 \mu$ M 6-OH-BDE-47 resulted in complete mortality after 24 hpf. Delayed hatching and reduction in pigmentation were observed in fish at doses tested in the nanomolar range (100 nM-250 nM) with severe developmental delays at concentrations  $\geq 100$  nM. The  $LC_{50}$  value was calculated to be 143 nM. The most common phenotypes observed in abnormal fish were a reduction or delay in development of melanophores associated with pigmentation, curvature of the spine, tail deformities, and edema of the pericardial and abdominal regions. A significant increase in type 1 DI expression was seen in midbrain of embryos that were treated with 6-OH-BDE-47 relative to control fish at 24hpf, and while not significant, there was a suggestion of an increase in type 2 DI ( $p=0.07$ ). There was also a significant increase of type 1 DI expression in embryos exposed to 100 nM BDE-47. These results indicate that exposure to relatively low levels of OH-BDEs can alter zebrafish embryonic development. The mechanism driving the observed developmental effects may be related to disruption of the thyroid system, specifically deiodinase enzymes. Ongoing studies will measure the accumulation of these chemicals and thyroid hormone levels in embryos using LC-MS-MS and gene expression in tissues.

**15 Levels of Non-Polybrominated Diphenyl Ether Halogenated Flame Retardants in Residential House Dust Samples and Firehouse Dust Samples in California** F.R. Brown, Department of Toxic Substances Control / Environmental Chemistry Laboratory; T. Whitehead, University of California Berkeley / School of Public Health; J. Park, Department of Toxic Substances Control / Environmental Chemistry Laboratory; C. Metayer, P.A. Buffler, University of California Berkeley / School of Public Health; M. Petreas, Department of Toxic Substances Control / Environmental Chemistry Laboratory. Because of concerns over their toxicity, PBDEs are being phased out of production, and other halogenated flame retardants (HFRs) are being substituted. However, there are data to suggest that these HFRs are also toxic, and like PBDEs, are found worldwide. This raises questions about the use of HFRs and the potential for humans to be exposed to them. One potential exposure pathway for many environmental contaminants is through dermal contact with or incidental ingestion of house dust. Our laboratory is measuring the levels of 13 HFRs in dust from both residences and fire house living quarters in California. Methods and Materials Dust samples were collected from the vacuum cleaner bags of homes participating in the Northern California Childhood Leukemia (NCCL) study, and a study of California firehouses. NCCL study samples were collected from 2001 – 2007, and again in 2010. Firehouse dust samples were collected in 2010 and again in 2011. Samples from both studies were subjected to extensive cleanup and analyzed using high resolution gas chromatography/mass spectrometry for PAHs, PCBs, and PBDEs, as well as HFRs. Thirteen HFRs were measured: allyl 2,4,6-tribromophenyl ether (ATE); a- and b-tetrabromoethylcyclohexane (a-,b-TBECHs); pentabromotoluene (PBT); pentabromoethylbenzene (PBEb); hexabromobenzene (HBB); 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE); 2,3-dibromopropyl 2,4,6-tribromophenyl ether (DPTE); 2-bromoallyl 2,4,6-tribromophenyl ether (BATE); bis(2-ethylhexyl)tetrabromophthalate (TBPH); 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB); and decabromodiphenylethane (DBDPE); and Tris(1,3-dichloro-2-propyl) phosphate (TDCPP). Results and Discussion Unlike what we observed for PBDEs, these preliminary results (9 of 59 NCCL samples, 8 of 23 Firehouse samples) for HFRs show roughly comparable levels in both house and firehouse dust. All analytes, except for ATE, were detected and TBB, BTBPE, TBPH, and DBDPE were the most abundant analytes. Similar to PBDEs, the levels of TBB, BTBPE, TBPH, and DBDPE in CA house dust are higher than levels found in house dust in the Boston, MA area. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

**16 Photolytic and microbial debromination of BDEs in San Francisco Bay** L.A. Rodenburg, Rutgers, the State University of New Jersey / Department of Environmental Sciences, Rutgers University / Department of Environmental Sciences; B.K. Greenfield, University of California, Berkeley, University of California, Berkeley / Berkeley Center for Green Chemistry; S. Klosterhaus, D. Yee, San Francisco Estuary Institute. Brominated diphenyl ethers (BDEs) are a class of flame retardants that have been classified as persistent organic pollutants under the Stockholm Convention and are targeted for phase-out. Despite their classification as persistent, BDEs undergo debromination in the environment, via both bacterial and photolytic pathways. We examined concentrations of 24 BDE congeners in 233 sediment samples from San Francisco Bay using a factor analysis technique called Positive Matrix Factorization (PMF). PMF analysis revealed five factors, two of which were dominated by congeners with two or three bromines, indicating that they appear to be related to debromination processes. One of the factors was dominated by BDE 15 (4,4'-dibromo diphenyl ether), which is a major product of the photolytic debromination of heavier congeners, and therefore appears to indicate photolysis. The other factor contained high proportions of BDE 7 (2,4-dibromo diphenyl ether) and BDE 17 (2,2',4-tribromo diphenyl ether). Because BDE 7 and BDE 17 have been observed as products of microbial debromination of heavier congeners, this factor appears to represent anaerobic microbial dehalogenation. Together, these two debromination factors represent about 8% of the mass in the data matrix, suggesting the BDEs undergo measurable degradation in San Francisco Bay sediment.

**17 An Integrated Approach Toward Understanding the Environmental Fate, Transport, Toxicity and Occupational Health Hazards of Nanomaterials** V. Grassian, University of Iowa / Department of Chemistry. Nanoparticles, the primary building blocks of many nanomaterials, may

become suspended in air or get into water systems, e.g. drinking water systems, ground water systems, estuaries and lakes etc. Therefore, manufactured nanoparticles can become a component of the air we breathe or the water we drink. One important issue in understanding the environmental fate, transport, toxicity and occupational health hazards of nanoparticles is in characterizing the nature and state of nanoparticles in air, water or in vivo. For the nanoparticles of interest in these studies, metals and metal oxides, it can be asked: (i) will metal oxide and metal nanoparticles be present in air or water as isolated particles or in the form of aggregates? (ii) will metal oxide and metal nanoparticles dissolve in aqueous solution or in vivo? and (iii) under what conditions will metal oxide and metal nanoparticles aggregate or dissolve? As the size regime will be very different depending on the state of the nanoparticles, as dissolved ions, isolated nanoparticles or nanoparticle aggregates, these questions are important to address as it impacts the size regime that needs to be considered or modeled in for example environmental transport or lung deposition models. Furthermore, the effect on biological systems including nanoparticle-biological interactions and toxicity will depend on the state of nanoparticles. In the studies discussed here, macroscopic and molecular-based probes that includes quantitative solution phase adsorption measurements, molecular based probes, light scattering and zeta-potential measurements to investigate the behavior of nanoparticles in aqueous suspensions. We have focused on several different metal and metal oxide nanoparticles including Fe, Ag, Zn, Cu, Ce and Ti. Some of our newest results which focus on aggregation and dissolution, including detailed size-dependent studies, in the presence and absence of organic acids will be discussed. This research is beneficial as it significantly contributes to the growing database as to the potential environmental and health implications of nanoscience and nanotechnology and how nanomaterials will behave in the environment and impact human health.

#### 18 Development of an In Vitro Test and a Prototype Model to Predict Cellular Penetration of Nanoparticles

Y. Chen, Georgia Institute of Technology; D. Capco, Arizona State University; Z. Chen, University of Puerto Rico. Concerns regarding the safety and health effects of engineered nanomaterials arise alongside the booming nanotechnology. This year, we investigated the toxicity mechanisms of selected nanoparticles (NPs) on a variety of organisms. 1) We examined the toxicity of metal oxide NPs to *E. coli* cells; the results showed that the cytotoxicity was quantitatively correlated with the reactive oxygen species (ROS) generation by NPs. The ROS generation mechanism was further elucidated by comparing the electronic structures of the metal oxides with the redox potentials of various ROS generation. 2) We tested the NP toxicity on *Paramecium* and found that surface interactions between NPs and cell surface largely affected the toxicity of metal oxide NPs to *Paramecium*. 3) The toxic effects of different sized hematite NPs on intestinal epithelia were examined and the results indicated that the epithelial integrity was affected by disruption of epithelial structures (e.g. apical microvilli) and cell-cell junctions. Epithelial integrity was also affected at the genetic level as shown by differential expression of genes related to cell junction maintenance, which was assessed by microarray analysis. 4) We explored the potential genotoxicity of NPs by investigating the interactions of NPs (e.g. quantum dots, hematite and silver NPs) with single DNA molecules using scanning probe techniques. DNA conformation was altered after the exposure to NPs with the formation of DNA condensates and DNA loops. The interaction energy between NPs and DNA molecules was computed, using the surface element integration (SEI) approach, to predict the affinity of NPs to DNA. The computational predictions agreed well with the binding phenomena observed by atomic force microscopy (AFM). This work should provide unique insights into the toxic effects of engineered nanomaterials at the cellular level and genetic level.

#### 19 Differential Impacts of Hydroxyl Radical and Singlet Oxygen on the Surface Chemistry and Colloidal Stability of Carboxylated Carbon Nanotubes

X. Qu, Q. Li, Rice University. Carbon nanotubes (CNTs) generate reactive oxygen species (ROS) under solar irradiation, which was hypothesized to cause CNT photochemical transformation in aquatic systems. The resulting changes in surface chemistry are expected to greatly affect their environmental fate and transport. This study investigates the impacts of two major ROS generated by CNTs, hydroxyl radical and singlet oxygen, on the surface chemistry of CNTs. Carboxylated multi-walled carbon nanotubes were exposed to hydroxyl radical and singlet oxygen respectively for varying periods of time. The resulting CNT samples were characterized using X-ray photoelectron spectroscopy in conjunction with

chemical derivatization to determine the evolution of major surface oxygen-containing functional groups. Hydroxyl radical and singlet oxygen were found to have differential impacts on CNT surface chemistry. Hydroxyl radical preferentially reacts with the oxygen-containing functional groups, mainly carboxyl groups, resulting in reduced surface oxygen concentration. On the contrary, singlet oxygen mainly reacts with the graphitic carbon, adding oxygen on the CNT surface. Raman spectrum analyses suggest both ROS create more defects on the CNT surface. The reactions of CNTs with both ROS significantly changed the colloidal stability of CNTs in water. Hydroxyl radical reduced the stability of carboxylated CNTs, while singlet oxygen enhanced its stability as measured by sedimentation experiments. This is consistent with previous findings that CNTs with higher surface oxygen content are more negatively charged and therefore more stable in the aqueous phase. These results suggest that solar irradiation induced ROS, either naturally occurring (e.g., formed by NOM) or self-generated by CNTs, play an important role in the environmental fate and transport of CNTs. These reactions may lead to photochemical degradation of CNTs.

#### 20 Effects of Surface Oxides on the Behavior of Carbon Nanotubes and their influence on the Mobility of Contaminants in Aquatic Environments

J. Yang, Johns Hopkins University / Department of Geography and Environmental Engineering; B.A. Smith, J.L. Bitter, D.H. Fairbrother, Johns Hopkins University / Department of Chemistry; W.P. Ball, Johns Hopkins University / Department of Geography and Environmental Engineering. Oxidized multi-walled carbon nanotubes (O-MWCNTs) are commercially available materials that will be increasingly found in natural waters, where their fate is important to understand in contexts of subsurface transport and engineered filtration. In this work our interest is in the transport and retention of both O-MWCNTs and co-occurring contaminants that adsorb to the O-MWCNTs. Our project therefore includes studies of both transport and sorption. In regard to transport through porous media, deposition processes are well understood for spherical particles moving in clean beds of spherical "collectors"; however, the associated theory has not yet been well tested for extremely high-aspect nano-materials such as O-MWCNTs. We have studied the transport and deposition of O-MWCNTs in well-defined silica-based media as a function of MWCNT surface oxidation and with varying aquatic chemistry. Temporal breakthrough curves and spatial retention profiles were obtained and evaluated using numerical models of particle transport. Fitting such models to both spatial and temporal data allows us to explore the relevance of current theory to MWCNTs and to also explore alternative modeling approaches. In regard to adsorption, our study has included batch isotherm work using both naphthalene and  $\text{Zn}^{2+}$  with O-MWCNTs as sorbents, toward understanding how such sorption can lead to facilitated transport or retention of the dissolved species during flow through porous media. For both contaminants, non-linear adsorption isotherms were fit to the data and effects of solution chemistry were observed to follow predictable trends. Complications were discovered, however, with regard to the impact of solid-to-liquid ratio and aggregation state. These issues are still under investigation. With independent understanding of deposition, transport, and co-contaminant adsorption (to both O-MWCNTs and media solids), we are able to parameterize a transport model that includes synergistic or antagonistic effects of O-MWCNTs on chemical pollutant transport. In addition, the presence of some co-solutes such as natural organic matter (NOM) can have dramatic effects on O-MWCNT properties, and related studies are underway. Although we expect the NOM-related phenomena will be more difficult to numerically model, the experimental results should provide valuable insight into combined transport under complex realistic conditions.

#### 21 Elucidating the mechanisms by which nanoparticles interact with membrane receptors and enter mammalian cells

R.R. Garner, Clemson University / Institute of Environmental Toxicology (CU-ENTOX), Clemson University / Institute of Environmental Toxicology; W.S. Baldwin, Clemson University / Institute of Environmental Toxicology; A.S. Mount, Clemson University / Department of Biological Sciences; S.J. Klaine, Clemson University / Institute of Environmental Toxicology (CU-ENTOX), Clemson University / Institute of Environmental Toxicology (ENTOX), Clemson University / Institute of Environmental Toxicology (ENTOX). There are currently over 1000 consumer products on the market that contain or utilize nanomaterials, and while these materials have been shown to cross cellular membranes, little research has examined the processes by which this occurs. Previously, we reported on the effects of particle

size, shape, and surface chemistry on cellular uptake of gold nanoparticles. The goal of this project was to characterize the mechanism of cell uptake for particle-serum protein complexes. Particles were characterized by TEM, DLS, UV-vis, and zeta potential in both their stock solutions as well as the exposure media. A549 carcinomic human alveolar cells were plated in 12-well plates at 100,000 cells per well and exposed to 1 mg/L gold for 0.5, 1, 1.5, and 2 hours. Fetal bovine serum (FBS) and Bovine Serum Albumin (BSA) were used as protein sources. Treatments varied by the amount and kind of protein source. Bioaccumulation of nanoparticles at each time point was quantified by inductively coupled plasma-mass spectrometry (ICP-MS), and movement was visualized through environmental scanning electron microscopy. Particle uptake was inversely related to FBS concentration ( $R^2=0.87$ ,  $p < 0.001$ ). Conversely, particle uptake increased as a function of BSA concentration ( $R^2=0.89$ ,  $p < 0.001$ ). This data suggests that albumin, one of a vast array of components in FBS, is associated with the transport of particles across membranes, and that other components of FBS may inhibit uptake due to their competition for particle complexation and inability to interact with membrane bound receptors. Particle uptake decreased when exposed in calcium free media, supporting the role of calcium in particle uptake. Cells were further exposed in ATP and potassium depleted media to determine if receptor mediated endocytosis was involved particle uptake. Finally, membrane receptors TGF- $\beta$ , megalin, and cubilin, which are known to interact with albumin, were inhibited and bioaccumulation was examined to further explore the mechanisms of nanoparticle uptake in cells. This research provides fundamental information on the interactions of nanoparticles with cells. Further, the utility of this high-throughput bioassay to screen large number of nanoparticles will facilitate future risk assessment endeavors.

**22 Environmental transformation and biological fate of fresh and aged cerium oxide nanoparticles** M. Morishita, The University of Michigan / Environmental Health Sciences; O. Joliet, The University of Michigan / School of Public Health, University of Michigan / Environmental Health Sciences, School of Public Health; D. Li, The University of Michigan / Environmental Health Sciences; M. Wooldridge, E. Eagle, E. Bumbalough, The University of Michigan / Department of Mechanical Engineering; J. Wagner, J. Harkema, Michigan State University / Department of Pathobiology and Diagnostic Investigation; C. Emond, University of Montreal. Cerium oxide ( $\text{CeO}_2$ ) has been used in petroleum refining and automotive catalytic converters, and  $\text{CeO}_2$  nanoparticles (NPs) are increasingly being employed as an additive to promote diesel fuel combustion in other countries. However, little is known regarding the mechanisms of transformation of  $\text{CeO}_2$  NPs in the atmosphere or their biological fate. The overall objective of our project is to improve our understanding of environmental exposure-dose pathways of  $\text{CeO}_2$  NPs. Our Specific Aims are: (1) characterize environmental transformation and physicochemical properties of aged  $\text{CeO}_2$  NPs using their interactions with UV radiation and ambient air co-pollutants, and compare them to freshly-combusted  $\text{CeO}_2$  NPs; (2) determine the biological fate of freshly-combusted and aged  $\text{CeO}_2$  NPs, comparing the concentrations in blood and target organs resulting from animal inhalation and intratracheal exposures; and (3) develop and evaluate a Physiologically Based Toxicokinetic (PBTK) model of  $\text{CeO}_2$  NPs to identify the main factors affecting translocation and distribution of  $\text{CeO}_2$  NPs in the body. We are currently conducting detailed physicochemical characterization of freshly-combusted  $\text{CeO}_2$  NPs and will next measure the degree of photochemical transformation during interactions with UV radiation and air co-pollutants. We will then conduct animal inhalation and intratracheal instillation exposure studies, and measure  $\text{CeO}_2$  NP concentrations in blood and multiple organs. Physicochemical characterization and the progress on animal exposure studies will be presented. The project will provide new insights into physicochemical transformation of  $\text{CeO}_2$  NPs in the atmosphere, biological fate and mass balance of  $\text{CeO}_2$  NP distribution via inhalation exposure routes, and the first PBTK model of environmentally relevant  $\text{CeO}_2$  NP inhalation exposure.

**23 Flexible Poly(amic) Acid Membrane Captures, Isolates & Simultaneously Detects Engineered Nanoparticles** W. Sadik, State University of New York at Binghamton / Chemistry Department, State Univ. of New York at Binghamton / Professor of Chemistry; N. Du, State University of New York-Binghamton / Chemistry; V. Okello, State University of New York-Binghamton / Department of Chemistry. The goal of this project is to develop nanocavity sensor (category II) arrays for the isolation, detection

and quantitation of engineered nanoparticles (ENPs) in complex environmental matrices. There is urgent demand for rapid screening methods to isolate, detect, and monitor engineered nanomaterials in the environment. Conventional methods for characterizing nanomaterials such as transmission electron microscopy, scanning electron microscopy and atomic force microscopy tend to be bulky and inadequate for field & rapid screening of free nanomaterials<sup>1</sup>. At SUNY-Binghamton, we have developed a new class of nanostructured poly(amic acid) -PAA-membranes that are conductive and electroactive by preventing its imidization to polyimide, while retaining its carboxylic acid and amine functionalities<sup>2-4</sup>. We have studied the effect of composition and microstructure on the optical and electrochemical properties of PAA hybrid composites. The uniqueness of PAA lies in its excellent physical and chemical properties: transparency, flexibility, electrical conductivity, and accessibility to forming large-area device. During the reporting period, our Group discovered that this new class of flexible, stand-alone membranes could be successfully used as both sensors and nanofilters. A new nanofilters device based on PAA membranes is hereby introduced. The nanofilters were derived from phase-inverted, copolymers of PAA and other polymers, with the surface and pore sizes systematically controlled by varying the conditions of the synthesis. This presentation will focus on the use of PAA membranes for simultaneous removal and electrochemical detection of silver nanoparticles, quantum dots and titanium dioxide nanocrystal from food supplements and environmental samples.

**24 Qualification and quantification of engineered nanoparticles in municipal wastewater systems** S. Choi, University of Delaware / Civil and Environmental Engineering; J. Eichhorn, M.V. Johnston, University of Delaware / Chemistry and Biochemistry; C. Huang, University of Delaware / Civil and Environmental Engineering. In spite of the mass effort focused on the development of engineered nanoparticles (ENPs), the amount of discharge into and the effect of ENPs on the environment are still yet to be known. This mainly can be attributed to the technical difficulties involved in the isolation and detection of ENPs in water and wastewater. This lack of technique for the study of free ENPs in wastewater treatment plants has prompted us to carry out the following investigation. The main focus of the research was on developing an appropriate methodology for detecting the distribution of engineered nano particles in municipal wastewater treatment systems. Sludge was sampled from various points in several regional municipal wastewater treatment facilities including the city of Wilmington, DE, Philadelphia, PA, Baltimore, MD, and Washington DC. The sludge samples, upon collection, were first cleaned using advanced oxidation process, by autoclaving in the presence of hydrogen peroxide, to remove the organic and biological constituents. The organic-free sludge samples were further cleaned using dialysis to remove salts. The remaining materials, mostly inorganic by nature, are further characterized for physical and chemical properties as to identify and quantifying the ENPs. Scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) were used to gain information on the type, size, and chemical composition of the ENPs. Inductively coupled plasma optical emission and mass spectroscopy (ICP-OES and ICP-MS) technique were used to identify and quantified the ENPs. Additionally, scanning mobility particle sizer (SMPS) coupled with LiquiScan NP nebulizer and condensation particle counter (CPC) was used to classify the particle size of ENPs. Results showed the presence of titanium, zinc, iron, and aluminum nanoparticles throughout the entire wastewater treatment systems, namely, secondary influents, aeration tank, secondary effluents and sludge. Concentration of metallic ENPs up to a level of 600 mg/kg -dried sludge was observed. Results also showed that the ENPs in the sludge had an average diameter of 10-20 nm and the particle size decreased with the degree of dilution with water indicating the aggregation nature of the ENPs in the sludge matrix. The number concentration also increased as the degree of dilution increased, which confirmed the destabilization of aggregates upon dilution.

**25 Exposure pathways for personal care products** D. Mackay, Trent University, Trent University / Environmental Studies; L. Hughes, Trent University / Environmental Studies. Exposure pathways to Personal Care Products (PCPs) are fundamentally different in nature from those of most conventional widely dispersed organic substances such as organo-chlorines and PAHs. The PCP ingredients may be applied directly to humans both outdoors and in the limited ventilation conditions indoors resulting in a significant pulse of exposure, dermally and by inhalation. Ingredients used domestically may be discharged to waste water treatment systems resulting

in measurable levels in treatment plants, in aquatic receiving ecosystems such as rivers and in sludges applied to soils. It is argued that there is a need to quantify these personal and environmental pathways to provide a picture of the relative magnitudes of the key exposure routes. To accomplish this four sets of data are required: (1) per capita usage information, (2) accurate partitioning and reactivity data, (3) results from well designed monitoring programs and (4) predictions of fate and pathways of exposure from mass balance models. Suitable models are described and the need for complementary uncertainty analyses is emphasized. The aim is to achieve consistency between analytical results and model predictions that are a sound basis for risk assessment, improved ingredient selection and possible regulation. This suggested assessment strategy is illustrated by a case study of the cyclic methyl siloxane, D5. This PCP has been the subject of recent risk assessments by Health Canada and Environment Canada and an independent Board of Review. The findings illustrate the need for credible and quantitative determination of exposure pathways based on the four components outlined above. Only then can estimates of toxicity or adverse effect levels be exploited to provide a meaningful assessment of risk.

## **26 ScenAT: a geo-referenced exposure model for assessing the aquatic risk of personal care ingredients in Asia**

R. Vamshi, C.M. Holmes, Waterborne Environmental, Inc.; J.E. Hodges, Unilever / Safety and Environmental Assurance Centre; O. Price, Unilever; M. Rowson, T. Miah, Unilever / Data Sciences. Economies across Asia are growing rapidly as has the consumer demand for a number of personal care products. Consequently, the quantity and detection of chemicals used in personal care products is increasing in profile across a large geographic expanse, such as Asia. However, to date few tools have been developed to predict chemical exposure in water bodies across Asia. Data required to predict relative environmental concentrations (PEC's) of ingredients used in personal care products include emission estimates, properties of the ingredient, socioeconomic and environment data (e.g. receiving water bodies, sewage treatment plant (STP) infrastructure). The majority of tools that have been developed over the past 30 years to assess exposure of chemicals used in personal care products have been developed in Europe and North America and little information is available to parameterise exposure models in Asia for use in environmental risk assessment. Over the past 18 months a novel geo-referenced exposure model has been developed for twelve countries in Asia (the "Asia 12": People's Republic of China, India, Bangladesh, Sri Lanka, Thailand, Laos PDR, Cambodia, Vietnam, Malaysia, Indonesia, Pakistan and the Philippines) to predict the exposure of personal care ingredients in freshwater ecosystems. We explore novel approaches to estimating chemical usage across the diverse continent using information on population, GDP distributions and the population's ability to purchase personal care products. The Koppen-Geiger classification for climate was used to characterise nine climate zones across the Asia 12; we then explore the driving variables in exposure within countries and across these diverse climatic zones. We present our data sources, model development and the utility of the model for predicting relative chemical exposure for a range of ingredients used in personal care products across Asia 12 and its application within a probabilistic risk assessment framework. The results of this exercise can be used to target future monitoring campaigns and could be used to parameterise regulatory models for use in environmental risk assessments for countries in Asia. Please note: This abstract has been submitted for presentation at SETAC-Asia Pacific (2012) by one of the authors listed. But is being submitted here to target and reach a totally different set of audience.

## **27 Evolution of the model SimpleTreat to predict the fate of personal care product ingredients in the sewage treatment plant**

A. Franco, Unilever / SEAC; J. Struijs, RIVM / Laboratory for Ecological Risk Assessment; O. Price, Unilever / SEAC; T. Gouin, Unilever / Safety and Environmental Assurance Centre. Sewage treatment plant (STP) models such as SimpleTreat are used in regulatory risk assessment to predict the discharge of personal care product (PCP) ingredients into the environment. SimpleTreat describes the fate of organic chemicals in a conventional activated sludge STP with primary and secondary sedimentation. Although the model is recommended in the EU regulatory context for personal care product ingredients, biocides and pharmaceuticals, concerns have been raised about a) the applicability domain to chemicals of emerging concern (such as those used in personal care products) and b) the lack of realism of the model default (worst case) parameterisation. Efforts have been made to evolve SimpleTreat and enlarge its applicability domain and to improve its parameterization to

achieve realistic estimation of the concentrations of chemicals in effluent water and sludge. A probabilistic parameterization, based on actual STPs conditions for the EU, was applied to achieve a more realistic representation of the variability of raw sewage characteristics, STP design and operational parameters. The uncertainty of chemical input properties, including degradation rates derived from continuously stirred activated sludge simulation tests (OECD 303A) was incorporated in the simulations. A validation study with ten selected chemicals from PCP ingredients showed good agreement with measured concentrations collected from the literature. The sludge loading rate, the sewage flow, the water temperature and the concentration of suspended solids in the effluent were the most sensitive model parameters and explained, although not completely, the variability in observed removal rates.

## **28 Relationship of Land Uses with Occurrence of Contaminants of Emerging Concern in Streams of Southeastern Minnesota**

D. Fairbairn, E. Spande, University of Minnesota / Water Resources Center; P. Rice, United States Department of Agriculture – Agricultural Research Service; W. Arnold, P. Novak, University of Minnesota / Civil Engineering; W. Koskinen, United States Department of Agriculture – Agricultural Research Service; B. Barber, University of Minnesota / Department of Soil, Water, and Chemistry; D. Swackhamer, University of Minnesota / Environmental Health Sciences. Endocrine disrupting compounds (EDC), pharmaceuticals, and other contaminants of emerging concern (CEC) have been detected in surface waters, including compounds suspected or known to cause adverse human or ecological effects. Goals of the project are to (1) characterize CEC profiles and land uses associated with sub-watersheds in the study area and (2) identify CEC-land use "fingerprints" (unique profiles of chemical markers) to indicate the influence of a given land use on water quality. Our approach includes collecting water (grab and time-composited), passive organic contaminant integrative sampler (POCIS), and sediment samples, ten weeks per year for two years, at four sites near Rochester, MN. Sample extracts (solvent and/or solid phase) are analyzed using liquid chromatography tandem-mass spectrometry for thirty CECs including pesticides, natural and synthetic hormones, household and industrial chemicals, pharmaceuticals and personal care products, veterinary medications, and phytoestrogens. Land use analysis (McGhie Betts, Inc), water chemistry, and flow data accompany the CEC data. CEC concentration profiles are analyzed in light of land use variations amongst subwatersheds, seasonal conditions, precipitation patterns and other hydrologic factors. Sampling began in 2011 and the project will be completed in June 2013. Anticipated results will provide tools to identify sources of surface water contaminants in Minnesota and other locations, providing insight for targeting the most effective mitigation approaches.

## **29 The ecological risk of naturally-occurring and anthropogenic sources of person care product ingredients: fatty alcohols and related surfactants**

S.M. Mudge, Exponent; P.C. DeLeo, American Cleaning Institute / Environmental Safety, American Cleaning Institute. Fatty alcohols are one of the major surfactant classes used in personal care products. These compounds are also synthesised naturally by a wide range of organisms and give rise to a complex mixture of chain lengths and ligands in the environment. The fatty alcohol-based detergents used in personal care products may occur as free alcohols, or as more complicated sulphated, ethoxylated and ethoxy-sulphated compounds which may degrade into free alcohols later found in the environment. They tend to be in the chain length range of C<sub>12</sub> to C<sub>16</sub> and are made from both petrochemical and oleochemical carbon sources. This chain length range overlaps with natural bacterial production as well as algal synthesis through the fatty acid synthase system. In contrast, terrestrial plants manufacture longer chain compounds, typically with chain lengths greater than C<sub>22</sub>. These compounds tend to be in the form of waxes used to prevent desiccation. Free fatty alcohols are relatively insoluble in water and the water solubility is a function of chain length. Compounds with an alkyl chain greater than C<sub>14</sub> are functionally insoluble in water as the Log K<sub>ow</sub> exceeds 6. This leads to strong particle associations in environmental systems with little available for biological uptake. Marketing data on the use of products containing fatty alcohols and measurements made in a wide range of sewerage systems has quantified the inputs and liquid discharges to receiving waters. The chain length profiles and stable isotopes indicate that the compounds in the effluent are not the same as those in the influent having been synthesised during the biological treatment stage. The environmental profiles also indicate a very small contribution from the wastewater

treatment plants (WWTPs) to the local sediments. The bulk of the fatty alcohols that enter the WWTP are removed in the solid phase which may undergo further treatment before being disposed of elsewhere. This may include spreading on agricultural land as a fertiliser. The ecological risk to the rivers from these compounds is very small, and the anthropogenic contribution to that risk is even smaller; the major component (84%) can be attributed to naturally occurring terrestrial plants. The bulk of the shorter chain compounds are bacterial or algal in origin and again are naturally occurring. The small component that may be attributed to discharges from the WWTPs is substantially under the PNEC for the free alcohols based on QSAR approaches.

**30 Impact of Triclosan in the Terrestrial Environment: A Comprehensive Evaluation of Terrestrial Risk** D. Fort, Fort Environmental Laboratories, Fort Environmental Laboratories, Inc.; M. Mathis, Fort Environmental Laboratories; S. Pawlowski, S. Champ, BASF SE. A comprehensive evaluation of the effects of the antimicrobial personal care product triclosan (TCS) in the terrestrial environment was performed. This evaluation evaluated the effects of TCS on acute and chronic toxicity to earthworm (*Eisenia fetida*), and effects on emergence and growth terrestrial plant species. In addition, the effects of TCS on soil microflora respiration and nitrification and the impact on terrestrial arthropods were also considered. The acute and chronic toxicity of TCS to earthworms were tested in an artificial soil in accordance with OECD guidelines 207 and 222. Test concentrations for acute and chronic toxicity studies with earthworms ranged from 64-1,026 and 0.3-100 mg/Kg soil (dw) for acute and chronic studies, respectively. Phytotoxicity studies evaluating survival, emergence, shoot biomass and length, and normalcy of development in 10 species of terrestrial plants were performed in accordance with OECD guideline 208 using 0.2-1,000 mg/Kg (dw) TCS for an exposure period of the median emergence time plus 14 days. Microbial respiration and nitrification were evaluated in soil treated with 0.1-2.0 mg/Kg TCS for 28 days. The effects of TCS on the predatory mite *Hypoaspis aculeifer* exposed to 0.3-320 mg/Kg (dw) TCS for 14 days were evaluated in accordance with OECD guideline 226. NOEC and LOEC values for acute and chronic toxicity to earthworms were 1,026 and >1,026 mg/Kg (dw) [survival], and 100 and >100 mg/Kg (dw) [survival and reproduction], respectively. NOEC and LOEC values in terrestrial plants ranged from 75 and 100 mg/Kg (dw) [biomass in lettuce] to 1,000 and >1,000 mg/Kg (dw) [emergence and phytotoxicity in vetch and phytotoxicity in cucumber]. No Observed Effects Concentrations (NOEC) and Lowest Observed Effects Concentrations (LOEC) for soil respiration and soil nitrification were 2 and >2 mg/Kg (dw), respectively. NOEC and Lowest Observed Effects Concentrations (LOEC) values for predatory mite survival and reproduction were 10 and 32 mg/Kg (dw) and 3.2 and 10 mg/Kg (dw), respectively. Overall, these studies demonstrate that TCS poses minimal risk in the terrestrial environment. These results will be discussed in the context of the terrestrial ecological risk assessment of TCS described by Reiss et al. (2002).

**31 Analysis of Pharmaceuticals and Personal Care Products in Marine Sediment and Biota Using Liquid Chromatography-Tandem Mass Spectrometry** F. Chen, National University of Singapore, National University of Singapore / Department of Civil and Environmental Engineering, National University of Singapore / Civil and Environmental Engineering; S. Bayen, University of Singapore; B.C. Kelly, National University of Singapore / Department of Civil and Environmental Engineering. The discharge of pharmaceuticals and personal care products (PPCPs) into the environment via household, municipal and industrial wastes is a pressing public health issue. Some of these chemicals have been reported as toxic to aquatic organisms in the literature and high environmental concentrations may cause toxic effects. Here we present the development of an analytical method for quantitative determination of key PPCPs, including 35 pharmaceuticals and 7 personal care products, in marine sediments and biota from Singapore's marine environment. Field collected sediments (2 g) and biota tissue (2-3g) samples were extracted and cleaned up by sonication and solid phase extraction (SPE). Identification and quantification of target compounds was performed using liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS). Separate analyses were conducted for negative and positive ionization mode. Isotopically labeled ( $^{13}\text{C}$  or deuterated) surrogate standards were used to correct matrix effects. Matrix effects (ionization suppression and enhancement) in sediment and tissue extracts were further assessed for the various analytes by standard addition tests.

Results of analyte recovery tests, procedural blanks and replicate sample analyses demonstrate generally good performance of the methods for the majority of target analytes. Trace residues of several PPCPs, including Caffeine, Carbamazepine, Diclofenac, Diphenhydramine, Estrone (E1), Estradiol (E2), Gemfibrozil, Ibuprofen, Linuron, Naproxen, Simvastatin and Triclosan, were detected in sediments and biota. The significance of the occurrence, levels and patterns of various PPCPs in Singapore's marine environment are discussed.

**32 Solid Waste Deposits as a significant source for contaminants of emerging concern to the environments – a case study from Owerri, Nigeria** A. Arukwe, Norwegian University of Science and Technology (NTNU) / Department of Biology, Norwegian University of Science and Technology (NTNU) / Biology, NTNU / Dept. of Biology; T. Eggen, Bioforsk, Norwegian Institute for Agricultural and Environmental Research; M. Moeder, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Chemistry. There are needs for scientific basis in developing countries, to sensitize communities on the problems arising from improper solid waste deposition and the acute and long-term consequences for areas receiving immobilized pollutants. In Nigeria, as in many other African countries, solid waste disposal by way of crude dumping has been the only management option of such wastes. In the present study, we have highlighted the challenges of solid waste deposit and management in developing countries, focusing on contaminants of emerging concern (including endocrine disrupting compounds: EDCs) and leaching into the environment. We have analyzed sediments and run-off water samples from a solid waste dumping site in Owerri, Nigeria for organic load and compared with representative world cities. Learning from previous incidents, we intend to introduce some perspective for awareness of contaminants of emerging concerns such as those with potential endocrine disrupting activities in wildlife and humans. Qualitative and quantitative data obtained by GC-MS provided an overview on lipophilic and semi-polar substances released from solid waste, accumulated in sediments and transported via leachates. The total ion current (TIC)-chromatograms of sediment extracts clearly point to contamination related to heavy oil. The homologous series of n-alkanes with chain lengths ranging between C16 and C30, as well as detected PAHs such as anthracene, phenanthrene, fluoranthene and pyrene support the assumption that diesel fuel or high boiling fractions of oil are deposited on the site. Targeted quantitative analysis for selected EDCs and pharmaceuticals showed high concentration of substances typically released from technical products such as plastics, textiles, household and consumer products. Phthalates, an integral component of plastic products, was the dominant compound group in all sediment samples and the run-off water sample. Technical nonylphenols (mixture of isomers), metabolites of non-ionic surfactants (nonylphenol-polyethoxylates), UV-filter compound ethyl methoxy cinnamate (EHMC) and bisphenol A (BPA) were particularly determined in the sediment samples at high  $\mu\text{g/kg}$  dry weight concentration. Overall, measuring contaminants in such areas will help in increasing governmental, societal and industrial awareness on the extent and seriousness of the situation both at contaminated sites and surrounding environments.

**33 A real-time antibody-based field assay to predict PAH bioaccumulation in oysters exposed to contaminated sediments** M.A Unger, Virginia Institute of Marine Science / Environmental and Aquatic Animal Health; S.L. Kaattari, Virginia Institute of Marine Science / Environmental and Aquatic Animal Health, Virginia Institute of Marine Science / Professor; W.K. Vogelbein, Virginia Institute of Marine Science / Environmental and Aquatic Animal Health; J. Rieger, The Elizabeth River Project. Lipophilic contaminants in sediments commonly accumulate in shellfish, potentially posing significant human health risk when consumed. Polycyclic aromatic hydrocarbon (PAH) bioaccumulation in shellfish is driven by lipid partitioning but multiple chemical, physical and environmental factors influence bioavailability and tissue concentrations in dynamic natural systems. Because measuring contaminant uptake in biota is time consuming and expensive, multi-phase models have been developed to predict contaminant fate and disposition. However, temporal variability and heterogeneity of natural habitats make it difficult to reliably predict bioaccumulation from measured bulk sediment concentrations and properties. Ultimately, site-specific pore water measurements are vital to accurately predict contaminant bioavailability and to evaluate the effectiveness of sediment remediation efforts. Recent advances in biosensor technology now allows near real-time measurement of contaminants at sub part per billion concentrations. A

quantitative, monoclonal antibody (mAb)-based sensor was used to measure PAH concentrations in sediment-associated water as a predictor of oyster tissue burdens. Oysters, sediment, surface water and sediment pore waters were collected at six sites in the Elizabeth River, Virginia that included a Superfund site and sites undergoing sediment remediation. PAH concentrations in surface water and sediment pore water were measured in the field within minutes of collection by biosensor. Total PAH concentrations ranged from  $< 1 \mu\text{g/L}$  to  $>100 \mu\text{g/L}$  in these aqueous samples. The relationships between measured aqueous PAH concentrations, oyster bioaccumulation, sediment properties and sediment remediation methods will be discussed.

**34 Addressing Risk Assessment Needs for Traditional and Emerging Contaminants Using the Innovative In Situ Sampling/Bioavailability (IS2B) Device** R.U. Halden, Arizona State University / Center for Environmental Security, The Biodesign Institute at Arizona State University; S.D. Supowit, Arizona State University / Department of Civil and Environmental Engineering; I.B. Roll, Arizona State University; V.D. Dang, K.J. Kroll, University of Florida; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology, University of Florida / Dept. of Physiological Sciences &. To address pressing needs in environmental risk assessment, we introduce the *in situ* sampling/bioavailability determination (IS2B) tool, a novel, patent-pending device designed to allow for simultaneous determination of contaminant levels in bulk water and pore water at hitherto unattainably low method detection limits (MDLs). When deployed, one half of the tubular IS2B device is buried in sediment and the other is exposed to bulk water. Integrated multi-channel pumps simultaneously draw bulk water and sediment pore water into the active sampling device and push it at, respectively, high and low desirable flow rates through an array of filters and adsorption media. Water samples either can be stored in the device or expelled into the bulk water at will. Due to unlimited access to pore and bulk water during deployment, the IS2B tool has the potential to provide ultra-low MDLs for a broad spectrum of contaminants, ranging from fully water-soluble to highly sorptive and hydrophobic. The working hypothesis of our research team is that the IS2B can serve to reliably (i) sample bulk and pore water pollutants for analysis in the sub-ng/L range, (ii) inform on the bioavailability and bioactivity of sediment contaminants, (iii) inform on human exposures and associated health risks from fish consumption, and (iv) track the progress of sediment remediation activities. We provide an overview of the device principles, preliminary performance data, and a set of laboratory and field studies designed to systematically assess the utility of the IS2B tool in contaminated sediments from Lake Apopka, Florida. To assess the breadth of IS2B applicability, the project utilizes mesocosm experiments with two traditional and three emerging contaminants (*p,p'*-DDE, dieldrin vs. fipronil, triclosan, triclocarban) and involves two test organisms: *Lumbricus variegatus* and *Pimephales promelas*. Biological responses to contaminant exposure are measured in fish using DNA microarray analysis to evaluate effects that may not be predicted solely based on body burden of parent compounds. Finally, the project involves the development of mathematical relationships between pollutant concentrations in bulk water, pore water, worms and fish to quantify exposure risks and track the effectiveness of two remediation approaches, granular activated carbon (GAC) amendment and deep tilling of contaminated sediment.

**35 Applications of Sediment Bioavailability Tools to Human Health Risk Assessment** T. Sorell, AMEC / Environment and Infrastructure; M. Murphy, AMEC. There is an expanding universe of tools used in sediment investigation to assess bioavailability to biota. These tools, which include direct measurement of pore water contaminant of concern (COC) concentrations (both dissolved and freely dissolved), measurement of ligands and other chemical parameters such as dissolved organic matter to estimate adsorption, and models to predict food chain transfer based on site-specific physical and chemical conditions, have become routine in predicting ecological risk. For example, it has become widely accepted that pore water concentrations correlate with toxicity to benthic organisms. However, application of these critical observations to human health risk is not routine. Rather, human health assessments tend to rely on default assumptions and food chain transfer factors derived from publicly available databases, empirical observations at other sites, or simplistic models that do not account for site chemistry. Site-specific sediment and pore water chemistry may be useful in evaluating and possibly modifying default values, such as food chain transfer factors, oral absorption efficiency, and dermal absorption factors.

Critical bioavailability-related considerations for assessing human health risk from sediment sites: Relationship between adsorbed and freely soluble COC thermodynamic equilibrium and assimilation at the base of the food chain Biomagnification behavior of the COC Importance of sediment ingestion as an assimilation mechanism in the local food chain Tendency of the COC to be metabolized Sensitive variables in food chain transfer models The routes of human exposures (biota consumption, direct contact via incidental ingestion and dermal contact) Relevance of adsorptive behavior in situ to human absorption via gastrointestinal and dermal exposure routes The evaluations presented here explore the mechanisms by which site information typically collected for ecological risk purposes may be of predictive value in the human health risk assessment process. Applying site bioavailability-related observations into the human health assessment may avoid over-estimation of exposure and provide integrated risk evaluations that support balanced risk management decisions.

**36 Bioavailability-based toxicity endpoints of bifenthrin for *Hyalella azteca* and *Chironomus dilutus*** A.D. Harwood, Southern Illinois University / Fisheries and Illinois Aquaculture Center and Department of Zoology; P.F. Landrum, Southern Illinois University; M. Lydy, Southern Illinois University Carbondale / Fisheries and Illinois Aquaculture Center and Department of Zoology. Recent studies have determined that techniques, such as solid phase microextraction (SPME) fibers and Tenax beads, can predict bioaccumulation and potentially toxicity for several compounds and species. The objectives of the current study were to determine median lethal concentrations (LC50) and median effect concentrations (EC50) of the pyrethroid insecticide bifenthrin using bioavailability-based metrics, compare their ability to access toxicity to the use of whole sediment concentrations, as well as to make comparisons of the concentrations derived using each method in order to make assessments of accuracy and extrapolation potential. Four metrics were compared including solid phase microextraction (SPME) fiber concentration, pore water concentration derived using SPMEs, 6 h Tenax extractable concentration, and 24 h Tenax extractable concentration. Toxicity of bifenthrin was determined using two standard benthic species: *Hyalella azteca* and *Chironomus dilutus*. The variation in the LC50s and EC50s derived using bioavailability-based methods was comparable to variation among organic carbon normalized sediment concentrations, but improved over whole sediment concentrations. There was a relationship between SPME or Tenax and organic carbon normalized sediment concentrations. Additionally, there was a significant relationship between the SPME and Tenax concentrations across sediments. These correlations among metrics further demonstrate the relationship among these bioavailability-based endpoints. This study not only emphasizes the value of these techniques, but also provides usable benchmarks for implementation of these methods in environmental assessments.

**37 Combining bioavailability assays with modeling to predict PCBs in fish after remediation** H.F. Khoei, University of Maryland Baltimore County; U. Ghosh, University of Maryland Baltimore County / Civil & Environmental Engineering, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering, University of Maryland Baltimore County / Chemical, Biochemical, and Environmental Engineering; A. Place, A. Watson, Institute of Marine and Environmental Technology. While several in-situ (non-removal) remediation approaches for contaminated sediments have been explored, a central challenge with in-situ remedies is the length of time necessary to observe impacts, particularly in fish. An alternative is to make timely assessment of remediation progress by performing bioavailability measurements that indicate key pathways of exposure to fish and use these assessments to in conjunction with bioaccumulation models to predict uptake in the food chain. This talk will present initial results from a 3-year study that is evaluating in laboratory mesocosm experiments the feasibility of bioavailability assessments to predict uptake in fish and response to in-situ remediation. In order to develop a fundamental understanding of biouptake in fish and how that is impacted with changes in exposure pathways, a preliminary laboratory exposure study was performed using three types of sediment: clean sediments, PCB impacted sediments, and PCB impacted sediments treated with activated carbon (AC) to reduce PCB bioavailability. Replicate aquaria were arranged in a parallel flow configuration and fed with recirculating water. Polyoxymethylene passive samplers were placed in the sediment and water column in each aquarium. Zebrafish were deployed in each aquarium and were fed with algae based PCB-free food. Porewater PCB concentration

in PCB impacted sediment was high and was reduced by two orders of magnitude upon amendment with 5% activated carbon by weight. Porewater PCB concentration in AC-treated sediment was similar to that in the clean sediment aquaria. PCB in overlying water in the AC-treated sediment tanks were an order of magnitude lower than that in the untreated sediment tanks. PCB uptake in fish reflected PCB levels seen in the porewater and overlying water in each tank. Higher levels of PCBs in porewater corresponded to higher levels of accumulation in fish. These results are being incorporated in a PCB bioaccumulation model to allow prediction of PCB bioaccumulation in fish based on the assessment of changes in exposure as a result of in-situ treatment. Ongoing work is evaluating uptake in benthic invertebrates (freshwater oligochaetes) to evaluate benthic exposure pathway, and uptake in algae and daphnia to evaluate pelagic exposure pathway of PCBs to fish.

**38 Development of Stable Isotope Based Methods to Predict Bioavailability of Hydrophobic Organic Contaminants in Sediments** J. Gan, X. Cui, L. Delgado-Moreno, University of California Riverside; F. Jia, University of California, Riverside / Department of Environmental Sciences, UC Riverside / Department of Environmental Sciences; L. Bao, University of California Riverside / Chinese Academy of Sciences, University of California, Riverside / Department of Environmental Sciences; R. Lavado, University of California Riverside / Department of Environmental Sciences, University of California Riverside / Department of Environmental Science; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; J. Gully, Environmental Scientist / Ocean Monitoring & Research Section, Supervising Environmental Scientist / Ocean Monitoring & Research Group; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP. Bioavailability of hydrophobic organic contaminants (HOCs) in impacted sediments is influenced by sediment properties (e.g., quantity and quality of organic carbon, black carbon), residence time, and other factors, making the bulk or total sediment concentration a poor predictor in risk assessment and management. Current methods for estimating the bioavailability of HOCs in sediments or soils suffer various theoretical or practical limitations. In this NIEHS project, we are exploring the use of stable isotope labeled reference compounds and the concept of isotope exchange to measure bioavailability in a versatile and reproducible manner. In the isotope exchange application,  $^{13}\text{C}$  or deuterium-labeled analogues are introduced into a sediment sample and mixed, and the aqueous phase obtained at the steady state by centrifugation or filtration is analyzed for the ratio of stable isotope labeled and native (non-labeled) concentrations, from which the exchangeability  $E$  of the native HOCs may be calculated. Preliminary results show that  $E$  is closely correlated with bioaccumulation of various HOCs into benthic invertebrates. In another application, stable isotope labeled standards are preloaded onto solid phase microextraction (SPME) fibers before placing the fiber into a sediment sample, and the exchange of labeled and non-labeled (native) HOCs on the fiber allows the estimation of absorption kinetics, enabling the estimation of freely dissolved concentration ( $C_{\text{free}}$ ) using short and flexible sampling times. Given that stable-isotope labeled standards are increasingly available, these methods are expected to be easily adoptable in most laboratories for investigation bioavailability of sediment-borne HOCs such as DDT, PCBs, PAH, and PBDEs, among others.

**39 Geochemical characteristics of the mine-impacted North Fork of Clear Creek and implications for stream recovery** J. Williamson, J. Ranville, Colorado School of Mines; J. Meyer, ARCADIS U.S. Inc; K. Dahl, S. Smith, N. Albuquerque, S. Johnson, Colorado School of Mines. Legacy acid generation, resulting from silver and gold mining wastes, has contaminated the North Fork of Clear Creek with high concentrations of metals such as aluminum, copper, iron, manganese and zinc. The U.S. Environmental Protection Agency (USEPA) has placed a high level of urgency on the remediation of this mine-impacted stream. In the fall of 2013, the USEPA will begin operating a new water treatment plant in the effort to remove the metals from the incoming point sources (Gregory Incline and National Tunnel) before they enter the stream. This presents an excellent pre- and post-remediation scenario in which metal-mixture toxicity and rate of aquatic geochemical recovery can be investigated in a natural water source. Elemental analysis of stream water samples are being performed to determine temporal and spatial variability of pre-remediation concentrations of metal contaminants; and laboratory experiments and geochemical speciation calculations are being performed to predict post-remediation in stream water chemistry. Concurrently, toxicity tests are being conducted with the

stream water and laboratory-prepared mimics of the stream water to help identify mechanisms of toxicity, support parallel modeling efforts and test whether single-metal biotic ligand models predict mixture toxicity well. The sediments, formed by metal oxide precipitation, may contribute metals to the water-column post-remediation. Metal-release rates are likely dependent on their physical and chemical characteristics. Experiments, performed at upstream locations, involving in-stream scouring/dissolution of metal-oxide coatings on rocks are being used to examine likely recovery rates.

**40 Monitoring PAH Bioavailability in Remediated Sediment Using Passive Sampling Devices** D. Shea, North Carolina State University / Department of Biology; K. O'Neal, X. Kong, X. Xia, P. Lazaro, W. Thorsen, North Carolina State University. The remediation of contaminated sediment is intended to either remove and or make unavailable the unacceptable exposure to sediment-bound chemicals. At a PAH-contaminated site near Tianjin, China we tested three remediation methods: removal of sediment, capping, and fortification with activated charcoal in replicate 1-m diameter microcosms and measured the PAH in caged bivalves and passive sampling devices (PSDs) deployed at the sediment-water interface and imbedded in the surface sediment. All three remediation methods dramatically decreased the dissolved PAH exposure in the surface sediment and overlying water. This decrease was reflected in much lower PAH concentrations in the bivalves and the PSDs. We used two different PSD polymers: polyoxymethylene (POM) and polyethylene (PE) and both gave equivalent results in post-remediation monitoring. The PE PSD had greater variability and higher PAH concentrations in the pre-treatment monitoring most likely due to the adherence of oil and/or coal tar product to the PE and not to the POM. There was also good agreement between PSDs and the bivalves, with greater differences observed in pre-treatment monitoring and with lower molecular weight PAH. Finally, we compared in-situ PSD data with ex-situ laboratory desorption experiments using the POM and again found good agreement. Our results indicate that both in-situ PSD deployment and the more easily measured ex-situ laboratory desorption experiments are adequate surrogates for measuring the bioavailable PAH in both baseline (pre-treatment) and post-remediation PAH contaminated sediment.

**41 Zebrafish as a model to address the impact of 17 $\alpha$  ethinylestradiol on fish health: a focus on down-regulated genes impacting innate immunity** J.D. Hansen, US Geological Survey-Western Fisheries Research Center, USGS WERC; J.C. Woodson, J.R. Winton, US Geological Survey-Western Fisheries Research Center; T.K. Bammler, R.P. Beyer, Department of Environmental and Occupational Health Sciences, University of Washington; E.P. Gallagher, Department of Environmental and Occupational Health Sciences, University of Washington / Department of Environmental and Occupational Health Sciences; D.E. Tillitt, US Geological Survey-Columbia Environmental Research Center. Environmental contaminants are believed to have profound impacts on fish health through modulation of immune responses. The innate immune response represents the first line of defense against microbial pathogens and is largely based upon the recognition and response to pathogen associated molecular patterns (PAMPs) through a range of pattern recognition receptors (PRRs) on cells of the innate immune system, leading to activation of inflammatory processes and the transition to adaptive immunity. To address the hypothesis that endocrine disrupting chemicals can lead to immune dysfunction in fish, zebrafish were sub-chronically exposed to environmentally relevant levels of 17 $\alpha$ -ethinylestradiol (EE2; 1ng/L and 10ng/L) and then injected with the microbial PAMPs, peptidoglycan and poly:IC to mimic infection. Tissues were then subjected to genome-wide microarray and pathway analyses, which revealed down regulation of key genes and pathways involved in innate immunity including pathogen recognition, complement activation and antigen presentation as verified by quantitative RT-PCR, Western blot and respiratory burst analyses of cells and tissues exposed to EE2. Taken together, our results strongly support the hypothesis that exposure to environmental concentrations of EE2 have profound impacts on fish health which would likely render fish more susceptible to pathogens.

**42 Gonadal gene expression profiles in Largemouth bass placed in organochlorine pesticide contaminated mesocosms surrounding Lake Apopka, Florida** C.J. Martyniuk, University of New Brunswick / Dept. of Biology/Canadian Rivers Institute, University of New Brunswick / Biology; M. Prucha, N. Doperalski, University of Florida; K.J. Kroll, University of Florida / Physiological Sciences; D. Barber, N. Denslow, University of

Florida. Lake Apopka (FL, USA) experienced heavy uses of organochlorine pesticides (OCPs) in the 1960s-1970 during an intense agricultural period and was declared a Superfund site by the US EPA. Aquatic organisms inhabit the freshwater systems in and around Lake Apopka, however the impacts of sub chronic exposure to OCPs in this natural environment are not known. We investigated the effects of the contamination on the reproductive axis of largemouth bass (LMB) (*Micropterus salmoides*), an apex predator, using a natural mesocosm. In October 2007, LMB were caught at DeLeon Springs (FL) and were stocked in the mesocosms, remaining there for 3 months before being sampled in January 2008 (early oogenesis). Additional fish were caught in February 2008 at DeLeon Springs, placed into mesocosms for 2 months, and sampled in April 2008 (oocyte maturation). LMB inhabiting the mesocosms for four months had a 2-20X higher contaminant load for OCPs (e.g. DDE, dieldrin, methoxychlor) than LMB collected at DeLeon Springs. GSI for fish collected in the mesocosm in April were not different compared to reference fish in early maturation phase. Vitellogenin levels in LMB collected from the mesocosms in January and April were not significantly different than fish collected from Welaka in late vitellogenin or early maturation respectively. Microarray analysis in the ovary revealed that the expression profiles of LMB found at reference sites were different compared to LMB in the mesocosms and formed a unique expression clade. Some notable transcripts that showed altered abundance in LMB from mesocosms were insulin-like growth factor I and steroidogenic acute regulatory protein. Interestingly, differentially expressed transcripts showed a significant and positive correlation for LMB sampled in January and April despite the 3 month period in between samplings. Sub-network enrichment analysis for cellular processes showed that retinoic acid metabolism and germ-cell development were decreased in mesocosm-exposed fish but processes such as vitellogenesis, amino acid catabolism, granulosa cell function, vitamin D metabolism, and hormone biosynthesis were increased in mesocosm-exposed fish. These data suggest that (1) LMB from the mesocosms are exhibiting unique gene profiles that may impair normal reproduction and that (2) microarray analysis in the field can provide site specific information by discriminating LMB from reference and polluted sites.

#### 43 Transcriptome analysis of BaP exposure in zebrafish embryos and larvae

**K.L. Willett**, University of Mississippi / Environmental Toxicology Research Program; **J. Corrales**, C. Thornton, University of Mississippi / Environmental Toxicology; **X. Fang**, Yale University; **L. Ballard**, B.E. Scheffler, USDA ARS. Polycyclic aromatic hydrocarbons (PAHs) are organic pollutants that arise from incomplete burning of carbon-containing materials, such as diesel, gas, petroleum, coal, wood, fat and tobacco. PAHs, like benzo(a)pyrene (BaP), are carcinogenic, mutagenic and teratogenic. Here we present differences in the transcriptome of developing zebrafish after a parental BaP waterborne exposure followed by an offspring exposure. Adult zebrafish (2 males x 4 females, N=3 replicate tanks per treatment) were exposed to control or  $42.0 \pm 1.9 \mu\text{g/L}$  BaP for 7 days. Eggs were collected and raised in normal conditions or continuously exposed to BaP until 3.3 and 96 hpf. Total RNA was extracted from a 30 embryo pool. Then, tagging and RNA-Seq libraries were constructed prior to Illumina HiSeq-2000 sequencing. To analyze data, RNA sequences were uploaded to galaxy <https://main.g2.bx.psu.edu/> and converted to FASTQsanger format with the "FASTQ Groomer" tool. RNA-seq reads were mapped to zebrafish genome (DanRer7) with the "Tophat for Illumina" tool in the galaxy. The resulting Binary Sequence Alignment/Map (BAM) files for each sample were merged into a single BAM file and imported to Partek Genomics Suite version 6.11. Differential expression on raw gene and transcript reads between treatments or time-points were analyzed with R package "EdgeR". Genes with false discovery rate (FDR) less than 0.05 were considered as genes with significantly altered expression. Functional ontology was conducted with the Database for Annotation, Visualization and Integrated Discovery (DAVID). Developmental differences between 3.3 and 96 hpf zebrafish were shown by 11823 differentially expressed genes and 12406 differentially expressed transcripts. BaP exposure resulted in 274 differentially expressed genes and 290 differentially expressed transcripts at 3.3 hpf and 930 genes and 885 transcripts at 96 hpf. The cluster with the highest enrichment score included functions such as gastrulation, cell migration, cell motility, localization of cell, embryonic morphogenesis, formation of primary germ layer and tissue morphogenesis. Supported by NIEHS R21ES019940.

**44 Genome-wide expression study reveals genetic determinants for the action of compounds as mixtures** **J.R. Shaw**, Dartmouth College / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; **S. Shankar**, Indiana University / The School of Informatics; **J.A. Lopez**, Indiana University / The Center for Genomics and Bioinformatics; **S.P. Glaholt**, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; **B.L. King**, Mount Desert Island Biological Laboratory; **J.K. Colbourne**, Indiana University / The Center for Genomics and Bioinformatics. At an annual "Environmental Genomics" summer course at the Mount Desert Island Biological Laboratory, participants learn how to design large scale experiments that are enabled by drastically increased sample-throughput. Experiments are conducted using 12-plex microarrays that are designed to study the freshwater microcrustacean *Daphnia* ([www.mdibl.org/courses/Environmental\\_Genomics](http://www.mdibl.org/courses/Environmental_Genomics)). We present a meta-analysis of two years of course data. For these experiments, two genetically and geographically unique *Daphnia pulex* isolates were exposed to incipient concentrations of six compounds (acetaminophen, arsenic, atrazine, cadmium, copper, nickel) and binary mixtures. The design includes four biological replicates per treatment, resulting in 200 comparative two-color hybridizations. For these analyses, signal data were normalized and fit to a linear model that evaluated main effects and interactions between contrasting variables of (1) every treatment and control, (2) binary mixtures and constituent compounds, and (3) genetic background. The analyses reveal that variation between genotypes is much greater than any treatment or treatment combination. Multi-dimensional scaling that reduces all variables along two axes segregates the response profiles by genotype along the first coordinate and by chemical class (metals vs non-metals) along the second. Interestingly, mixture response differed by genotype regardless of chemical class. One genotype produced additive response profiles for mixtures, while the other produced non-additive profiles that were either antagonistic or synergistic depending on mixture components. These results highlight the promise of environmental transcriptomics, while advising caution about the required scale of experiments needed to accurately interpret results. These studies contribute to and benefit from the *Daphnia* Genomics Consortium.

**45 Analysis of the Transcriptome of the Fathead Minnow to Determine Mechanisms of Toxic Action of Oil Sands Process Affected Water** **S.B. Wiseman**, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / Post-Doctoral Fellow; **Y. He**, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / PHD student; **P. Jones**, University of Saskatchewan / School of Environment and Sustainability, University of Saskatchewan / School of Environment and Sustainability and Toxicology Center; **M. Hecker**, University of Saskatchewan / Toxicology Centre; **J.W. Martin**, Trent University / Division of Analytical and Environmental Toxicology; **M.G. El-Din**, University of Alberta / Department of Civil and Environmental Engineering; **J.P. Giesy**, University of Saskatchewan / Biomedical Veterinary Sciences & Toxicology Centre, Michigan State University / Department of Animal Science, University of Saskatchewan / Toxicology Centre. Oil sands process-affected water (OSPW) is produced by the oil sands industry in North Eastern Alberta, Canada. This OSPW is a complex mixture of clay, residual bitumen, salts, metals, and dissolved organic compounds of which naphthenic acids are hypothesized to be the primary toxicant. Because OSPW is acutely and chronically toxic to aquatic organisms it must be stored in tailings ponds due to a policy of zero discharge. The mechanism(s) of toxicity of OSPW has received little attention. Because NAs are surfactants OSPW might be acutely toxic because of polar narcosis. However, due to the complexity of the mixture, it can be hypothesized that OSPW might exert its toxicity via multiple mechanisms. Understanding the toxicity of OSPW is required to effectively establish methods of assessing and predicting the toxicity of OSPW. Effects at the cellular, tissue, or whole organism level are often initiated at the molecular level, so investigation of the effects of exposure to OSPW on gene expression might provide insight into the mechanisms of toxicity of OSPW. The goal of this study was to use RNAseq to quantify changes in the abundances of transcripts in the livers of fathead minnows (*Pimephales promelas*) exposed to OSPW. A reference transcriptome was assembled from 877,829,873 paired-end and single-end reads generated from RNA isolated from livers of fathead minnows exposed to various stressors. Reads were *de novo* assembled into 62,103 contigs of 200bp or greater and annotation of the contigs against the NCBI non-redundant protein database identified 25,342 contigs with an e-value of  $\leq 10^{-5}$ . Mapping of paired-end reads generated from sequencing

RNA isolated from livers of sexually immature male fathead minnows exposed to freshwater or OSPW to the reference transcriptome resulted in significantly greater abundance of 109 transcripts and significantly lesser abundance of 95 transcripts in livers of fathead minnows exposed to OSPW. By assigning Gene Ontology (GO) terms the biological processes of “cellular processes”, “metabolic processes”, “biological regulation”, and “response to stimulus” were identified as being affected by OSPW. Analysis of GO terms and Kyoto Encyclopedia of Genes and Genomes (KEGG) annotations identified oxidative metabolism, oxidative stress, apoptosis, and immune function as processes affected by OSPW, and which might explain some of the acute and chronic toxicity of OSPW.

#### 46 Gene Expression of Fathead Minnows Exposed to Municipal

**Wastewater Effluents** D. Vidal-Dorsch, Southern California Coastal Water Research Project / Toxicology, Southern California Research Project / Toxicology, Southern California Research Project; S.M. Bay, D. Greenstein, SCCWRP; C. Colli-Dula, University of Florida; L. Wiborg, City of San Diego Public Utilities Department, Environmental Monitoring and Technical Services Division; D. Petschauer, City of Los Angeles, Environmental Monitoring Division; N. Denslow, University of Florida. Although we can measure and detect the presence of contaminants of emerging concern (CECs) in wastewater effluents and receiving waters, we still do not have a good understanding of the ecological implications of their presence in aquatic environments. Effects caused by CECs may be subtle and diverse, comprehensive tools such as microarrays are necessary to identify toxicity mechanisms involved in these types of responses. In this study, we conducted laboratory exposures to investigate the use of gene microarray analysis in effluent exposures. We measured 32 CECs in effluents, plasma concentrations of vitellogenin (VTG), changes in secondary sexual characteristics, and performed microarray and pathway analyses in sexually mature male fathead minnows (*Pimephales promelas*). An Agilent, 8x15000, one color array was used. Fish were exposed for 14 days to control treatments and 5% concentrations of municipal wastewater effluents. Secondary and chemically enhanced advanced primary treated effluents were used. Males exposed to effluent had significantly higher concentrations of plasma VTG when compared to controls. Changes in secondary sexual characteristics (e.g., development of ovipositors) were observed in some fish exposed to effluent. Effluent exposure caused differential gene expression (vs. controls) in genes involved in several functions including, xenobiotic metabolism, estrogenicity and energy/metabolism processes, with different processes influenced by effluent type. Fish exposed to primary treated effluent had differentially expressed genes related to metabolic pathways (e.g., biosynthesis of cholesterol, aromatic acid metabolism, metabolism of estrogens and androgens). Exposure to secondary treated effluent affected genes involved in signaling pathways (e.g., regulation gap junction b, cell cycle regulation). Gene expression data provided valuable information regarding some of the mechanisms associated with effects observed at higher biological levels.

#### 47 Omic-based Effects Monitoring – Assessing Contribution of Treated Wastewater to Downstream Pollution

D. Martinovic, University of Saint Thomas, University of St. Thomas / Dept. of Biology, U.S. EPA, Mid-Continent Ecology Division / Mid-Continent Ecology Division, University of St. Thomas / Biology, University of Saint Thomas / Biology; A.C. Mehinto, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology, University of Florida / Dept. of Physiological Sciences & D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory; H. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory, St. Cloud State University / Department of Biological Sciences WSB-273, St. Cloud State University / Department of Biological Sciences MS-273. The effects of wastewater treatment plant (WWTP) effluents on fish were studied at three Minnesota locations selected to represent a variety of treatment technologies, population sizes and geographic distributions. At each location, a mobile exposure laboratory trailer was set up to conduct 96-hr exposures of male fathead minnows to the wastewater effluent, and upstream and downstream receiving waters. Following the exposures, we conducted analyses of gene expression in the livers using a 15,000 gene microarray developed

specifically for fathead minnow. Gene ontology and gene set enrichment analysis (GSEA) were conducted. GSEA utilized gene sets corresponding to features represented within the gonad compartment of a conceptual model of the teleost brain-pituitary-gonadal axis (BPGA). Gene expression in fish was altered when they were exposed to WWTP effluents, or to the surface water collected either upstream or downstream of WWTPs. One of the prominent observations made in the microarray study was that the all effluents had an effect on genes that regulate reproduction (e.g., BPGA axis) and immune responses in fish. Overall, WWTP effluents had an effect on gene expression that was more similar to downstream sites than the upstream sites, suggesting a detectable effluent signature at all of the downstream sites. These findings suggest that WWTPs are an important contributor to the aquatic pollution, and that they have potential to adversely impact multiple physiological pathways important for organism's fitness (immune system functioning, reproductive success), which is consistent with the complex composition of WWTP effluents. We are currently integrating the results of this study with the apical organismal, metabolomic and chemical data to facilitate use of omic approaches for effects-based monitoring.

#### 48 Molecular insights into heavy metal tolerance in an extremophile polychaete

J. McQuillan, University of Exeter / Biosciences. Coastal and estuarine sediments are an effective sink for heavy metals from anthropogenic sources around river catchments and from the sea, driving the selection of tolerance traits amongst the endobenthic fauna. The best characterised example of an inherited tolerance to heavy metals in animals is considered to be the population of *Nereis (Hediste) diversicolor* (Harbour Ragworm) within Restronguet Creek, a branch of the Fal estuary, Cornwall, UK. The sediments within the upper reaches of Restronguet creek are burdened with extreme levels of Cu, Zn, As, Cd, Mn and Fe; and restrict macro and meiofaunal communities, with the exception of the local population of *Nereis diversicolor*. The Restronguet Creek population is significantly more resilient to metal cations than populations from elsewhere within the Fal estuary, and accumulate significantly higher levels of heavy metals within their tissues, yet little is known about the molecular mechanisms underlying tolerance. Understanding how estuarine organisms adapt and survive under such circumstances is of paramount importance if we are to forecast and manage the impact of global change in these and other marine systems. To elucidate the molecular basis for metal resistance in *N. diversicolor* we utilised 454 sequencing to generate a transcriptome from normalised cDNA libraries, and identified unique transcripts with homology to metal handling and detoxification-associated genes in model organisms. The regulation of select copper-associated gene transcripts was measured in *Nereis diversicolor* from Restronguet Creek and compared with animals from adjacent sites within the Fal estuary having intermediate and low levels of metal contamination. The results indicate that the Restronguet Creek population undergo regulatory changes at the transcriptome level, implying a mechanism for heavy metal detoxification based upon metal cation binding and sequestration, compartmentalisation and storage, and efflux.

#### 49 Canary in a coal mine: Marine mammals as indicators of contamination by persistent organic pollutants (POPs) in the Pacific Ocean

P.S. Ross, Fisheries and Oceans Canada / Institute of Ocean Sciences. A variety of abiotic and biotic matrices have been used in studies documenting trends in Persistent Organic Pollutants (POPs) in the aquatic environment and effects on the health of organisms. Monitoring of effluent discharges, sediments and sessile species have pinpointed contaminant sources and informed management on the effectiveness of regulations on anthropogenic emissions. However, such focussed efforts provide an incomplete picture of the implications of POP contamination for aquatic food webs, habitat, and health of biota. Marine mammals have long provided an integrated overview of POP contamination of aquatic food webs. In the NE Pacific Ocean, our research has centered on killer whales (*Orcinus orca*), which are among the most PCB-contaminated marine mammals in the world. We recently reported significant relationships between PCBs and the upregulation of five gene transcripts, including Aryl hydrocarbon, thyroid, estrogen, metallothionein and interleukin-10 receptors. We have also shown that while ‘local’ sources explain some of PCBs in killer whales, ‘global’ or trans-Pacific sources also contribute. Unlike killer whales, harbour seals (*Phoca vitulina*) provide a more regional source signal, as they are non-migratory and consume primarily resident fish species. Harbour seal samples reveal a steady decline in PCBs in coastal food webs until recently, but an exponential increase in PBDEs until 2005. Research on these two marine mammals indicates that

regulations and international treaties can lead to positive outcomes in upper trophic level marine mammals. However, we suggest that more precaution is needed in the regulation of chemicals deemed to be persistent and bioaccumulative; modelling suggests that killer whales will not be 'protected' from PCB-related health risks until the end of the 21<sup>st</sup> century. The interpretive strength of studies in marine mammal ecotoxicology is clearly improved when such factors as age, sex, feeding ecology, distribution, and metabolism are incorporated into study designs and data interpretation. Marine mammals can serve as informative 'sentinels' of food web contamination when such biological and ecological features are carefully considered.

#### **50 Persistent Organic Pollutants (POPs) in the Puget Sound Ecosystem: An evaluation of POPs in fecal samples of Southern Resident killer whales**

**J.I. Lundin**, University of Washington, Center for Conservation Biology; D. Boyd, NOAA, Northwest Fisheries Science Center; K.A. Parsons, NOAA, Northwest Fisheries Science Center and Alaska Fisheries Science Center; B. Anulacion, NOAA, Northwest Fisheries Science Center; R.K. Booth, University of Washington, Center for Conservation Biology; G.M. Ylitalo, NOAA, Northwest Fisheries Science Center; S.K. Wasser, University of Washington, Center for Conservation Biology. The Puget Sound ecosystem of Washington State has been riddled with human impacts. Exposure to persistent organic pollutants (POPs) has been listed as a primary risk factor for the endangered Southern Resident killer whale (SRKWs, *Orcinus orca*) population that resides in these waters. The objective of this study was to evaluate POPs (PBDEs, PCBs, DDTs, and other chlorinated pesticides) associated with endocrine disruption in SRKW scat (feces) and to describe POP contamination level by pod, age, sex and prey availability. Samples were collected using highly trained detection dogs that ride on the bow of a boat and use scent to locate floating killer whale scat. Using this non-invasive method we collected more than 90 samples across our 5 month study period, allowing an evaluation of temporal patterns of toxicant excretion in killer whale scat relative to prey availability and other environmental pressures. Laboratory analyses of the samples include contaminant quantification using gas chromatography/mass spectrometry, DNA confirmation of species, sex, and individual identity, and reproductive and thyroid hormones measurements by radioimmunoassay. Scat samples analyzed to date demonstrate a congener profile of PCBs similar to the profile found in blubber samples of the same population. This is particularly the case early in the season, when prey abundance is relatively low; specifically, the proportion of PCB138, 149, and 153 (6 chlorine PCBs) in the scat closely match the pattern found in blubber samples during that time. Scat collected during the peak Chinook salmon run tend to contain a disproportionate amount of the lesser chlorinated (< 6 chlorines) PCBs compared to blubber. Pod, sex and age pod differences in fecal POP levels are also consistent with expectations based on measures in blubber biopsy samples. The toxicant profiles in the scat demonstrate significantly higher  $\Sigma DDT/\Sigma PCB$  ratios in K and L pods, known to forage off the California coast, compared to J pod ( $p=0.05$ ), and  $\Sigma PCB$  and  $\Sigma PBDE$  levels are lower in adult females compared to the level in an adult male (J pod, age 19) for the samples analyzed thus far. The study is ongoing with the ultimate goal of evaluating population- and individual-based models that associate temporal contaminant levels with endocrine disruption and adverse reproductive health outcomes.

#### **51 Towards PBDE sediment quality guidelines that are protective of killer whales in British Columbia, Canada: insight from foodweb bioaccumulation models**

**J. Alava**, Simon Fraser University / School of Resource and Environmental Management (Faculty of Environment), Fundacion Ecuatoriana para el Estudio de Mamíferos Marinos (FEMM) / FEMM Filial Playas, Simon Fraser University / School of Resource and Environmental Management, Faculty of Environment; P.S. Ross, Fisheries and Oceans Canada / Institute of Ocean Sciences. At the top of the marine food web, resident killer whales in the coastal waters of British Columbia are heavily contaminated with persistent organic pollutants (POPs), including polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs). The northern and southern populations of resident killer whales are listed, respectively, as threatened and endangered under the Canadian *Species at Risk Act* (SARA), which protects species at risk from being killed or harmed and protects any part of their Critical Habitat from destruction. The Resident Killer Whale Recovery Strategy identified contaminants, reduced prey and disturbance (noise and physical) as conservation threats to population recovery. Sediments in areas and Critical Habitat of resident killer whales contain complex mixtures of contaminants, and material intended

to be dredged, resuspended and disposed of at sea is screened for a select list of contaminants. Because killer whales are long-lived and occupy a very high trophic level, they are at particular risk to accumulating high concentrations of not only PCBs, but PBDEs and several other related compounds. In order to assess the impact of PBDE contaminated sediments and given the complexity of killer whale ecology and that of their primary prey (Chinook salmon), we developed a novel food web modeling tool for the Strait of Georgia, BC, Canada. The modeling approach is based on the distribution of PBDEs among sediments, the water column, and biota, and predicts concentrations that will accumulate in animals throughout a lifetime of exposure. We predicted that that PBDE concentrations in both populations of resident killer whales exceed between 32 and 100% three health effect thresholds for PCBs established for marine mammals (i.e. 1.3, 10, and 17 mg/kg, lipid weight) should their prey be exposed throughout their lives to PBDE concentrations in sediments that are equivalent to the CCME ISQG, the CEPA Action Level Low and the BCMWLAP Sediment Quality Criteria for PCBs. We derived a preliminary sediment PBDE concentration that would protect 95% of resident killer whales of 1.0  $\mu\text{g/kg}$  dry weight. This newly developed food web model can be employed as a risk management tool in support of endangered species protections for killer whales.

#### **52 Persistent Pollutants in Paradise: What stranded Hawaiian cetaceans can tell us about biomarkers in the context of multiple stressors and disease**

**B. Jensen**, Hawai'i Pacific University / Natural sciences. Understanding the factors that tip the balance toward mortality and morbidity in vulnerable cetacean populations is a primary concern in marine mammal toxicology. We have recently identified several diseases of concern in stranded Hawaiian cetaceans, including *Cryptococcus*, *Brucella*, herpesvirus, and most recently (and troublingly), cetacean morbillivirus. The aryl hydrocarbon receptor (AHR) signal transduction pathway is well known to mediate the effects of planar halogenated aromatic subsets of persistent organic pollutants (POPs), resulting in cytochrome P450 1A1 (CYP1A1) induction, carcinogenesis, endocrine disruption, and immunosuppression. This pathway has been the focus of our initial work in understanding POP effects in Hawaiian cetaceans. Unlike regions that have a few dominant cetacean species, Hawaii claims 19 "common" cetacean species, and nearly all are high trophic level odontocetes. Work with this sample archive requires a multispecies approach to understand how certain biomarkers can (and cannot) be used toward inferring health status. Despite their geographically remote habitat in the central North Pacific, Hawaiian cetaceans have organic and trace element contaminant burdens comparable to cetaceans residing near continental coastlines. We assessed the species and inter-individual variability in the AHR, a biomarker for susceptibility, and found that the ligand binding domain of the AHR is highly conserved across 13 species with very low polymorphism, suggesting that odontocetes in general share the previously established potential for high sensitivity to AHR-mediated effects. Next, we assessed the species and tissue-specific expression of CYP1A1 using immunohistochemistry, western blotting, and real time PCR. These results suggest an extremely dynamic state of contaminant distribution and effect across tissue compartments at critical stages of disease progression. Several lines of evidence suggest that persistent POPs as well as non-persistent agonists activate the AHR pathway. Our work on stranded Hawaiian cetaceans is allowing us to build a case for the use of biomarkers for health assessment and to better understand relationships to life history and physiological parameters. Despite the number of confounding factors that stranded animals bring to toxicological analyses, contaminant impacts in health-compromised animals continue to be our primary conservation concern.

#### **53 Persistent organic pollutant concentrations in cetaceans stranded in the Hawaiian Islands, 1997 – 2011**

**M.J. Bachman**, Hawai'i Pacific University / Natural sciences; J.M. Keller, National Institute of Standards and Technology (NIST) / Analytical Chemistry Division; K. West, Hawai'i Pacific University; B. Jensen, Hawai'i Pacific University / Natural sciences. Persistent organic pollutants (POPs) are man-made chemicals that bioaccumulate, persist in the environment for long time periods, and are toxic. Many studies have determined concentrations of POPs in sentinel species, such as cetaceans (dolphins and whales), but no studies have quantified POPs in stranded cetaceans within the last 30 years around the Hawaiian Islands. A suite of 132 POPs were measured in the blubber of 16 species of cetaceans that stranded in Hawai'i from 1997 to 2011. The sample set represents both toothed dolphins and whales ( $n=33$ ) and baleen whales ( $n=3$ ) with additional samples pending analysis ( $n=6$ ). Detectable contaminants

included from highest to lowest general concentration are dichlorodiphenyltrichloroethanes (DDTs), polychlorinated biphenyls (PCBs), chlordanes, toxaphenes, polybrominated diphenyl ethers (PBDEs), hexachlorobenzene (HCB), mirex, hexachlorocyclohexanes (HCHs), hexabromocyclododecanes (HBCDs) and octachlorostyrene. Preliminary medians (standard deviation) in ng/g lipid are: 9,070 (24,400) for  $\Sigma$ DDTs, 5,280 (18,000) for  $\Sigma$ PCBs, 868 (2,230) for  $\Sigma$ chlordanes, 864 (1,690) for  $\Sigma$ toxaphenes, 197 (1,710) for  $\Sigma$ PBDEs, 186 (207) for HCB, 152 (951) for mirex, 99.0 (84.7) for  $\Sigma$ HCHs, 33.9 (178) for  $\Sigma$ HBCDs, and 2.36 (2.66) for octachlorostyrene. Significant species differences were observed for all compound classes. Calves were significantly lower than juvenile, subadult, and adult age classes for  $\Sigma$ PCBs,  $\Sigma$ DDTs, and  $\Sigma$ chlordanes. Decreasing temporal trends were evident for  $\Sigma$ HBCDs and mirex. This presentation will also compare these concentrations to other marine mammal POP data on a global scale as well as against threshold values previously determined for marine mammal toxicity.

#### 54 Methylmercury metabolism across six Arctic marine mammals

– **Interspecies differences in exposure and neurotoxic risk** N. Basu, University of Michigan / Department of Environmental Health Sciences, University of Michigan / Department of Environmental Health; D. Nam, Chonnam University; J. Rutkiewicz, University of Michigan; C. Sonne, R. Dietz, University of Aarhus; T. Beschoft, Aarhus University; P. Leifsson, Royal Veterinary and Agricultural University. Arctic marine mammals bioaccumulate some of the highest methylmercury burdens of any species, though little is known about internal metabolic processes and ultimately adverse outcomes and inter-species sensitivities. Here we performed a comparative study whereby liver and brain tissue was studied from polar bears, pilot whales, harbor porpoises, narwhal, Baikal seal, and ringed seal. For most animals, the brain was dissected into several regions of functional significance (frontal cortex, temporal cortex, occipital cortex, basal ganglia, brain stem, cerebellum, hippocampus, hypothalamus, thalamus, and pituitary). In all tissues, total and organic (methyl) mercury were determined. In some cases selenium (which binds to mercury in a 1:1 molar ratio) was measured, in addition to other persistent contaminants (e.g., PCBs, PBDEs). To explore whether exposures were of neurological concern, a suite of neurochemical biomarkers (e.g., NMDA receptor) was measured across the brain regions and then related back to the measured contaminants. Several results are noteworthy and highlight tremendous inter-species variability in exposure and risk. Across species, the highest mercury levels were generally found in the pituitary tissue. While in most brain regions organic mercury was >80% of total mercury, in the pituitary this value was only ~50%. Brain mercury content was much greater in pilot whales, narwhal, and harbor porpoises (many exceeded 10ppm) versus polar bear, ringed seal, and Baikal seal (few exceeded 1ppm). Changes in some neurochemical biomarkers could be related to brain mercury levels in the aforementioned species with the highest mercury exposures. In a sub-study of polar bears, PCBs and PBDEs did not relate to any neurochemical biomarker. Differences in selenium handling and mercury demethylation are also apparent across species. Overall, these results suggest that certain marine mammals (pilot whales, harbor porpoise) accumulate mercury at levels capable of causing subclinical neurological effect, but others (e.g., polar bears) may have developed unique schemes to sequester or eliminate mercury and thus limit brain exposures.

#### 55 Health risks in ringed seals associated with a point source release of PCBs at a military station in Arctic Canada

T.M. Brown, / Department of Biochemistry and Microbiology, Royal Military College of Canada / Environmental Sciences Group, University of Victoria, Institute of Ocean Sciences; P.S. Ross, Fisheries and Oceans Canada / Institute of Ocean Sciences; C. Helbing, N. Veldhoen, University of Victoria; A. Fisk, University of Windsor; K. Reimer, Royal Military College of Canada. Despite the widespread contamination of aquatic food-webs by polychlorinated biphenyls (PCBs), few studies have unequivocally demonstrated adverse effects specifically attributed to this industrial chemical on marine mammals. Causal evidence linking PCBs to toxic effects in free-ranging marine mammals is generally confounded by the highly complex contaminant mixtures to which they are exposed. Elevated levels of PCBs have been measured in ringed seals (*Pusa hispida*) from the north Labrador coast. Although long-range transport of PCBs through air and ocean currents deliver PCBs and related compounds to Labrador, local sources of PCBs from military facilities along the Labrador coast also exist. Saglek, a former 'Pole Vault' military

radar station, is one of two sites where PCB releases have contaminated the adjacent marine environment. Approximately 25% of ringed seals sampled from 2009-2011 had levels of PCBs that exceed health effects thresholds for another pinniped species, the harbour seal (*Phoca vitulina*). In order to evaluate the implications for ringed seal health, we developed quantitative real-time PCR assay to evaluate the mRNA expression of contaminant-sensitive endpoints, including transcripts encoding the aryl hydrocarbon, thyroid hormone, estrogen, and retinoic acid receptors. Preliminary results show that higher mRNA expression of the AhR receptor and thyroid receptor are correlated with increasing levels of PCBs. The combination of gene expression endpoints, contaminant profiles, and insight into habitat use and feeding ecology afforded us a unique opportunity to explore source, transport, fate of PCBs in a coastal area, and assess the effects of PCBs on the health of ringed seals. Results are relevant not only in terms of the health of the ringed seal population, but also the local Inuit who rely heavily on seals and fish for their subsistence.

#### 56 Are PBT evaluation and environmental criteria protecting marine mammals?

EA Gobas, Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment. Fifty years after Rachel Carson's book *Silent Spring* revealed publicly the potential devastating effects of commercial pesticides on wildlife, many countries including the members of the EU, the US, Canada, Australia and Japan have developed regulations for screening commercial chemicals for their persistence (P), bioaccumulation (B) and toxicological (T) properties. But are we any closer to protecting the wildlife species that Rachel Carson was alerting us about? This presentation discusses the current regulatory methods and risk assessment methods that are used to date to assess the environmental in the context of their ability to adequately protect marine mammals and other high trophic level organisms from harmful environmental pollutants. The presentation evaluates criteria for bioaccumulation and toxicity, water and sediment quality guidelines, tissue consumption criteria for fish consuming wildlife and methods for ecological risk assessment. It is concluded that current methods for the evaluation and management of chemical pollutants are not adequate and appropriate for the protection of marine mammals. Recommendations for further improvement of international regulations and management practices are presented.

#### 57 Sources of Pyrethroids in Municipal Wastewater

K.D. Moran, TDC Environmental, LLC; P.L. TenBrook, U.S. Environmental Protection Agency, Region IX. Pyrethroid insecticides have been linked to widespread toxicity in California surface waters. Published and unpublished studies have also linked pyrethroids in municipal wastewater treatment plant effluent to toxicity to *Hyaella azteca* and *Americamysis bahia*. Recently, researchers and municipal wastewater treatment plants have developed analytical methods capable of measuring nanogram per liter concentrations of pyrethroids in municipal wastewater effluent. Initial studies applying these new methods reported detection of bifenthrin, cyfluthrin, cypermethrin, lambda-cyhalothrin, and permethrin in effluents, sometimes at concentrations higher than potential water quality criteria developed by U.C. Davis for the Central Valley Water Board. Most of the pyrethroids detected in municipal wastewater do not have obvious pathways for discharge to sewer systems. To address this information gap, a conceptual model was developed to describe the sources and pathways for pyrethroids discharges to municipal wastewater treatment plants. This model is based on a review of scientific and engineering literature, pesticide product labels, previously identified discharge pathways for other pollutants, and unpublished data from municipal wastewater treatment plants. The conceptual model categorizes urban pesticide use patterns and disposal practices, and identifies pathways linking pesticide applications with sewer discharges. The model assumes that the bulk of pesticide applications are made to sites specified on product labels, but considers both legal and illegal disposal practices. The model was developed to serve as a tool to prioritize data collection to characterize potential sewer discharge sources of pyrethroids. Understanding pyrethroids sources is critical for development of targeted risk management actions to respond to the pyrethroid-related compliance challenges facing municipal wastewater treatment plants.

#### 58 Fate of pyrethroids through wastewater treatment processes: Bench-scale and full-scale evaluations

J. McGrath, HDR Inc; D. Tessier, A. Barefoot, DuPont Crop Protection; J. Cleary, HDR Inc; H. Monteith, Hydromantis; K. Ohlinger, Sacramento Regional Wastewater Treatment Plant;

H. Ramil, Sacramento Regional Wastewater Facility. The fate of pyrethroids through typical wastewater treatment processes was evaluated through laboratory bench-scale testing and full-scale wastewater plant sampling. At the bench-scale level, removal of pyrethroids through primary settling, anaerobic and aerobic biological treatment and ultra-filtration was investigated. Pyrethroid concentration data were used to quantify removal via sorption and degradation in each process and pyrethroid concentrations exiting the system. Removals achieved depended on the pyrethroid. Similar removals were observed via anaerobic and aerobic biological degradation ranging from approximately 32 to 81%. In the aerobic system, sorption accounted for an additional 4 to 14% removal. Filtration was shown to significantly reduce the concentration of pyrethroids in the simulated effluent. Full-scale wastewater plant sampling was conducted at two facilities, located in California and in New York. At each facility, sampling of influent, effluent, sludges and intra-process locations was conducted. Each facility was modeled using TOXCHEM+, a commercially available program that predicts the fate of trace organic contaminants through wastewater collection and treatment processes using mass transfer and mass balance principles. From the modeling effort, the physical chemical properties describing the fate of the pyrethroids were determined as well as biodegradation rates. Generally, sorption to biosolids and biodegradation were the major removal mechanisms of the pyrethroids accounting for more than 93% removal of the total pyrethroid. Sorption and biodegradation appeared to be competing removal mechanisms. At the New York facility, sorption and biodegradation removals were on average 65 and 30%, respectively. At the California facility, biodegradation removals were higher and averaged 56% and sorption removals were on average 37%. Volatilization losses were negligible for most of the pyrethroids. For both facilities, 2 to 6 % of the input mass of pyrethroids was discharged via the effluent.

**59 Pyrethroid pesticides in municipal wastewater: sources, treatment effectiveness, and effluent quality** D. Weston, University of California / Department of Integrative Biology; H. Ramil, Sacramento Regional Wastewater Treatment Plant; M. Lydy, Southern Illinois University. Pyrethroid insecticides can enter municipal wastewater through drain disposal or urban runoff, but little published information is available on their presence in wastewater in the United States, or their extent of removal during treatment. Influent and effluent of the treatment plant serving communities surrounding Sacramento, California were sampled for pyrethroid insecticides for approximately one year. The compounds were in influent at a total concentration of 200-500 ng/L, with permethrin, bifenthrin, cypermethrin, and lambda-cyhalothrin commonly detected. Sampling within the wastewater collection system suggested the pyrethroids often originated from drain disposal, not entry of urban runoff into the system, and that wastewater from residential areas was similar in pyrethroid composition to the larger metropolitan area as a whole. Secondary wastewater treatment removed approximately 90% of pyrethroids, but those remaining in final effluent still exceeded concentrations acutely toxic to sensitive species. Toxicity was consistently evident in the final effluent. The extent of toxicity in receiving waters will be site-specific, but the large river into which this particular plant discharged provided sufficient dilution such that only slight toxicity of unknown cause was found in one sample.

**60 Distribution of the pyrethroid insecticide concentration between freely dissolved and particle-bound forms in dechlorinated secondary effluent** E. Parry, University of California, Davis / Agricultural and Environmental Chemistry, University of California, Davis / Agricultural and Environmental Chemistry Graduate Group, University of California, Davis; T.M. Young, University of California-Davis / Dept. of Civil & Environ. Engineering. Pyrethroid insecticides are a major current use insecticide class in the US. Pyrethroids have been detected in the dechlorinated final effluent (DFE) of Municipal Wastewater Treatment Facilities at levels toxic to aquatic arthropods. Pyrethroids could pass through the treatment process in a variety of forms: freely dissolved, complexed with organic matter, and adsorbed to sub-micron particles. Effluent from a secondary treatment system was sampled six times in the course of a yearlong study. The DFE was fractionated by laboratory centrifugation to separate different particle size cuts. The pyrethroid concentration associated with each fraction was quantified. Solid phase microextraction (SPME) was used with pyrethroid serial additions to measure an organic carbon normalized distribution coefficient ( $K_{oc}$ ) between pyrethroids and the suspended wastewater particulate matter. Values for log  $K_{oc}$  ranged between 6.5-7.4 depending on sampling event and

chemical. Calculation with the measured  $K_{oc}$  and whole water pyrethroid concentration predicts that < 5% of the pyrethroid is in the freely dissolved phase. The sorbed portion was subdivided by particle size based upon the particle fractionation. The form of the chemical in the effluent has implications for removal mechanisms, bioavailability and fate and transport.

**61 Pesticide Detections and Toxicity in Urban Runoff from Neighborhoods in Northern and Southern California** M.P. Enslinger, R. Budd, California EPA / California Department of Pesticide Regulation; K.S. Goh, California EPA / Department of Pesticide Regulation; L. Deanovic, S. Teh, University California, Davis / Aquatic Health Program. Since 2008 the California Department of Pesticide Regulation has conducted monitoring studies to determine pesticide content in urban runoff. Recently, toxicity testing has been added to this monitoring. Water samples from 11 sites in northern and southern California collected during rainstorm and dry season monitoring were analyzed for pesticides and tested on *Hyalella azteca*. Sediment samples with concomitant sediment toxicity were analyzed from some of the sites. Water samples collected during rainstorm events contained an average of nine pesticides per sample; none of the *H. azteca* survived in the toxicity tests. Based on benchmarks or water quality criteria, bifenthrin, fipronil, cyfluthrin, cypermethrin, and malathion likely contributed to the toxicity. Samples also contained 2,4-D, dicamba, triclopyr, desulfinyl fipronil, imidacloprid, and permethrin; the combined effects of all the detected pesticides as well as other environmental stressors may have impacted toxicity. Water samples collected during dry season monitoring have fewer pesticides and likely affect toxicity accordingly. Sediment samples were toxic to *H. azteca*. Bifenthrin was the most commonly detected pyrethroid and gave the highest toxicity units; lambda-cyhalothrin, cyfluthrin, and cypermethrin were also implicated in sediment toxicity.

**62 Trends in Stream Contaminants and Toxicity in California: The SPoT Program** K. Siegler, University of California – Davis / Environmental Toxicology; B.M. Phillips, University of California – Davis / Environmental Toxicology, University of California-Davis / Granite Canyon; B. Anderson, University of California – Davis / Department of Environmental Toxicology; J. Voorhees, University of California – Davis / MPSSL – Environmental Toxicology; L. Jennings, R. Tjeerdema, University of California – Davis / Environmental Toxicology. The Stream Pollution Trends (SPoT) program is a statewide monitoring program under the umbrella of the Surface Water Ambient Monitoring Program (SWAMP). SPoT is designed to detect trends in contamination and toxicity in major watersheds of California. Sites at the base of 100 watersheds were selected for integrative measurements of sediment toxicity and a suite of pesticides, trace metals, and industrial compounds. Toxicity was observed at 22% (2008), 35% (2009), 25% (2010), and 19% (2011) of the sites using the 10d *Hyalella azteca* test. The prevalence of pyrethroid pesticide detections increased from 55% in 2008 to 76% in 2010, with maximum concentrations of sum pyrethroids increasing from 113.0 ng/g to 1043.1 ng/g. In 2010 and 2011, a subset of sites was tested for toxicity at 15°C, as well as the standard test temperature of 23°C. Within this subset, the percent of sites that were toxic increased from 35%, when tested at 23°C, to 62% when tested at 15°C. This suggests pyrethroid pesticides contributed to the observed toxicity. Land use in each watershed was characterized using data from the National Land Cover Database and Spearman multivariate correlations were conducted to determine correlations between land use type, sediment toxicity, and contaminant concentrations. In 2008, pyrethroid pesticides were significantly correlated with urban watersheds. The overall trends suggest that sediment toxicity is fairly consistent, pyrethroid detections are increasing, and detections of pyrethroid pesticides are more strongly correlated with urbanized watersheds.

**63 Pesticides, Urban Streams, and Pacific Salmon: What Have We Learned Over the Last 10 Years** C. Grue, Washington Cooperative Fish and Wildlife Research Unit, University of Washington / School of Aquatic and Fishery Sciences, USGS, Washington Cooperative Fish and Wildlife Research Unit / University of Washington; K.A. King. Pesticides are frequently detected in urban streams and are believed to be primarily the result of homeowner use with concentrations often exceeding those reported in surface waters associated with agricultural areas. The listing of several runs of Pacific salmon as threatened or endangered and associated federal, state, and local efforts to restore/enhance salmon habitat in the Pacific Northwest make it imperative that the factors associated with these population declines are understood. We review the results of laboratory studies conducted over

the last 10 years that have examined direct toxic effects on most aspects of the life cycle of Pacific salmon using primarily juvenile coho (*Oncorhynchus kisutch*) and surrogate rainbow trout (*O. mykiss*). Exposures include single active ingredients, formulated products, or mixtures ("cocktails") representative of those most frequently reported in urban streams in western Washington State. Endpoints include brain acetylcholinesterase (AChE) activity, pre-spawn survival, growth and survival during early life stages, smoltification, olfaction, immune competence, and return rates of adults exposed to pesticides as juveniles. Results of studies by the authors as well as others will be included. Exposures will be compared to data available on environmental concentrations of pesticides within surface waters in both urban and agricultural areas. Data gaps will be identified. We conclude with directions for future research.

**64 Occurrence and toxicity of current-use pesticides in sediment from an urban stream in Guangzhou, China** H. Li, Guangzhou Institute of Geochemistry / Chinese Academy of Sciences, Graduate School of the Chinese Academy of Sciences; B. Sun, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; J. You, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences / State Key Laboratory of Organic Geochemistry. Non-point source runoff greatly contributed to pesticide contamination in urban aquatic ecosystems, and the contribution increased with the reduction of contribution from the wastewater plant effluents due to the improvement of sewage treatment capability in the cities. Research on environmental occurrences and ecotoxicological significance of current-use pesticides (CUPs), however, was limited in China. In the present study, sixteen sediments were collected from an urban stream in a Chinese city, Guangzhou. Four classes of CUPs including organophosphates (OPs), pyrethroids, fipronil and abamectin, were analyzed. Chlorpyrifos was the only OPs detected above the reporting limit, while pyrethroids, especially cypermethrin, were the most dominant pesticides in the sediments, with a mean concentration being 140 ng/g dry weight (dw). Additionally, fipronil and its two metabolites, fipronil sulfide and fipronil sulfone, were also detected in all sediments with a mean concentration being 13.7 ng/g dw. Elevated concentrations of abamectin were also detected with a mean concentration of 12.6 ng/g dw. On the other hand, sediment toxicity was evaluated using *Chironomus dilutus* and 15 of 16 sediments collected from the stream exhibited acute toxicity, within which 81% of sediment samples caused 100% mortality. Abamectin, fipronil and pyrethroids (mainly cypermethrin), were regarded as the principal contributors to the noted toxicity to the midges, with average predict toxic units being 2.44, 2.13, and 1.88, respectively. Results also showed that sediments in the downstream of the stream, where residential and industrial regions were located, had elevated CUP concentrations and sediment toxicity. Principal component analysis indicated that chlorpyrifos, fipronil and abamectin mainly originated from agricultural use in the urban villages, whereas pyrethroids were mainly released from residential use. As the first study to link sediment residues of fipronil and abamectin with toxicity to non-target species in urban streams in China, the present study urged more research on ecotoxicological effects of CUPs in order to catch up the rapid changes in pesticide application patterns in China.

**65 Change in Inputs to Coastal Waters off Southern California in the Forty Years Since Adoption of the Federal Clean Water Act** G. McGowen, City of Los Angeles / Environmental Monitoring Division. The southern California coast is an economic engine for the region, drawing in both residents and visitors. It supports a multitude of industries, businesses, and jobs, as well as recreation. Like developed coastlines around the world, the coastal waters off southern California also serve as a disposal site for the residues of human life and activities, including stormwater runoff and treated wastewater. By the 1960s, the conventional wisdom about the effects of wastes in the environment was being increasingly called into question as adverse impacts became increasingly obvious. The result was a flurry of legislative activity between 1960 and 1980, including the Federal Clean Water Act in 1972. In the forty years since enactment of the Federal Clean Water Act, a lot of resources have been expended to comply with it. Was anything accomplished? Was it worth it? How have things changed? The Technical Advisory Group to the Commission of the Southern California Coastal Water Research Project recently undertook a collaborative effort to assess the impact of the Federal Clean Water Act on southern California Coastal waters. This presentation addressed one aspect of this: changes in what we put into southern California Coastal waters.

**66 Trends and factors affecting coastal hypoxia in the Southern California Bight (SCB)** J.T. Booth, UCLA / Department of Atmospheric and Oceanic Sciences; C. Woodson, Stanford University / Department of Civil and Environmental Engineering; F. Micheli, Stanford University / Hopkins Marine Station; L. Crowder, Center For Ocean Solutions; E. Hazen, National Oceanographic and Atmospheric Administration / Pacific Fisheries Environmental Laboratory; E. McPhee-Shaw, Moss Landing Marine Laboratory; S.B. Weisberg, Southern California Coastal Water Research Project; M. Sutula, Southern California Coastal Water Research Project / Biogeochemistry Department; S.Y. Litvin, Stanford University / Hopkins Marine Station. Coastal hypoxia has been increasingly documented in nearshore waters the California Current Large Marine Ecosystem (CCLME). While in other regions of the world, coastal hypoxia has a strong linkage to anthropogenic nutrient inputs, low dissolved oxygen (DO) in California's nearshore has been linked to offshore influences such as upwelling, which can transport hypoxic bottom-waters to the shelf. For Southern California, a heavily populated region which discharges treated municipal effluent as well as urban runoff to the SCB, the extent of coastal hypoxia and the contribution of anthropogenic nutrients versus offshore processes to the problem have not been investigated. In this study, we utilize a 30 year time series of coastal transects (< 15km from shore) collected during quarterly surveys by the four major sanitation districts to investigate spatial patterns and trends in DO concentration. Significant negative trends in DO occurred in all agencies from 1998 to present, though data for several transects dating back to 1981 show a significant but mild positive DO trend prior to 1998. Comparisons with profiles from the CalCOFI time series (inshore of 200 km) showed similar regional trends, with little trend before 1998 and strong negative trends after 1998. While DO concentrations within the nearshore transects has a 3 fold larger negative trend than CalCOFI data, suggesting that anthropogenic inputs may be causing some localized declines in DO, the large regional scale of the declines suggest that negative trends in coastal oxygen are due to changing source waters, brought into the shallow nearshore by upwelling.

**67 Changes over the Past Four Decades in Fishability and Ecosystem Health in the Southern California Coastal Ocean** K. Setty, Southern California Coastal Water Research Project (SCCWRP). Two primary goals of the Clean Water Act were to make the nation's surface waters "fishable" and restore the integrity of aquatic ecosystems. In southern California, many efforts have been made across different sectors to achieve these goals. The Southern California Coastal Water Research Project's Commission's Technical Advisory Group recently undertook a collaborative effort to analyze historical data trends and determine whether conditions in coastal marine waters have improved as a result. Levels of bioaccumulative pollutants like DDT and PCBs have declined dramatically in fish populations. Still, fish consumption advisories remain for much of the coastline, often due to widespread moderate mercury contamination. The incidence of fish disease has also been greatly reduced, and fish and invertebrate community integrity has improved to a fair degree. Birds of prey like the brown pelican are on the rebound, though their recovery has been slowed by legacy contamination. Kelp forests and rocky reef habitat show some positive effects of improved water quality management, but are also impacted by other factors like natural climate cycles, coastal development, and fishing pressure. Future challenges facing regulators and environmental managers include the greater pollution impacts in enclosed coastal embayments and novel water pollution issues like ocean acidification, global climate change, marine debris, and the subtle toxicological effects of emerging contaminants.

**68 Forty Years of Progress: Recreational Water Quality Management in California** J.F. Griffith, Southern California Coastal Water Research Project / Department of Microbiology. California recreational water quality management has evolved steadily over the past decades. With the highest rates of beach visitation in the nation, California's coastal waters are recognized as a valuable economic resource and aesthetic benefit to all. In the past decade multiple examples of regional stakeholder collaboration have led to steady improvement in beach water quality, indicating the common concern for successful ambient water quality management. There are multiple examples of collaborative efforts that have led to water quality improvement, including dry and wet weather diversion of stormwater and urban runoff for treatment and use of advanced modeling and BMP-based approaches for water quality management. California has also led scientific advancement in the area of technology development and implementation including

development and implementation of novel microbial source tracking and rapid beach water quality measurements methods. This presentation will focus on trends in regional water quality and technological advancements.

**69 Long-Term Trends in Water Quality in San Francisco Bay** J.A. Davis, J. Ross, San Francisco Estuary Institute; M. Kellogg, San Francisco Public Utilities Commission; A. Cohen, Center for Research on Aquatic Bioinvasions. A new State of the Bay Report for San Francisco Bay summarizes progress in attaining management goals relating to habitat, water supply and quality, living resources, ecological processes, and stewardship. A water quality evaluation is a component of the Report that assesses whether the Bay is safe for aquatic life, whether Bay fish are safe to eat, and whether the Bay is safe for swimming. Many monitored pollutants are considered to pose very low risk to Bay aquatic life, but a few (especially methylmercury, exotic species, the toxicity of sediments, and trash) pose substantial threats. Several other pollutants appear to pose risks to Bay aquatic life, but definitive regulatory goals for the Bay have not yet been developed. A few prominent examples include selenium, polynuclear aromatic hydrocarbons, and perfluorooctanesulfonate (PFOS). Fish from the Bay are not entirely safe to eat, due mainly to polychlorinated biphenyls (PCBs), methylmercury, and dioxins. Most Bay beaches are safe for swimming in the summer, but bacterial contamination is a concern at a few beaches in the summer, and at most beaches in wet weather. Overall, thanks to the considerable investment that has been made in wastewater treatment infrastructure and the diligent efforts of water quality managers, the Bay is much safer for aquatic life and for people to fish and swim in than it was in the 1960s. Substantial control efforts that began in the 1970s as a result of the Clean Water Act solved most of the obvious problems of the 1960s and set the Bay on a course for gradual recovery for many pollutants. However, challenges, information gaps, and uncertainties remain to respond to legacy contaminants, such as mercury and PCBs, emerging contaminants, nutrients, and other threats to water quality. Complete and timely resolution of remaining and emerging water quality challenges will require significant investments of resources to replace and improve our aging water quality infrastructure.

**70 Meta-Analysis of Selected Puget Sound Initiative Sites: Remediation Progress and Possible Geographic Influences** R. Combs; R. Combs, Western Washington University; A. Spanjer, Western Washington University / Huxley College of the Environment; J. Barnes, D. Cheyette, K. Woolsey, R. Green, Western Washington University; R.M. Sofield, Western Washington University / Huxley College of Environment. This study is a secondary analysis of sediment data comparing different cleanup project successes across the Puget Sound using data from the early 1980s to the present. The analysis focuses on six bays within the Puget Sound identified as part of the Puget Sound Initiative (PSI). It compares current levels of sediment contamination and expected exposure to biota with current state sediment standards and other accepted guidelines for each bay using Apparent Effects Threshold, PEL/TEL, and ERM/ERL values. Measured sediment and tissue concentrations of arsenic, mercury, PAHs, and total PCBs in each bay were retrieved from the Washington State Environmental Information Monitoring System (myEIM) and compared to the sediment standards and guidelines. Percent contamination above the sediment guidelines and standards by surface weighted average concentration area per bay and per chemical, and for percent contamination above the values by year per bay and chemical were calculated. Correlations were also calculated for sediment contamination with a selected range of environmental parameters shown in the literature to influence contamination levels in sediments, such as average sediment loading, freshwater discharge runoff rate and percent land use categories. Of the selected chemicals analyzed, mercury, PCBs, and arsenic had significant correlations with these environmental parameters. Animal tissue data taken synoptically with sediment data was also compared to these same environmental parameters. Future work will include correlating geographic and anthropogenic factors that may influence sediment concentrations and analyzing the progress and stage of remediation each bay is currently engaged.

**71 Changes in the Northeast U.S. as a Result of the Clean Water Act: The Chesapeake Bay Watershed Experience** C.W. Abdalla, Pennsylvania State University / Department of Agricultural Economics, Sociology and Education. The Chesapeake Bay is North America's largest and most biologically diverse estuary and is an important commercial and recreational resource. The Bay is estimated to contribute an annual economic

benefit estimated at \$33 to \$60 billion (2010 dollars). Seventeen million people currently live with the Bay's 64,000 square mile watershed in the District of Columbia or within portions of Delaware, Maryland, New York, Pennsylvania, Virginia and West Virginia. Most of the Bay's waters are listed as impaired because of excess nutrients (nitrogen and phosphorus) and sediment. These pollutants have disrupted the Bay's ecosystem, creating conditions that impact the survival of aquatic life. Man's activities (e.g. land development, agricultural operations, urban and suburban runoff, wastewater discharges, and air pollution) have degraded the Bay. Important phases in public policies and programs implemented under the auspices of the federal Clean Water Act to improve quality of the Chesapeake Bay include: 1) a partnership – the Chesapeake Bay Program – created in 1983 among the EPA, Maryland, Pennsylvania, and Virginia, and the District of Columbia to address the extent, complexity, and sources of pollutants entering the Bay; 2) In 1987, the partners committed to reduce controllable nutrients loadings by 40 percent by 2000; 3) In 2000, the partnership signed an agreement that provided an alternative to developing a Bay-wide Total Maximum Daily Load (TMDL) based on the expectation that actions would be taken to meet water quality standards within the Bay by 2010. 4) In 2007, EPA concluded that despite extensive efforts by federal, multi-state, state/local governments, non-governmental organizations, and other stakeholders insufficient progress had been made toward meeting the water quality goals for the Chesapeake Bay and its tidal waters. As a result, EPA issued a Bay-wide TMDL – the most complex ever approved by EPA – to achieve reductions in nutrient and sediment pollution throughout the Bay watershed. This presentation will review the major phases in federal, multi-state and state policies and programs under the Clean Water Act's authority from the 1980s to the Chesapeake Bay-wide TMDL that is currently being implemented. Observations will be made about each phase's goals, approaches, outcomes, limitations and lessons learned.

**72 Ambient water quality in the Southeastern US: Trends and advancements in water quality management** R. Noble, D. Blackwood, UNC Chapel Hill / Institute of Marine Sciences. In the past several decades, the coastal and estuarine shorelines of the Southeastern USA have undergone dramatic development, resulting in increased use and appreciation of the beautiful beaches, but with concomitant increases in the delivery of microbial contaminants to receiving waters due to stormwater, increased impervious surface coverage, and increased sewage inputs, to name a few. For the past several years, states such as North Carolina have risen in their importance and rate of visitation from tourists, and the recreational activities possible in this region have expanded to include kayaking, canoeing, parasailing, ecotourism, kitesurfing and surfing. In response to the growth and development along the coastlines of Virginia, North Carolina, South Carolina, Georgia, and Florida, increased attention has turned to stormwater research, stormwater controls, and stormwater mitigation, as storms are major forces contributing pulses of microbial contaminants to systems. Storms are highly variable, with ranging levels of intensity and duration corresponding to seasonal change and vegetation. Extreme storm events play an important role in the contamination of surface waters of the region, with hurricanes and Nor'easters sometimes causing contamination that persists over the duration of months. Furthermore, common BMPs are of limited use due to the shallow nature of the water table, and flat landscape. We will present case studies that demonstrate some of the major issues facing the Southeastern states in preserving and restoring surface water quality. In addition, we will discuss trends in water quality over the past decades, including an examination of major trends in water quality in North Carolina using multiple linear regression techniques. When considering long term water quality management in the Southeastern states, a common theme is watershed based management, because watersheds are vast due to the topographic nature of the flat coastal plain. Therefore, a common thread for this presentation will be the importance of the linkage of data from tidal streams through estuaries to the barrier island beaches. The success of water quality management in this region is dependent, finally, upon stakeholders of all perspectives working together to solve problems. Highlights in successful water quality management over the past decades, along with observation of trends and consideration for the future will be presented.

**73 Birds as a Tool in the Great Lakes AOC Delisting Process** C.M. Custer, U.S. Geological Survey / Upper Midwest Environmental Sciences Center, U.S. Geological Survey / Upper Midwest Environ. Sciences Center; T.W. Custer, U.S. Geological Survey / Upper Midwest Environmental

Sciences Center, U.S. Geological Survey; P.M. Dummer, U.S. Geological Survey. Two wildlife-related Beneficial Use Impairments (BUIs) are present at many of the Great Lakes' Areas of Concern (AOCs): Bird or Animal Deformities or Reproduction Problems and Degradation of Fish and Wildlife Populations. Tree swallows (*Tachycineta bicolor*) are an ideal species to address these two BUIs because they can be attracted to specific AOCs, even to highly urbanized and industrial environments, in large enough numbers to collect statistically valid reproductive and contaminant exposure data. Because tree swallows are aquatic insectivores, contaminant concentrations in their tissues reflect what is present and bioavailable in AOC sediments. Nest boxes can be placed so that their feeding range represents sediment contamination at the AOC and not other aquatic habitats in the general vicinity. Because of the wide-spread use of tree swallow for contaminant assessment studies, there are benchmark contaminant-effect threshold values now available for various contaminant classes. This Great Lakes Restoration Initiative funded project has now collected three years of data at 20 AOCs encompassing 40 unique study sites, as well as, data from 6 nearby reference areas. Data have been collected on both organic and inorganic contaminants including legacy contaminants of concern (e.g., polychlorinated biphenyls [PCBs], dioxins and furans, pesticides, and mercury), as well as many new and emerging contaminants such as polybrominated diphenyl ethers (PDBEs) and perfluorinated compounds (PFCs). Data have also been collected on reproductive, physiological, and genetic endpoints at each of these sites, and will be used in conjunction with contaminant concentrations to ascertain whether there is an association between chemical exposure and these effect endpoints. These data are providing a valuable tool for both State and Federal agencies to assess the status of these two wildlife-related BUIs and whether they can be removed.

#### **74 Demonstrating the restoration of Great Lakes AOC Beneficial Uses: Ashtabula River Case Study**

**A.P. Mucha**, U.S. Environmental Protection Agency / Great Lakes National Program Office; A. Klei, P. Anderson, Ohio EPA; M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development; S. Cieniawski, U.S. Environmental Protection Agency / Great Lakes National Program Office. The Great Lakes designated 43 Areas of Concern (AOCs) are defined by the number and extent of Beneficial Use Impairments (BUIs) present. The 14 potential BUIs span a wide range of impacts and endpoints and include restrictions on dredging, restriction on fish and wildlife consumption, and degradation of benthos. To restore AOCs, individual BUIs must be removed and requires building a scientific case demonstrating improvement. The Ashtabula River AOC is a priority site where all key management actions must be completed by 2012. At the Ashtabula River AOC, there are currently 6 BUIs, including degradation of benthos, fish tumors and deformities, and restrictions on fish and wildlife consumption. To effectively document the function of the ecosystem and to assess the status of the beneficial use impairments requires extensive data and documentation. Over 500,000 yds<sup>3</sup> of contaminated sediment was dredged from the river along with in water and riparian habitat restoration under the Great Lake Legacy Act Program in 2007. Additional and more significant habitat restoration was done by Ohio EPA using GLRI funding. In 2011, a multi-Agency sampling effort took place on the Ashtabula AOC to address multiple regulatory and AOC goals. The data that resulted from this effort were critical in defining actions needed at the AOC as well as help define the status of restoration at the AOC. The plan was a multiple Agency effort involving EPA, USFWS, NOAA, and the Ohio state agencies. The sampling and data collection included such measures as surface weighted average concentration (SWAC) established with surface sediment concentrations, biota contaminant concentrations (i.e. fish, macrobenthos), etc. These data have been collected and compared to historic data collected historically and immediately prior to remediation and restoration. Trends indicate that there has been recovery within the AOC following the management actions to date. These data will be presented and discussed as well as additional management actions that remain.

#### **75 Expanded Mussel Watch AOC Assessment as part of Great Lakes Restoration Initiative**

**K. Kimbrough**, W. Johnson, NOAA/National Centers for Coastal Ocean Science / NCCOS Mussel Watch Program; T. Nalepa, NOAA/GLERL / GLERL; J. Hyland, NOAA/National Centers for Coastal Ocean Science / Center for Coastal Environmental Health and Biomolecular Research; M. Fulton, NOAA/National Centers for Coastal

Ocean Science / Marine Ecotoxicology Division; A. Jacob, Consolidated Safety Services. NOAA's Mussel Watch, a nationally recognized contaminant monitoring program, has been monitoring chemical contaminants in the Great Lakes since 1992. Two decades of monitoring has documented the continuing presence of legacy contaminants and heavy metals at many locations within the Great Lakes. Recently, through coordination with Great Lakes Restoration Initiative, Mussel Watch has expanded its monitoring efforts to include all U.S. Great Lakes Areas of Concern (AOC), with the objective of providing data and information in support of decision making for removal of Beneficial Use Impairment targets and delisting of AOCs. In addition to routine monitoring of more than 150 contaminants in bivalve tissues, Mussel Watch will provide data on sediment contamination, benthic infaunal composition, sediment toxicity and cellular biomarkers of exposure and effects. Data from AOCs can be meaningfully interpreted by comparisons to long-term historic Mussel Watch sites, which can provide important baseline data as well as serve as reference sites. Enhanced Mussel Watch efforts can thus aid resource managers and policy makers in making informed management decisions, and contribute to the overall restoration and protection of the Great Lakes.

#### **76 Fish Population Modeling Approaches for Assessing Direct Effects and Recovery Following Mitigation of a Pulp Mill Effluent in Jackfish Bay**

**D.H. Miller**, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; J.E. Tietge, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; M.E. McMaster, Environment Canada / National Water Research Institute; K.R. Munkittrick, University of New Brunswick / Canadian Rivers Institute, University of New Brunswick / Department of Biology; X. Xia, D.A. Griesmer, Computer Sciences Corporation; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division. We present an approach to link chemically induced alterations in molecular and biochemical endpoints to adverse outcomes in whole organisms and populations. A predictive population model was developed to translate changes in fecundity measures of white sucker (*Catostomus commersoni*) collected at Jackfish Bay, Lake Superior to alterations in population growth. Individual-level responses of fish exposed to pulp mill effluent were used to demonstrate the model's capability to project alterations in population status, both in terms of ongoing impact and subsequent recovery after stressor mitigation associated with process changes at the mill. Long term monitoring data from the Jackfish Bay site includes biochemical endpoints, such as steroid measurements, relevant to an adverse outcome pathway (AOP) resulting in decreased fecundity. In combination with population modeling, the AOP framework can be used as an organizing principle by which mechanistic data (e.g. circulating steroid concentrations) can be effectively translated into endpoints meaningful to ecological risk (e.g. population status). Extrapolation of the population modeling construct demonstrated at the Jackfish Bay site can be made to characterize white sucker population trends at other sites that are less data rich. This abstract does not necessarily reflect U.S. EPA Policy.

#### **77 Metabolomic Approaches for Characterizing Impaired Aquatic Ecosystems**

**T. Collette**, U.S. EPA / National Exposure Research Laboratory; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; E. Durhan, US EPA / Mid-Continent Ecology Division / Research Chemist; K. Jensen, M. Kahl, U.S. EPA / National Health and Environmental Effects Research Laboratory; K. Lee, U.S. Geological Survey; E. Makynen, US EPA / Mid-Continent Ecology Division; D. Skelton, U.S. EPA; Q. Teng, US EPA / National Exposure Research Laboratory; A. Trowbridge, U.S. Fish and Wildlife Service; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; D.R. Ekman, US EPA / National Exposure Research Laboratory. Metabolomics is becoming a well-established tool for studying how organisms, such as fish, respond to various stressors. For example, the literature is rich with laboratory studies involving analysis of samples from organisms exposed to individual chemical toxicants. These studies have demonstrated the ability to rapidly screen and prioritize chemicals for adverse effects, and to determine mode-of-action-specific exposure biomarkers. In addition, there has been promising laboratory work with metabolomics for characterizing an organism's compensation and recovery from toxic effects, and for defining

the complex temporal nature of responses to stressors. Our group has recently leveraged information gained from these laboratory studies in order to use metabolomics for biological-based exposure monitoring in Great Lakes Areas of Concern (AOCs), using field-deployed caged fish. One promising outcome of this work has been recognition of the potential to correlate adverse outcomes (as measured by metabolomics) with individual stressors that occur in the AOCs. For example, with this approach, information from metabolomics may contribute to the weight of evidence that a particular chemical contaminant (or class of contaminants) is causing a particular Beneficial Use Impairment (BUI) within an AOC. Information of this type could be very valuable for designing effective remediation strategies. In addition, metabolomics has emerged as an ideal candidate tool for characterizing recovery trends in fish and other organisms, suggesting its use in long term biological-based monitoring studies over the course of restoration activities. As such, metabolomics may provide critical information in ongoing efforts to eliminate BUIs and to delist AOCs. Results from preliminary studies that illustrate the potential for these applications will be presented.

#### **78 Pathway-based Monitoring of Biological Effects at Great Lakes sites**

N. Vinas, Mississippi State University; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory; L. Escalon, US Army Engineer Research and Development; T. Habib, BTS; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; E. Durhan, US EPA / Mid-Continent Ecology Division; M. Kahl, K. Jensen, U.S. EPA / National Health and Environmental Effects Research Laboratory; J. Cavallin, U.S. EPA, ORISE / National Health and Environmental Effects Research Laboratory; E.J. Perkins, US Army Engineering Research & Development / Environmental Laboratory, US Army ERDC / Environmental Processes & Effect Division, US Army Engineering Research & Development / Environmental Genomics and Genetics Team. The Great Lakes region suffers from degradation of water and environmental quality due to release of chemicals of emerging concern (CEC) that may threaten near shore health. Critical issues remain in delisting AOC including determining sources of chemicals causing fish health impacts (sediment, sewage overflow, effluent discharges, or tributary waters), relating health impacts to chemical exposure or specific source points, and identifying causes of adverse health effects such as tumors and reproductive effects. Causal information would enable decision makers to identify more appropriate remedial actions thereby facilitating delisting of AOC. Fish placed in floating cages at different locations within AOC can be used to rapidly monitor the impacts of chemicals on fish health by monitoring chemicals in water, fish, and resulting impacts to fish health in terms of reproductive, physiological and genetic measures. Specific changes found in fish organs such as gonads and liver can be associated with specific effects. For example impacts on egg protein and hormone production related genes are associated with classes of chemicals causing reproductive impacts. Similarly changes in specific genes can be associated with exposure to polycyclic aromatic hydrocarbons and other chemicals. We are using molecular changes in liver and gonad tissues to identify the health impacts, if any, caused by several high-priority AOC. We will also use gene changes in liver and gonads to identify possible chemicals of concern based on gene changes associated with specific chemical exposures in the laboratory. We expect that this work will identify any potential health effects in fish leading to more accurate assessment of contaminant effects on near shore health. We also expect that this would provide more accurate monitoring of effects during restoration and other efforts in the Great Lakes Restoration Initiative program.

#### **79 Riparian indicators of PCB exposure in Manistique River and Harbor AOC**

D. Walters, USGS / Fort Collins Science Center; M.A. Mills, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development; A.P. Mucha, U.S. Environmental Protection Agency / Great Lakes National Program Office; S. Cieniawski, U.S. Environmental Protection Agency / Great Lakes National Program Office. The Manistique Area of Concern (AOC) in northern Lake Michigan is contaminated with polychlorinated biphenyls (PCBs). This AOC includes ~2.8 km of the Manistique River and Harbor as well as backwater habitats that are part of a system of docks constructed during an earlier lumbering era. These backwaters are connected to historic PCB sources and remain prone to high, patchy sediment PCB concentrations. We initiated a 2011 study designed to 1) characterize aquatic habitats (backwaters, river, harbor, and

Lake Michigan) using biogeochemical attributes; 2) quantify PCB exposure in riparian predators relative to contaminated sediments; and 3) develop indicators and tools to assess the effectiveness of future remedies. We collected water quality data, sediments, and riparian spiders (Araneida and Tetragnathidae) at 10 sites encompassing backwater, river and harbor sites, an upstream reference site, and a beach/lake site that is subjected to episodic and large pulses of woodchips and sawdust from Manistique River. Backwaters had distinctive biogeochemistry due to a combination of factors related to groundwater inputs (e.g., higher conductivity) and ecosystem processes (e.g., lower DO). Sediment concentrations in the AOC varied from 135 – 10200 ng/g ΣPCB (dry weight) and were typically higher at backwater and harbor sites. Spider concentrations varied from 47 – 370 ng/g ΣPCB (wet weight) and were significantly, positively correlated with sediment ΣPCB<sub>TOC</sub> concentrations ( $r^2 = 0.48$ ;  $p = 0.002$ ). Sediment PCBs within the AOC were dominated by low-chlorinated congeners and were strongly dissimilar from lake and reference sites. We conclude that (1) distinctive chemistry and organic matter dynamics in backwaters could influence PCBs cycling and bioaccumulation within these habitats as well as PCB fate and transport within the AOC; 2) spiders are good indicators for assessing riparian PCB exposure and for assessing the effectiveness of future remedies; and 3) patterns of congener distributions can provide critical information regarding source control and remedy effectiveness.

#### **80 Mink jaw lesions, a sensitive indicator criteria for BUI delisting**

M.J. Zwiernik, Michigan State University, Wildlife Toxicology Laboratory / Department of Animal Science, College of Veterinary Medicine; W.R. Folland, Michigan State University, Wildlife Toxicology Laboratory / Department of Animal Science, College of Veterinary Medicine; J. Moore, Michigan State University, Wildlife Toxicology Laboratory / Dept. of Animal Science; S.J. Bursian, Michigan State University / Department of Animal Science. The ultimate goal for any Area of Concern (AOC) is the elimination of Biological Use Impairments (BUIs) and subsequent site delisting. One of major obstacle to AOC delisting is that BUIs are often noted in multiple ecological compartments with assessment endpoints that are not clearly linked to measureable goals. Here we present a newly identified sensitive biomarker in a recognized sentinel species to identify contaminant exposure and establish a measurable criteria for ecologically relevant BUI listing and delisting for AOCs containing polychlorinated biphenyls, dioxins, and other dioxin-like compounds (DLCs). The American mink is an ideal sentinel receptor species for assessing the ecological risk of AOCs containing DLCs, because mink are exquisitely sensitive to this class of compounds and have great exposure potential as territorial, year round resident apex predators. We have identified jaw lesions as a sensitive biomarker that responds over a wide range of DLC exposures in wild and controlled study mink exposed to DLCs. The biomarker is easily quantifiable by gross examination in severe cases, resulting in visible lesions and microscopically for animals exposed to concentrations 2- to 10-fold lesser than those known to adversely affect reproduction and health. The direct relationship between dose and response severity, anchored on the most severe end with an ecological relevant response, adds utility to the response as a biomarker allowing an estimation of risk distribution based on the severity of the biomarker as seen among individuals or populations. The majority of the response curve is not associated with an adverse impact on individuals thus its presence is not selected against within the population. This is important because growth and reproductive parameters are often key assessment endpoints associated with ecological BUIs criteria, however both are virtually impossible to measure in the field. In addition to the biomarker distribution, abundance, demographics, and morphological measures can also be used to assess population structure and status, which can provide additional support to BUI delisting criteria. Finally, mink tissues may be easily and inexpensively obtained as byproducts of the trapping industry thus acquiring individuals often require minimal effort while providing public education and involvement.

#### **81 Tidal induce transport of mercury in salt-marsh sediments**

L. Canario, IPMA I.P. / Aquatic Environment and Biodiversity; M. Caetano, IPMA I.P.; L. Poissant, Environment Canada; C. Vale, IPMA I.P.; N.J. O'Driscoll, Acadia University, Acadia University / Department of Earth & Environmental Sciences. Intertidal environments are characterized by complex subsurface hydrologies regulated by topography, sedimentology, groundwater discharge, as well as tidal pressure and wave action. In these environments vertical flow at ebb tide increase hydrostatic pressure at depth and forces the release of pore water to the surface. In order to assess how

this force influences mercury fate in intertidal sediments and the associated biogeochemical processes, several inundation experiments were performed in vegetated and non-vegetated intertidal sediments in three sites of the Tagus Estuary (Portugal). Sediments and overlying water were collected at a high temporal resolution after inundation at each sampling site. Dissolved gaseous mercury (DGM) and water-to-air volatilization was measured using a floating dynamic flux chamber. In the laboratory, water (pore water – PW – and overlying water – D) samples were analysed for dissolved mercury species ( $\text{Hg}_\text{D}$  and  $\text{Hg}_\text{PW}$ ), methyl mercury ( $\text{MeHg}$ ), dissolved organic carbon and suspended particulate matter (SPM) content. Salinity, dissolved oxygen and pH were measured in situ. Solid sediments were analysed for Hg, MeHg and organic carbon content. In vegetated sediments Hg and MeHg content were also determined in the root biomass. Concentrations of dissolved mercury species in flooded water increased up to 10 times during the first 5 minutes of tidal flooding in vegetated and non-vegetated sediments. Concurrently MeHg concentrations decreased in solids and in pore waters. A strong correlation ( $R = 0.99$ ;  $p < 0.01$ ) was found between mercury volatilization from water and DGM concentrations indicating the escape of recently formed  $\text{Hg}^0$  to the atmosphere. During the inundation of vegetated sediments MeHg concentrations in roots decreased as much as 31% in the first 8 minutes after the inundation. This suggests that MeHg is far mobile that would be expected if the sequestration processes in roots was dominated by affinity to cysteine-rich peptides. The short-time variations registered in this work indicates a shift in the mercury equilibrium between pore waters, solid sediments and root surfaces. As water floods salt marsh sediments, MeHg, escapes from the sediments being potentially available to biota living those environments. The results obtained in this study clearly points to the importance of tides in Hg and MeHg export from sediments, DGM formation and Hg volatilization in shallow meso- and macrotidal estuaries.

**82 Determining rate constants for photochemical reduction of mercury in Arctic snow – Effects of site specific factors and irradiation intensity** E. Mann, Memorial University of Newfoundland / Environmental Science, University of Toronto Scarborough / Chemistry; N. O'Driscoll, M. Mallory, Acadia University; A. Qureshi, Harvard University; T. Avery, Acadia University; J. Dalziel, R. Tordon, Environment Canada; S. Ziegler, Memorial University of Newfoundland. The arctic is a region where mercury (Hg) contamination is a problem. Snow is an important scavenger for atmospheric mercury, and once present in the snowpack, Hg may be transported to aquatic food webs. Photochemical oxidation and reduction reactions largely control mercury retention in snow; however, the rates of these reactions are uncertain. To accurately model mercury behavior in Arctic regions and to better understand exposures and risk, reliable Hg reduction rate constants are required. This work presents photoreduction rate constants for mercury in solid snow with varying radiation intensity and snow chemistry. Snow was sampled in the high Arctic from 3 sites near Resolute, NU in March 2012 using 2L Teflon containers and clean techniques. Triplicate samples were exposed to a range of environmentally realistic intensities of ultra-violet radiation ( $1.26 - 5.78 \text{ W/m}^2$  for  $\lambda = 280$  to  $400 \text{ nm}$ ) using a quartz beaker inside a Luzchem photoreactor maintained at  $-10^\circ\text{C}$ . Elemental mercury produced in snow was quantified using continuous analysis by gold amalgamation AFS (Tekran model 2537A). Pseudo-first order reaction rate constants were found to range between  $0.5 \pm 0.07 \text{ h}^{-1}$  and  $0.1 \pm 0.03$  for triplicate analyses. These rate constants were then compared over the studied irradiation intensities, and the range of snow chloride and DOC concentrations observed, to generate empirical relationships for pseudo-first order reaction rate constants. Mercury reduction rate constants were linearly related to UV intensity ( $R^2 > 0.9$ ,  $p < 0.05$ ). This study is the first to generate controlled pseudo-first order mercury reduction rate constants in snow which will be useful for modeling mercury retention in the Arctic.

**83 Total and monomethyl mercury in fog water and spiders from the central California coast** P. Weiss-Penzias, University of California Santa Cruz / Microbiology and Environmental Toxicology; C. Ortiz, University of California, Santa Cruz. Total mercury ( $\text{HgT}$ ) and monomethyl mercury (MMHg) concentrations in fog collected from 4 locations in and around Monterey Bay, California during June-August of 2011 were  $10.7 \pm 6.8$  and  $3.4 \pm 3.8 \text{ ng L}^{-1}$  respectively. In contrast, mean  $\text{HgT}$  and MMHg concentrations in rain water from March-June, 2011 were  $1.8 \pm 0.9$  and  $0.1 \pm 0.04 \text{ ng L}^{-1}$  respectively. Using estimates of fog water deposition from 6 sites in the region using a standard fog water collector (SFC), depositions of  $\text{HgT}$  and MMHg via fog were found to range from 42-4600 and 14-1500

$\text{ng m}^{-2} \text{ yr}^{-1}$ , which accounted for 7-42% of  $\text{HgT}$  and 61-99% of MMHg in total atmospheric deposition (fog, rain, and dry deposition), estimated for the coastal area. These initial measurements suggest that fog precipitation may constitute an important but previously overlooked input of MMHg to coastal environments. Preliminary comparisons of these data with associated chemical, meteorological and oceanic data suggest that biotically formed MMHg from coastal upwelling may contribute to the MMHg in fog water. Wolf spiders collected at locations the Monterey Bay were also analyzed for  $\text{HgT}$  and MMHg with the goal of determining if Hg could be accumulating in these species due to fog deposition. We found mean concentrations of  $\text{HgT}$  and MMHg of 360 and 270  $\text{ng g}^{-1}$ , respectively. Comparing these results with previous studies on Hg in orb-weaving spiders and mosquitos, suggests that spiders in the Monterey Bay area have enhanced concentrations, similar to those found in insects near Hg contaminated sites.

**84 Migration and mercury in fish-eating birds** R.A. Lavoie, Queen's University / Biology; K. Kyser, Queen's University / Geological Sciences & Geological Engineering; L. Campbell, Saint Mary's University / Biology. Birds can transport contaminants between ecosystems during their annual cycle (e.g., through feather molt) and this leads to unexplained variations in mercury (Hg) concentrations within and among bird species. The objective of this study was to test whether migration explains variations in Hg concentrations observed in migratory fish-eating birds. Two migratory piscivorous bird species, the double-crested cormorant (*Phalacrocorax auritus*; short migrant) and the Caspian tern (*Hydroprogne caspia*; long migrant) were caught during the breeding season in Lake Ontario (Laurentian Great Lakes) and feathers grown during the winter and summer were collected to analyze for total Hg and stable carbon ( $\delta^{13}\text{C}$ ), nitrogen ( $\delta^{15}\text{N}$ ), hydrogen ( $\delta\text{D}$ ) and sulfur ( $\delta^{34}\text{S}$ ) isotopes to estimate wintering habitats and migration. Light-level geolocators were installed on birds for a full annual cycle to validate stable isotope estimations of wintering sites. Geolocators were also used to measure the importance of migration sites on Hg exposure. Results indicate that a proportion of individuals had higher total Hg concentrations than the adverse effect threshold for adult piscivorous birds. Mercury and isotopic values were highly variable for winter feathers which suggest high intra- and inter-specific migration patterns and Hg exposure. On the other hand, summer feathers showed little intra- and inter-specific variation consistent with similar breeding habitat and diet. Specific relationships between Hg, stable isotopes and geolocators will be presented. This research project allowed a better understanding of the effect of migration on Hg concentration and the importance of biovector transport of Hg through birds.

**85 Design of a mechanistic model for mercury bioaccumulation in fish: a bioenergetic-pharmacokinetic approach** C.A. Ng, ETH, ETH Zurich / Inst. for Chemical and Bioengineering, S&U Group, ETH Zurich / Institute for Chemical and Bioengineering; K. Hungerbuehler, Swiss Federal Institute of Technology (ETH Zurich) / Institute for Chemical and Bioengineering. As we approach the first internationally binding treaty on mercury, this pervasive environmental pollutant remains one of the primary chemicals of toxic concern in aquatic ecosystems. Given its long history of use and known harmful effects, research efforts continue to pursue a better understanding of its fate, global distribution and eventual exposure in organisms. Consumption of contaminated fish is a leading exposure pathway for human populations, yet the mechanisms determining mercury fate in aquatic ecosystems are still poorly described. Importantly, there is a need for a more mechanistic understanding of its bioaccumulation in aquatic food webs. Here, we develop a bioenergetics-based pharmacokinetic model for mercury bioaccumulation in fish. Our model has two key features; first, it explicitly considers the uptake routes via gill and gut surfaces in fish for different mercury species, including both passive diffusion (for neutral organic mercury) and facilitated transport (for charged species). Second, the model uses a pharmacokinetic framework to predict the transport to and accumulation of mercury species in different fish tissues. This framework is informed by recent empirical work tracking tissue distribution in both aquatic ecosystems and from the more substantial mammalian pharmaceutical literature, and may help provide some insights into the accumulation of proteinophilic (protein-associated) chemicals in organisms. The model features are aimed at enabling application to multiple sites and multiple species based on the parameterization of the bioenergetic component, and thus removes one of the main limitations of empirical site-specific models. It may also aid in developing risk assessments for mercury toxicity that benefit from knowledge regarding tissue-specific and mercury-species-specific body burdens.

**86 Non-steady state mercury bioaccumulation and its drivers in predatory fish** R. Abma, University of Windsor / Great Lakes Institute for Environmental Research; D. Haffner, University of Windsor / GLIER; G. Paterson, University of Windsor / Great Lakes Institute for Environmental Research. Mercury toxicity has been a relevant, global issue since the 1950s, when fish consumption was discovered to be the primary route of human exposure to the toxin. Mercury was responsible for the closure of many fisheries in the Great Lakes region in the 1970s, and since then mercury levels have been monitored and government programs have been put in place to encourage cleanup and prevention of mercury pollution. Despite these efforts, however, fish tissue levels of mercury remain a concern. Understanding the bioaccumulation of mercury in fish tissues has been an important focus in the Great Lakes region. Bioaccumulation models have been used to predict the dose of mercury that enters Great Lakes food chains, the level of mercury in top predators, and mercury exposure to humans through consumption of fish. Current mercury bioaccumulation models assume steady state dynamics, but accumulation patterns rarely follow this trend. This study investigated mercury accumulation in lake trout over time, and results revealed exponential increase of mercury concentration in fish tissues with increasing age. Thus, mercury accumulation reflects non-steady state dynamics. Potential causes for this accumulation pattern were also explored. Trout from the three basins of Lake Huron exhibit different overall mercury body burdens and growth rates. Growth dilution were explored as a regulator of non-steady state mercury accumulation both within and among lake trout populations. Growth dilution was shown to regulate mercury accumulation within populations in Lake Huron, with slow growers accumulating mercury at a significantly faster rate than fast growers. These results emphasize the need for non-steady state mercury bioaccumulation models, and promote further study on the nature of mercury bioaccumulation dynamics.

**87 Combined Role of Natural Organic Matter and Base Cations on Hg(II) uptake** S. Chiasson-Gould, University of Ottawa / Biology; J. Blais, Ottawa University; A. Poulain, University of Ottawa / Biology. Despite the alarming trends of declining base cation concentrations in boreal lakes, no studies have attempted to predict the consequences of this decline on the geochemical cycle of mercury, a top priority contaminant worldwide. In this study, we used a whole-cell gram-negative bioreporter to evaluate the direction and magnitude of changes in net accumulation of  $\text{Hg}^{\text{II}}$  by bacteria in response to changing base cation concentrations. We show that regardless of the speciation of  $\text{Hg}^{\text{II}}$  in solution, increasing divalent base cation concentrations decrease net  $\text{Hg}^{\text{II}}$  accumulation by the bioreporter, suggesting a protective effect of these cations. This work suggests that the complexity of the cell wall of gram-negative bacteria must be considered when modeling Hg uptake pathways; we propose that base divalent cations contribute to hamper net  $\text{Hg}^{\text{II}}$  accumulation by decreasing outer membrane permeability and, therefore, the passive diffusion of  $\text{Hg}^{\text{II}}$  species to the periplasmic space. To further test the environmental relevance of this finding with performed a series of experiments investigating Hg uptake in the presence of both base cations and natural organic matter consisting of fulvic and humic acids.

**88 The Impact of Eutrophication on Mercury Cycling in Lake 227 at the Experimental Lakes Area in Northwestern Ontario** J.L. Kirk, Environment Canada / Research Scientist, Environment Canada / Aquatic Contaminants Research Division, Environment Canada; I. Lehnher, University of Waterloo; A. Gleason, Environment Canada; D. Muir, Environment Canada / Aquatic Ecosystem Protection Research Division, Environment Canada / Aquatic Contaminants Research Division; V. St Louis, Environment Canada. Mercury (Hg) is a pollutant of global concern as concentrations of methyl mercury (MeHg), the toxic and bioaccumulative form of Hg, in fish are often present at levels high enough to pose health risks to consumers. Although we are beginning to understand the factors controlling MeHg production in freshwater lakes, the impacts of environmental disturbances, such as eutrophication, on Hg cycling are not known. As part of a larger project examining controls on eutrophication, we are studying the impacts of eutrophication on Hg cycling and MeHg production in the artificially eutrophic Lake 227 at the Experimental Lakes Area in northwestern Ontario. In addition to 40 years of ancillary data, Lake 227 is ideal for this study as it has an anoxic hypolimnion which may be an important zone of microbial MeHg production. To determine sources and losses of inorganic  $\text{Hg}(\text{II})$  and MeHg from the lake, we are using a mass balance approach including: detailed lake profiles to determine the water column pools of inorganic  $\text{Hg}(\text{II})$  and MeHg,  $\text{Hg}(\text{II})$  and MeHg inputs via

precipitation, and losses of Hg from the lake via gaseous elemental  $\text{Hg}(0)$  evasion and MeHg photodemethylation. In addition, rates of water column MeHg production are being determined using state-of-the-art Hg stable isotope experiments. 2010 results suggest that eutrophication has a dramatic impact on the Hg cycle in Lake 227. For example, the zone of elevated water column MeHg migrated throughout the summer following the zone of anoxia, suggesting MeHg is being produced in the anoxic hypolimnion. 2011 results will be presented in the context of phosphorus and nitrogen cycling as well as numerous other water chemistry parameters.

**89 Risk assessment of rare earth metals on ecological receptors at a hypothetical mine development** J.R. Phibbs, University of Saskatchewan / Toxicology Centre, AECOM / M.Sc. Candidate; M. Sanborn, AECOM. The use of ecological risk assessments in support of mining environmental approvals in the last half decade has become more formalized and quantitative in nature. The use of a risk assessment during the planning and approval stage of a proposed mine facilitates quantitative predictions of risk which aids the development of future operational management goals, facilitates long term monitoring requirements/goals and creates greater transparency. The rare earth metals (REM), niobium and tantalum are in high demand for military applications such as superalloys, magnets, and lasers used in propulsion and combustion equipment. Canada has many potential high grade REM resources that are rapidly being evaluated in order to meet the increasing world demand. Viable rare earth metal developments typically have co-occurring radionuclides associated with the deposit. We propose to quantify terrestrial and aquatic ecological risks at a simulated REM mine development with co-occurring radionuclides from a hypothetical mineral deposit based on publicly available geological information. The radionuclides that will be assessed as part of the aquatic and terrestrial ecological risk assessment are the long lived parent and daughter products of the uranium-238, uranium-235, and thorium-232 decay chains. These radionuclides transfer naturally into vegetation, terrestrial receptors and aquatic receptors via food, water and air. In aquatic systems impacted by mine activities the surface water and sediment pathways to aquatic invertebrates, fish, amphibians, and aquatic plants are generally considered to be complete for both REMs and radionuclides. This study aims to identify elements and radionuclides of importance to ecological receptors, and quantify the magnitude of risk using a quantitative risk assessment framework. Preliminary results indicate that potentially significant exposures may be limited to radionuclides and the rare earths with high crustal abundance. Overall, the results of this study will add to our understanding of the potential risks caused by these types of mining developments and highlight the unique challenges of quantifying risks caused by the development of REM ore bodies with co-occurring radionuclides.

**90 Human health risk assessment of the rare earth metals and radionuclides: a simulation study based on a hypothetical Canadian mine** M. Sanborn, AECOM; J. Phibbs, AECOM Canada Ltd.. The rare earth metals (REM) niobium and tantalum are used in nickel-, cobalt- and iron-base superalloys for such applications as jet engine components, rocket subassemblies, and heat-resisting and combustion equipment. The increasing demand for REMs coupled with China's decision to reduce/cease export has resulted in increased interest in exploration and development of REM deposits globally, and particularly in Canada. The development of REM mines can involve additional issues for examination when seeking environmental/regulatory approvals in comparison with base metal mines. The use of environmental risk assessment in support of mining environmental approvals in the last half decade has become more formalized and quantitative in nature. Quantitative predictions of risk can reduce enhance transparency, reduce the potential for disagreements that would otherwise arise from over-reliance on professional judgement, and can aid in the development of risk management/mitigative needs including future operational management goals, and long term monitoring requirements/goals. We present here a human health risk assessment of a simulated REM mine in Canada. The study is based on publicly available information gathered from the Geological Survey of Canada. Exposure assumptions for human receptors are based on values published by Health Canada and the US EPA. Niobium and tantalum regularly co-occur with uranium, thorium and other naturally occurring radioactive elements. While heavy metals are undoubtedly of concern as well, this study is focused on the human health risks associated with REMs and co-occurring radionuclides. Uranium and thorium series radionuclides transfer naturally into vegetation, terrestrial receptors and aquatic receptors

via food, water and air. Human receptors can be exposed to REMs and radionuclides through the ingestion, inhalation, or contact pathways. This simulation study will be used to assess potential risks associated with a typical remote rare earth element mine to the workers and local people involved in traditional land use activities. Results of this study, supported by lessons learned from other active rare earth element mines, indicate that radiological risks can be significant. This study further examines the chemical risks of rare earth elements and provides support for the careful consideration and management of waste streams originating from rare earth element extraction activities.

**91 Sorption of Munitions Constituents by Soil** R. Gonzalez, University of Delaware / Department of Civil and Environmental Engineering; D.M. Di Toro, University of Delaware / Dept. of Civil & Environmental Engineering; H.E. Allen, University of Delaware / Dept. Civil & Environmental Engineering. Many military ranges contain high residual amounts of munitions constituents (MCs) in their soil. These residues may be transported to groundwater thus posing a risk and potentially limiting site use. We have studied adsorption and desorption of MCs on several soils with different properties and have developed new models to describe the partitioning. There is considerable literature on the adsorption of MCs, particularly nitroaromatic compounds, onto soils. These reports focus on whether adsorption is controlled by the organic matter or the clay in soil. Our adsorption model incorporates both organic matter and clay with predictive capability significantly better than a model in which only one of the factors was considered.

**92 Modeling Adsorption and Desorption Partitioning of Munitions Constituents to Soil** A. Miglino, R. Gonzalez, H.E. Allen, D.M. Di Toro, University of Delaware / Dept. of Civil & Environmental Engineering. It is a common observation that adsorption and desorption isotherms are not equivalent. A reversible – resistant component model has been proposed that separates the adsorption and desorption data into a reversibly sorbed component and a resistant component that does not desorb during the time span of the experiment. Adsorption and desorption of munitions constituents (MCs) on several soils with different properties exhibit reversible-resistant partitioning. The reversible/resistant model applied to our partitioning data indicates that a large fraction of many compounds are not recovered in typical desorption tests. A model, based on physicochemical processes will be presented that successfully reproduces the experimental results. The model assumes a rapid equilibrium between soil solution and a surficial soil layer and diffusive transport into the interior of the particle. Data for differing adsorption and desorption times and cycles of desorption are all successfully reproduced for RDX and nitroglycerin. The resistant component is due to the MC in the core of a soil particle that is trapped by partitioning and the slow mass transport due to the small aqueous concentration. Although the model assumes complete reversibility for the sorption process, the mass transfer-limited rate of release limits concentrations in soil solution, thus limiting the potential for risk.

**93 Energetic Contamination at Canadian Military Training Facilities: Updated Soil Concentrations for Military Training Sustainability (SCMTS)** P. Robidoux, National Research Council Canada / Aquatic and Crop Resource Development Portfolio, National Research Council Canada / Project Leader; Y. Berthelot, J. Dumas, S. Rocheleau, N. Besnier, V. Berube, National Research Council Canada; G.I. Sunahara, National Research Council Canada / NRC-Biotechnology Research Institute; J. Hawari, National Research Council Canada. Some operational activities of the Canadian Forces such as firing practice and munitions testing have led to the dispersion of energetic materials and metals in the Range and Training Areas (RTA). Sites contaminated by trinitrotoluene (TNT), hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX), 2,4-dinitrotoluene (2,4-DNT), 2,6-dinitrotoluene (2,6-DNT), and nitroglycerine (NG) may present a risk for the ecological receptors as well as to humans. The management of soils contaminated by these compounds on Canadian RTA is made on a case-by-case basis, using risk assessment methods, in the absence of generic soil quality guidelines. In order to simplify the environmental management of RTA, preliminary environmental and human health based Soil Concentrations for Military Training Sustainability (SCMTS) were developed in 2006 to support environmentally sustainable military training practices in Canada. Over the past years, ecotoxicity and bioaccumulation data have been generated. The SCMTS developed

for TNT, RDX, HMX, 2,4-DNT, 2,6-DNT, and NG have been recently updated. These new values and the results of ecotoxicological assessments using field collected soil and mesocosm studies used to validate the soil concentrations values will be discussed. Ecotoxicological assessment using field collected soils evaluated the effect of contaminated soils on direct contact organisms (plants, invertebrates) using standard parameters (lethality growth, reproduction) and selected sublethal parameters (biomarkers). Ecotoxicological assessment using mesocosms studies (field bioassays) evaluated the effect of contaminated soils on earthworms under field conditions using the lethality endpoint and validated sublethal parameters including immunotoxicity, oxidative and cellular stress responses.

**94 A case study of inter- and intra-species sensitivity differences to traditional and insensitive munitions** A.J. Kennedy, US Army Engineer Research and Development Center, CEERD-EPR; P. Gong, Specpro; S. Brasifield, J. Laird, ERDC; C. Lounds, Badger; M. Johnson, US Army Public Health Command; N. Barker, Badger; D. Gent, ERDC. The characterization for adverse environmental outcomes from discharging effluent is critical for understanding life cycle consequences for manufacturing. Aquatic toxicity is relevant to munitions production effluents discharged to surface water or waste water treatment facilities. However, the selection of test species or even populations within the same species may result in different toxicological thresholds. We employed laboratory populations of fish (*Pimephales promelas*) and cladocerans (*Ceriodaphnia dubia*, *Daphnia magna*) as well as both field and laboratory populations of the cladoceran *Daphnia pulex* to characterize the toxicity of a traditional munition (lead) and an insensitive munition (dinitroanisole, or DNAN). Insensitive munitions containing DNAN are proposed to replace trinitrotoluene (TNT) due to greater stability, safety and fewer restrictions on transport. While *P. promelas* is often more tolerant than cladocerans to many contaminants including lead, its sensitivity to DNAN was similar. Within one species (*D. pulex*), the expression of phenotypes such as fecundity and chemical sensitivity varied between laboratory and field genotypes. Further, variability within and between populations of *D. pulex* and associated selection of statistical (e.g., lowest and maximum allowable concentrations) versus point estimate (median lethal and inhibition concentrations) based toxicological endpoints resulted in a nearly 5-fold different threshold values. This reinforces the need for the multiple species approach and prior discussion and consensus on methods used for generating toxicity reference values for munitions. Despite this variability, the acute and chronic toxicity of DNAN was 14 and 9 fold less toxic than TNT, respectively, suggesting it may also be a more environmentally benign alternative. Further work involves confirming trends for additional *D. pulex* genotypes and determining a mechanistic explanation for differences in chemical sensitivity. Toxicological testing relying on a single species should be avoided to reduce the risk of misrepresentative information leading to incorrect or less economically feasible management alternatives when considering acquisitions or future clean up costs.

**95 Nano Particle Dispersion, Aggregation, and Bio-concentration within Whole Body and Target Organs of Aquatic Organisms** J.G. Coleman, US Army Engineer Research and Development Center, US Research and Development Center / Environmental Laboratory, US Army Engineer Research and Development Center / Research Biologist, US Research and Development Center / Research Biologist; A.J. Kennedy, US Army Engineer Research and Development Center, CEERD-EPR; J.D. Laird, US Army Engineer Research & Development Center / SpecPro Incorporated, U.S. Army Engineer Research & Development Center / Environmental Laboratory; A.J. Bednar, US Army Engineer Research and Development Center / Environmental Laboratory; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry, Colorado School of Mines; A. Harmon, US Army Engineer Research and Development Center / Environmental Laboratory. As the production and applications of nanomaterials increase, it is essential to characterize the fate, transport, and effects in environmental systems and ecological receptor organisms. Our objective was to investigate the impact and target location of military-relevant nanoparticles within fish (*Pimephales promelas*, *Danio rerio*) and worms (*Lumbriculus variegatus*) following a direct, aquatic exposure. The present study utilized multiple detection instruments including single particle detection and field flow fractionation (FFF) coupled with inductively coupled plasma mass spectroscopy (ICP-MS), Dynamic Light Scattering (DLS), and CytoViva® hyperspectral microscopy to determine particle location, size, and concentration in treatments and target organs such as the gills, gut, and tissue. The extensive characterization

techniques were combined to assess potential for aggregation/dispersion within *in vivo* systems and detect target areas of bio-concentration. Treatment suspensions with various nanoparticles were created in serial dilutions of synthetic freshwater media with bath sonication (1 hour), *P. promelas* and *D. rerio* were exposed to 23 nm nano titanium dioxide (TiO<sub>2</sub>), 20-30 nm polyvinylpyrrolidone (PVP) coated nano silver, and 41 nm bovine serum albumin (BSA) nano gold for 96 hours at 25 ppm utilizing a continuous delivery system. *Lumbriculus variegatus* (n=3) were exposed to 30 nm and 70 nm PVP coated silver for 24 hours at a 5 ppm concentration. Post exposure, *L. variegatus* were depurated for 0, 8, 24, and 48 hours to assess relative gut residency time and potential to cross the digestive track into body tissue. In *D. rerio* and *P. promelas*, presence of nanoparticle aggregates was confirmed in the gut and gills of exposed fish. Particle retention in *L. variegatus* up to 48 hours was confirmed with the single particle detection-FFF and ICP-MS; hyperspectral imaging detected PVP particles within the gut compartment and potential translocation across the gut lining into tissue. Additionally, FFF of the *L. variegatus* suggested degradation of 70 nm PVP silver, resulting in a 50-60 nm particle, potential degradation mechanisms are being investigated. The proposed research will aid in determining bioaccumulation factors for nanomaterials within aquatic organisms and provide information about how these materials may enter the food chain through trophic transfer.

#### 96 Fate of Pb/Cu and 2,4-dinitrotoluene in Soil Slurries During Fenton Degradation

E. Jho, Seoul National University / Department of Civil and Environmental Engineering, Seoul National University; J. Jung, Seoul National University / Department of Civil and Environmental Engineering; K. Nam, Seoul National University / Department of Civil and Environmental Engineering, Seoul National University / Dept. of Civil and Environmental Engineering. Many contaminated sites such as firing ranges contain multiple contaminants such as heavy metals and organic contaminants. This study investigates the fate of heavy metals such as lead (Pb) and copper (Cu) and 2,4-dinitrotoluene (2,4-DNT) in soil slurries during modified Fenton reactions with lab-scale experiments. In the soil slurries (1:4 (w/v)) containing 2,4-DNT-only, 2,4-DNT-Pb, and 2,4-DNT-Cu, Fe(II)-citrate and a range of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) were added to initiate Fenton reactions. The addition of Fe(II)-citrate in the soil slurries, even in the presence of a large amount of Fe (37 g Fe kg<sup>-1</sup>) in the soil, increased the life-time of H<sub>2</sub>O<sub>2</sub> in the system. During 24 h Fenton reactions, the aqueous Pb mass decreased, while the aqueous Cu mass increased significantly resulting in almost complete mobilization of Cu. The residual 2,4-DNT in the aqueous and the soil phases decreased with increasing H<sub>2</sub>O<sub>2</sub> concentrations. The greater amount of reactive moieties produced and the production of reductive moieties for desorption at higher H<sub>2</sub>O<sub>2</sub> concentrations are likely the cause of such observation. Complete 2,4-DNT degradation in both aqueous and soil phases were achieved at 1 M H<sub>2</sub>O<sub>2</sub> in the 2,4-DNT-only and the 2,4-DNT-Cu systems; however, only ~80% of 2,4-DNT in both systems were degraded in the 2,4-DNT-Pb system. The lower 2,4-DNT degradation in the 2,4-DNT-Pb system could be attributed to the stronger binding of Pb on Fe oxide in soil than Cu, which leads to the reduced amount of available Fe for H<sub>2</sub>O<sub>2</sub> consumption and hence 2,4-DNT degradation. Interestingly, the 2,4-DNT degradation at lower H<sub>2</sub>O<sub>2</sub> concentrations was lower in the 2,4-DNT-Cu system, but higher at higher H<sub>2</sub>O<sub>2</sub> concentrations. This could be because Fenton-like reactions by Cu, which dominates the system over Fe at lower H<sub>2</sub>O<sub>2</sub> concentrations, degrade 2,4-DNT. With further increase in H<sub>2</sub>O<sub>2</sub> to 2 M in the 2,4-DNT-Pb system, further degradation of 2,4-DNT in soil phase was observed, while no enhancement was observed in the aqueous phase. The findings from this study suggest the prior removal of Pb and Cu before 2,4-DNT degradation by Fenton reactions and the use of higher H<sub>2</sub>O<sub>2</sub> concentrations (>1 M) for complete removal of 2,4-DNT from contaminated soils.

#### 97 Examination of Transport Mechanisms and Challenges of Chemical Fingerprinting of MC252 and Other Petroleum Sources in the Deep Sea Sediments

P.D Boehm, Exponent, Inc. / Environmental & EcoScience Group, Exponent / Environmental Group, Exponent, Inc. / Environmental & EcoScience Group; J.S. Brown, Exponent Inc.; L. Cook, Exponent. Extensive sampling and detailed chemical analyses (>1000 samples) of sediments and oil seeps within 20 miles of the Deepwater Horizon (Block MC252) wellhead and elsewhere have indicated that MC252 oil can be detected in sediments near the wellhead and that seep influences are pervasive in sediment in the area to the southwest of the wellhead over which the

physically and chemically dispersed oil in deepwater transited after release. The available data indicate that some naturally-occurring seeps oils in this study area, within 20 miles of the wellhead (especially around the Biloxi and Dauphin Domes) and fresh oil from MC252 are very similar in chemical composition – alkanes, polycyclic aromatics, saturated biomarkers (hopanes and steranes). Furthermore both seep oils and MC252 oil in the sediments appear to biodegrade similarly. As part of this biodegradation, the C27 steranes, previously thought to be highly resistant to biodegradation, are themselves biodegrading, thus altering sterane patterns and confounding the ability to distinguish sources (seeps and MC252) from one another. Thus the possibility of false positive identifications of sedimented MC252 oil is significant. Approaches to using the biodegradation patterns of steranes and other hydrocarbon compounds, degradation resistant biomarker ratios, and other chemical indicators to distinguish sources and to map the oil footprint will be discussed. The fingerprinting results along with the observed levels of hydrocarbons and PAHs in samples from the deep se area around the well are combined to discuss the conceptual model for transport of oil to the sediments. The vast majority of quantifiable MC-252 oil that reached the sediments in the offshore Gulf of Mexico did so through a single primary mechanism of deposition: adsorption of oil to heavy drilling muds and subsequent sedimentation as a consequence of the unsuccessful top kill effort. The area impacted by the top kill drilling mud deposition was limited and in close proximity to the Deepwater Horizon wellhead. To varying degrees, limited empirical evidence exists to support the plausibility of two secondary or isolated transport pathways for deposition of small amounts of MC-252 oil to the sediment – sorption onto particles/detritus; very minor and isolated sinking of *in situ* burn residues.

#### 98 MC252 oil spill post-incident finfish and shellfish PAH and dispersant (DoSS) tissue concentrations

G.R Mancini, E.R. Mancini & Associates; J. McCoy, Cardno Entrix; R. Barrick, Infinity Solutions Group; L. Elmore, Cardno Entrix. Total body burden tissue concentrations for total PAH (tPAH) and the dispersant compound dioctyl sodium sulfosuccinate (DoSS) were analyzed for six finfish and shellfish species (295 total specimens) collected from Louisiana shallow water coastal habitats in late 2010 (Oct. – Dec.) and mid-2011 (May – Aug.). Concentration data were developed for each species within each of seven state-established *Coastal Study Areas* (CSA 1 through 7) between the borders of TX and MS. Arithmetic mean tPAH concentrations for finfish and crustacean species ranged from 9.7–26.4 µg/Kg wwt while oyster concentrations ranged from 44.3–63.7 µg/Kg wwt across all CSAs. Mean concentrations were not significantly different between the reference CSA (CSA 7) and any other study area for four of the six species (anchovy, brown and white shrimp, and blue crab). For oyster and Atlantic croaker, statistical differences in mean tPAH concentrations were noted in only one and two CSAs, respectively. Mean tPAH tissue concentration data were also characterized according to “oiling categories” including reference condition [no known MC252 slick exposure], light exposure condition [1-20 days of documented slick exposure] and undetermined exposure condition, based on observed slick proximity to specimen capture locations. For two of the six species (Atlantic croaker and anchovy), the mean tissue concentrations from the reference area were slightly greater than the light exposure and undetermined exposure category tissue concentrations. For blue crab, brown shrimp, white shrimp, and oyster, tissue concentrations were within -1, -3, -2.5, and -4.5 µg/Kg wwt among the oiling categories, respectively. DoSS was detected in only 4 of 280 tissue samples (~1.4% of total; 79 µg/Kg dwt [blue crab]; 440 µg/Kg dwt [anchovy]; and 310 and 32 µg/Kg dwt [brown shrimp]) and these detected DoSS concentrations were less than established LOCs. In fact, for all tested species, documented tissue concentrations for tPAH and DoSS were orders of magnitude lower than *Levels of Concern* established by the Fish Consumption Advisory Group. The mean oyster tissue tPAH concentration documented in this study (430 µg/Kg dwt [Louisiana]) was also less than the mean Mussel Watch Program concentrations for oyster reported in either 1988 or 2008 (536 µg/Kg dwt [Gulf of Mexico] and 463 µg/Kg dwt [Louisiana], respectively).

#### 99 Photoenhanced Toxicity of WAF Oil to Early Lifestages of Gulf of Mexico Aquatic Species

A. Roberts, University of North Texas; J.T. Oris, Miami University / Department of Zoology, Miami University / Office for the Advancement of Research & Scholarship; M. Alloy, University of North Texas / Department of Biological Sciences; A. Tucker, Miami University; T. Curran, University of North Texas; D. Baxter, University of North Texas / Department of Biology, Institute of Applied Sciences; M. Grosell, RSMAS,

University of Miami; A. Volety, Florida Gulf Coast University; R. Griffin, University of Southern Mississippi; J.M. Morris, J. Lipton, D. Cacula, Stratus Consulting. The 2010 Deepwater Horizon Oil Spill resulted in a large release of polycyclic aromatic hydrocarbons (PAH) into the Gulf of Mexico. PAH exert a variety of effects on aquatic organisms including photoenhanced toxicity. Photoenhanced toxicity is a well described phenomenon in which molecules of certain PAH interact synergistically with ultraviolet radiation (UV). This interaction generates reactive oxygen species resulting in oxidative stress and acute toxicity. Early life stages of aquatic organisms are generally more susceptible to photoenhanced PAH toxicity than juvenile and adult stages. The purpose of this study was to assess the sensitivity of early life stages of Gulf of Mexico aquatic species to PAH photoenhanced toxicity. Test organisms included early life stages of blue crab (*Callinectes sapidus*), sheepshead minnow (*Cyprinodon variegatus*), and mahi-mahi (*Coryphaena hippurus*). Exposure media consisted of PAHs in water accommodated fractions prepared using slick or weathered source oil dispersed using a high energy method (HEWAF) or chemical dispersants (CEWAF). Four UV conditions were achieved using an outdoor microcosm exposure system to simulate high intensity light conditions and an indoor simulator to achieve low intensity light conditions. Survival was assessed as the endpoint for most species but hatching success was included for some life stages. Phototoxic effects on survival and hatching were observed in both a UV- and PAH concentration-dependent manner. These data may be used in models estimating site-specific risk for photoenhanced toxicity in the waters of the Gulf of Mexico.

**100 Nearshore Sediment Exposure to Louisiana Crude Oil: Spatial and Temporal Patterns in the Northern Gulf of Mexico** L. Riege, Cardno Entrix / Natural Resources; R. Dickey, C. Thomas, J. Brewer, S. Villanueva, Cardno Entrix. Sediments of the northern Gulf of Mexico are exposed to hydrocarbons from a variety of sources. In response to the Deepwater Horizon Oil Spill, BP and state and federal natural resource trustees are working cooperatively to gather data on potential injury from the spill to the nearshore resources during the Natural Resource Damage Assessment (NRDA). This talk summarizes the analysis of over 1,100 sediment samples collected as part of Response, NRDA cooperative and NRDA independent studies in 2010 and 2011 to provide the most complete picture possible of exposure to MC252 oil in the nearshore subtidal zone from the Texas/Louisiana boarder to Apalachee Bay, Florida. We report on spatial and temporal patterns of total PAH concentrations and petrogenic PAHs for the near-surface sediments and compare these results to the December 2010 Deepwater Horizon MC252 Operational Scientific Advisory Team (OSAT) report, providing updated information on the nature and distribution of spill-related hydrocarbons in the nearshore environment.

**101 Effects of exposure to oiled sediment from Barataria Bay, LA on the development of Gulf killifish (*Fundulus grandis*) embryos** F. Galvez, Louisiana State University / Dept. of Biological Sciences; C. Brown, Louisiana State University; A. Kuhl, LSU Aquaculture Research Station; C.C. Green, Louisiana State University / Renewable Natural Resources; J.A. Nyman, Louisiana State University / School of Renewable Natural Resources; A. Whitehead, University of California Davis; B.D. Dubansky, Louisiana State University / Department of Biological Sciences, Louisiana State University / graduate student. Preliminary data show that Gulf killifish (*Fundulus grandis*) sampled along Louisiana coastal marsh were impacted by the Deepwater Horizon (DWH) oil spill and displayed genomic responses that were predictive of toxicity and reproductive impairment, the latter of which is of particular concern. Marine fish embryos are highly sensitive to chemical components of weathered crude oil. Exposure can cause significant developmental defects, including cardiac dysmorphogenesis, which results in a cascade of pathologies including edema and hemorrhage. In the current study, developing killifish embryos were exposed to oiled water and sediments derived either from laboratory mesocosms, or collected from Louisiana marsh oiled by the DWH oil spill. Embryos exposed to sediments collected from oiled sites demonstrated delayed hatch rates, were smaller at hatch, and exhibited developmental abnormalities characteristic of exposure to the chemicals found in crude oil including cardiac dysmorphogenesis and associated pathologies. We are currently assessing the early-life stage effects on embryos exposed to sediments and water containing mixtures of crude oil and COREXIT dispersant at varying stages of weathering, and at varying salinities. Our overarching goal is to determine whether exposure to oil contaminated sediments will cause biological effects that emerge at the

population-level, and to characterize the spatial extent of such effects across the Louisiana coast of the northern Gulf of Mexico (nGOM).

**102 Post-Deepwater Horizon Toxicity Study of Gulf of Mexico Sediments using the Amphipod *Leptocheirus Plumulosus*** G.M. Huddleston III, ENTRIX, Cardno Entrix; A.D. McQueen, J. Kubitz, M. Cejas, Cardno Entrix; R. Barrick, Infinity Solutions; O.X. Pelz, BP Gulf Coast Restoration Organization. Toxicity tests were conducted on offshore sediment samples collected approximately one year after the Deepwater Horizon accident occurred. Samples were collected from May 25, 2011 to June 11, 2011 as part of a follow-up study of offshore and deepwater sediments (>200 m depth) to identify potential oil-related impacts on sediments and resident benthic fauna. A total of 38 sites were sampled, including: 17 sites within approximately 3 km of the MC 252 wellhead (1439-1607 m depth); 10 sites between 3 to 25 km of the wellhead (1025-1607 m depth); four sites beyond 25 km of the wellhead (1303-1516 m depth); and seven historic/pre-spill reference sites. Toxicity tests supplemented biological, chemical, and physical analyses of these sediments, which were collected using a multicorer (12 core system) device. Samples used in toxicity tests were composites of the top 3 cm of sediment cores from three replicate samples from 37 of the 38 stations. Static, 10-day bioassays using the amphipod *Leptocheirus plumulosus* (mortality and growth) were conducted to provide standard, naïve (non-tolerant) laboratory organism response to sediment exposures. Test organism mortality was statistically significant relative to laboratory controls (control sediment source: Lake Pontchartrain, Louisiana) in 12 of the 37 samples (ToxCalc 5.0.32  $p=0.05$ ). Within a 3-km radius of the wellhead, 10 of 17 samples exhibited significant mortality relative to laboratory controls. Between 3 and 25 km of the wellhead, only 1 of 10 samples exhibited significant mortality compared to laboratory controls. One sample beyond 25 km (approximately 62 km from wellhead) resulted in significant mortality relative to laboratory controls; however, evidence of drilling mud contamination unrelated to MC-252 was present. These results, along with other sediment information associated with this plan (e.g., grain size, chemical fingerprinting, and macrofauna and meiofauna data) help identify the spatial extent of MC-252 oil in sediments, and potential for associated injury to benthic biota.

**103 Development of oil product toxicity benchmarks using SSDs** M.G. Barron, US EPA / Gulf Ecology Division; C.R. Jackson, H.J. Michael, US EPA. Determining the sensitivity of a diversity of species to spilled oil and chemically dispersed oil continues to be a significant challenge in spill response and impact assessment. We developed species sensitivity distributions (SSDs) of acute toxicity values using standardized tests from the literature for several petroleum products and two Corexit oil dispersants that had data for ten or more aquatic species. Fifth percentile hazard concentrations (HC5s) were computed from the SSDs and used to assess relative oil product toxicity and to determine the feasibility of establishing toxicity benchmarks for a community of species. The sensitivity of mysids (*Americamysis bahia*) and silversides (*Menidia beryllina*) were evaluated within the SSDs to determine if these common test species were good surrogates for a broader range of species. In general, SSD development was limited by the availability of acute toxicity values that met standardization criteria for a diversity of species. Because there was only small variability in the HC5s for the compiled oils, pooled SSDs were also developed by oil type (e.g., crude, middle distillate). There was only limited variability in HC5 values determined from dispersant-only testing for the two Corexit products. The relative sensitivity of mysids and silversides varied across the oil products, with the toxicity values always greater than the HC5. Application of SSDs appears to be a reasonable approach to developing oil product toxicity benchmarks, but additional toxicity data are needed for a larger range of species conducted under standardized test conditions.

**104 Impacts of Deepwater Horizon Sub-Lethal PAH Exposure On Late Life Stage Pelagic Gamefish: Utilization Of Marine Finfish Aquaculture In Toxicology** J. Stieglitz, University of Miami, RSMAS / Department of Marine Biology and Fisheries, University of Miami – RSMAS; R. Hoenig, University of Miami, RSMAS; E. Mager, University of Miami / Rosenstiel School of Marine and Atmospheric Science, University of Miami, RSMAS / Division of Marine Biology & Fisheries; A. Esbaugh, University of Miami, RSMAS / Rosenstiel School of Marine and Atmospheric Science, University of Texas – Austin, Marine Science Institute / Post-Doctoral Fellow; D. Benetti, University of Miami, RSMAS; M. Grosell, RSMAS,

University of Miami. The Deepwater Horizon (DWH) oil spill in 2010 resulted in the release of approximately 200 million gallons of crude oil into the Gulf of Mexico (GOM). In addition, over 1.8 million gallons of dispersants (primarily Corexit) were used as part of the cleanup effort, with roughly 40% of this total applied at depth near the wellhead. The aim of the described research is to determine sub-lethal physiological impacts of polycyclic aromatic hydrocarbon (PAH) exposure on sub-adult and adult life stages of species representative of GOM finfish. Incorporation of advanced marine aquaculture technology to develop and maintain captive spawning broodstock populations of mahi-mahi (*Coryphaena hippurus*) and cobia (*Rachycentron canadum*) will be discussed, as well as techniques used to obtain blackfin tuna (*Thunnus atlanticus*) specimens for use in the toxicological bioassays. Preliminary tests have focused on establishment of baseline physiological data for the aforementioned species, including aerobic scope, maximum swim speed, and critical swim speeds ( $U_{crit}$ ). Sub-lethal acute PAH exposure tests are being implemented at the University of Miami to assess the aerobic scope and swim performance of the aforementioned pelagic gamefish utilizing swim chamber respirometry. Preliminary results indicate mahi-mahi possess superior maximum swim speeds as compared to blackfin tuna, as well as a greater aerobic scope. PAH-induced aerobic scope reduction is of particular concern for such high-performance species, due to potential subsequent reductions in migratory, feeding, fleeing abilities and vital physiological functions. Testing sub-lethal effects of acute PAH exposure on later life-stage specimens allows for elucidation of the potential impact of the DWH oil spill on high-performance and economically valuable pelagic gamefish.

**105 Estimation of the inventory of PBDEs in consumer products in municipalities adjacent the Great Lakes** G. Abbasi, University of Toronto / Geography and urban planning; M.L. Diamond, University of Toronto / Department of Geography and program in planning, University of Toronto / Department of Geography. Poly brominated diphenyl ethers (PBDEs) have been used as flame retardants in consumer products during the past few decades. Recent studies have revealed the rapid accumulation of widely used flame retardant chemicals in humans and wildlife, and new findings linked the human exposure to this class of chemicals to adverse health effects ranging from cancer to learning disabilities. Further the higher levels of PBDEs in the breast milk of women in North America as compared to other European countries, has raised public concern about the usage of these toxic chemicals in consumer products. Although these chemicals have been regulated or phased out in Canada since 2009 and in the United States since 2011, they have continued to be used in recycled products imported from other countries. These problems demonstrate a failure in both consumer product design and strategic policies to regulate toxic chemicals to protect human health and the environment. We believe that these initiatives are a direct response to the lack of adequate knowledge about the level of these hazardous substances in consumer products. Therefore our main goal is to quantify the human exposure to PBDEs based on their levels in in-use consumer products. Accordingly, we will estimate the current regional PBDE inventory based on two components: the inventory of PBDE-containing products and quantification of PBDEs contained within the inventory of products using Toronto and Chicago as two case studies. The result of this study will provide valuable metrics to quantify the present inventory of PBDEs in in-use products and anticipate the magnitude of PBDE reductions as a result of new regulations.

**106 Dechlorane Plus, a Chlorinated Flame Retardant, in the Great Lakes' Atmosphere** A. Salamova, Indiana University / School of Public and Environmental Affairs, Indiana University / SPEA; R.A. Hites, Indiana University / School of Public & Environmental Affairs,. Dechlorane Plus (DP,  $C_{18}H_{12}Cl_{12}$ ) is a highly chlorinated flame retardant that was introduced by Hooker Chemical (now known as OxyChem) in the 1960s as a replacement for Dechlorane (also known as Mirex). The technical DP mixture consists of *syn*- and *anti*-DP conformers in a ratio of 1:3 (i.e., the fraction of the *anti* isomer is 75%). DP is used as an additive flame retardant in wire and cable coatings, in hard plastic connectors used in televisions and computers, and in furniture. Although DP is a high production volume chemical and has been used for decades, it was first detected in the atmosphere, sediments, and fish of the North America Great Lakes only in 2006. After this finding, DP has been detected in air, sediments, precipitation, biota, house dust, tree bark, and humans in different parts of the world, suggesting that DP is a worldwide contaminant. Here we present temporal and spatial trends

in both *syn*-, *anti*-, and total DP concentrations in air (vapor and particle phases) and in precipitation at the five United States Integrated Atmospheric Deposition Network sites located in the Great Lakes basin. These samples were collected from January 2005 to December 2009, inclusive. The highest concentrations of these compounds were generally observed at the rural site at Sturgeon Point, New York, which is located near DP's manufacturing facility in Niagara Falls, New York, and at the urban site at Cleveland, Ohio. A multiple linear regression model was applied to the concentrations of these compounds in the vapor phase, particle phase, precipitation, and for the three phases combined. This regression resulted in an overall (three phases combined) doubling time of  $9.5 \pm 3.6$  years for the atmospheric concentrations of *anti*-DP, a clear indication of the continued use of DP.

**107 Contribution of Wastewater Treatment Plants to Concentrations of PBDEs, PFCs, PCBs, DDT, and Synthetic Musks in Fish Tissue from U.S. Urban Waters** J.B. Wathen, U.S. EPA Office of Water, Office of Science and Technology / Office of Science and Technology, U.S. EPA, Office of Water / Office of Science and Technology; L.L. Stahl, US EPA, Office of Water / Office of Science and Technology; J.M. Lazorchak, U.S. EPA, US Environmental Protection Agency / Office of Research and Development, U.S. EPA Office of Research and Development / National Exposure Research Laboratory, U.S. EPA / Molecular Indicators Research Branch, U.S. EPA / Molecular Ecology Research Branch; A.L. Batt, U.S. EPA Office of Research and Development / National Exposure Research Laboratory, US EPA; L. Osemwengie, U.S. EPA; A.R. Olsen, U.S. EPA Office of Research and Development / Western Ecology Division, National Health and Environmental Effects Laboratory; B.D. Snyder, Tetra Tech, Inc. / Center for Ecological Sciences. Wastewater treatment plants (WWTPs) are tasked with removing a wide variety of contaminants from influents, including BOD and nutrients from human waste as well as any and all other compounds that emanate from homes and commercial facilities in the communities they serve. Traces of these compounds, including PBDEs, PFCs, PCBs, DDT, and personal care products, have been found in fish tissues from U.S. rivers that are receiving waters for WWTPs. The extent to which organic contaminant compounds found to occur in fish tissue in may be attributable to facility discharges can depend on sources served by the collection system for the WWTP, the treatment system employed at the facility, and the chemical nature of the specific compound. We compared the concentrations of organic compounds analyzed in fish tissue relative to the location of the sampling point either upstream or proximally downstream of WWTPs at 160 statistically-representative urban water sites in U.S. rivers collected as part of EPA's National Rivers and Streams Assessment. The results of analyses of 124 water-column samples for 48 active pharmaceutical ingredients and 6 selected metabolites are also compared on the basis of their sampling locations relative to WWTPs. Preliminary analyses of data for PFCs did not suggest contributions from WWTPs, but sources for PBDEs are not well understood, PCB discharges likely are continuing from many WWTPs, and WWTP discharges are the likely source for synthetic musks.

**108 Estimating PBDE and PCB Loadings to the Lake Washington Watershed from Non-point Sources** J.A. Colton, King County Department of Natural Resources / Water and Land Resources Division, King Cty. Dept. of Nat. Resources / Water and Land Resources Division; R. Jack, King County / Department of Natural Resources. Polychlorinated biphenyl (PCB) and polybrominated diphenyl ether (PBDE) concentrations in Puget Sound harbor seal and orca blubber samples are some of the highest ever measured in marine mammals worldwide. Manufacture, sale and distribution of penta-, octa-, and some deca-PBDEs were banned in Washington State in January 2008 with a complete ban in January 2011. Like PCBs, PBDE sources in urban areas tend to be diffuse and non-point. The Lake Washington watershed is the most populous watershed in the state and considered a substantial source of contaminants to Puget Sound. However, data on PBTs in lake water and fish tissue are sparse. A fish consumption advisory is in effect on Lake Washington due to high tissue concentrations of PCBs; PBDE concentrations in fish tissue have not been examined. The goals of the current King County project are to quantify PBDE and PCB loadings to L. Washington and Puget Sound via the Ship Canal, identify the most important transport pathways needing PBDE and PCB loading reduction to the Lake Washington watershed, and quantify PBDE's bioaccumulating in lake fishes. This presentation reveals the first measurements of PBDEs in Lake Washington water and fish tissue as well as the first estimates of annual PCB and PBDE loadings from five major transport pathways into the

Lake. The input pathways studied were bulk air deposition, highway runoff, general stormwater runoff, CSO discharges, and major incoming streams. The fish species evaluated include smallmouth bass, northern pikeminnow, yellow perch, sculpin spp., and peamouth. This presentation focuses on the pre-modeling phase of an EPA-funded, 3-year project awarded to King County. Future project work will include fate and transport model and bioaccumulation model development. These models will enable prediction of improvements gained in fish tissue concentrations resulting from different loadings reduction scenarios.

**109 Is There an Unknown Exposure Pathway for PBDEs? Evidence from North American Biomonitoring Data** F. Wong, University of Toronto / Chemistry, Stockholm University / Applied Environmental Science (ITM); I. Cousins, M. Macleod, Stockholm University / Applied Environmental Science (ITM). The body burden of persistent chemical pollutants in members of the general population is determined jointly by the rate of intake of the chemical and the rate of removal from the body. We have examined this balance between intake and intrinsic elimination half-lives for polybrominated diphenyl ethers (PBDEs) in the North American population using the population-level pharmacokinetic model developed by Ritter et al. (2011). The model calculates the burden of chemicals in the bodies of representative members of the population as a function of age and calendar time from intake from all exposure pathways and a chemical-specific intrinsic elimination rate constant. The model can be fitted to empirical information from exposure and biomonitoring studies using a least-square optimization method. In this study, we collected empirical data from two studies that made total exposure estimates for the North American population for the years 2004 and 2005, and eight biomonitoring studies for the years 1992 to 2009. We assume intake of PBDEs increased exponentially to a peak in 2004, and has since been declining exponentially. The model fitting parameters are the intake of PBDEs in 2004 and 2038, and the intrinsic elimination rate constants, which can be expressed as equivalent half-lives. Fitting the model simultaneously with the biomonitoring and exposure data results in infinite elimination half-lives for all PBDE congeners. This result is not plausible since physical removal processes should limit the half-life of PBDEs to at most 15 years. Thus the modeling suggests that there is an inconsistency between the exposure studies and the biomonitoring data. When we calculate intakes using the biomonitoring data and elimination half-lives extrapolated to humans from a rat study we obtain intake estimates that are a factor of 5 higher than the empirical estimates for BDE-47 and -153. Even when we assume the maximum plausible elimination half-life of 15 years, intakes are still 2 and 5 times greater than empirical estimates for BDE-47 and -153 respectively. These intakes represent the plausible minimum that is required to explain the biomonitoring data. Our results thus indicate that a discrepancy between empirical exposure and biomonitoring studies exists, and that exposure of the North American population to PBDEs may have been underestimated in previous studies.

**110 Anthropogenic and naturally occurring halogenated phenolic compounds in the blood of Japanese terrestrial mammals** H. Mizukawa, K. Nomiyama, Ehime University; S. Nakatsu, Nakatsu Veterinary Surgery; S. Yachimori, Shikoku Institute of Natural History; T. Hayashi, Tochigi Prefectural Museum; Y. Tashiro, Meio University; M. Yamamoto, Y. Nagano, S. Tanabe, Ehime University. The present study elucidates the accumulation features of PCBs, PBDEs, their hydroxylated metabolites, and naturally occurring brominated compounds (methoxy PBDEs and bromophenols) in the blood samples of various carnivores such as cats, dogs, raccoon dogs, masked palm civets (MPC), foxes, raccoons, mongooses, and badgers collected from Japan. Moreover, the specific differences in metabolic capacities of different species for these compounds by analyzing the blood samples were investigated. Metabolic capacity for PCBs in terrestrial mammals was found to vary widely among species. Lower chlorinated OH-PCB congeners (3-5 Cl) were predominant in cat blood, whereas higher chlorinated OH-PCBs (6-8 Cl) were found in other carnivores. In particular, it can be presumed that cats may preferentially metabolize lower chlorinated PCBs and retain hydroxylated metabolites in their blood. The PBDE congener pattern in terrestrial mammals indicated a high proportion of BDE209, suggesting exposure to garbage and soil containing higher levels of deca-BDE products. The dominant congeners of OH-/MeO-PBDEs found in our study were 6OH-/MeO-BDE47 and 2'OH-/MeO-BDE68, which were already reported as natural products in the marine environment, accounted for up to 80% of total OH-/MeO-PBDEs in all the terrestrial mammals

investigated in this study. Moreover, higher accumulation of OH-PBDEs and MeO-PBDEs were found in cats than other carnivorous species, suggesting that cats may be intake of these compounds from food such as fish. Moreover, 2, 4, 6-tribromophenol, which was reported as both a natural compound and a man-made flame retardant, was dominant in all analyzed species except mongooses. Penta bromophenol and 2, 4, 5-tribromophenol were found in the blood of dogs, raccoons, foxes, MPCs, raccoon dogs, mongooses and cats, suggesting that these compounds could be the metabolites of PBDEs. As cats exhibit higher accumulation and a specific pattern of OH-PCBs, OH-PBDEs, and MeO-PBDEs, they may be at a high risk from these metabolites. To our knowledge, this study is the first report to comprehensively document the accumulation profiles of organohalogen metabolites and metabolic capacities in terrestrial mammals.

**111 Can hair be used to examine dose dependent pharmacokinetics of polybrominated diphenyl ethers (PBDE) in rat hair?** K. Aleksa, Hospital for Sick Children / Department of Clinical Pharmacology and Toxicology, University of Waterloo / School of Pharmacy, Hospital for Sick Children / Dept Clinical Pharmacology/Toxicology; A. Carnevale, University of Toronto; S. Ernest, McGill University; M. Wade, Health Canada; B. Hales, C. Goodyer, McGill University; G. Koren, Hospital for Sick Children. The ability to detect increasing levels of a xenobiotic in biological samples (e.g., blood or urine) has been long established thus enabling physicians to infer the amount of chemical present in the organism and the amount individuals was exposed to in their environment. However, there are times when obtaining these matrices can be difficult, such as in newborns, and there is a need to find an alternate matrix that can reflect long-term exposure and not just at the time of sampling. Hair offers a wider window for retrospective detection of chronic and past exposure/consumption of xenobiotics. Such information is commonly lacking in the case of environmental toxins. Polybrominated diphenyl ethers (PBDE) are implicated as endocrine-disrupters and are used worldwide in polymers incorporated into a variety of consumer products to prevent flammability. To determine if PBDEs are use full biomarkers of systemic exposure and whether a dose-response can be detected in hair, increasing amounts of BDEs were administered to rats and the hair was analyzed for the presence of BDEs. Methods: Adult Sprague Dawley rats were divided into 5 groups (n=10/group) and administered, by gavage, a BDE mixture (0, 0.02, 0.2, 2 or 20 mg/kg/day) mimicking house dust levels for 60 days. Thirty mg of hair was analyzed by GC/MS for BDE-28, 47, 99, 100, 153, 154, 183 and 209. Results: PBDEs were detected in all treatment groups (0.02 to 20 mg/kg/day). There was a clear dose response curve. The  $\Sigma$ PBDE was  $0.169 \pm 0.157$ ,  $0.265 \pm 0.089$ ,  $1.706 \pm 0.918$  and  $7.504 \pm 2.595$  ng/mg hair for 0.02, 0.2, 2 and 20 mg/kg/day treatments, respectively. The levels were statistically significant ( $p < 0.001$ ) from control for each group. BDE-28 was not detected in any treatment group; BDE-183 was present in only the 20mg/kg/day group and; BDE-209 was present in all groups including control ( $0.041 \pm 0.011$  ng/mg). BDE-47, 99, 100, 153, 154, and 209) levels increased with increasing levels of administered BDEs, with the levels being statistically significant ( $p < 0.001$ ) for the 2 and 20 mg/kg/day. Conclusion: BDE accumulates in a dose response manner. Variations may be due to differences in individual congener metabolism prior to incorporation. Although not all congeners showed a dose response in the hair, further work to determine the *in vitro* metabolic pathway is needed to determine why these differences are present.

**112 How Toxic Are Halogen-Free Flame Retardants? Aquatic toxicity of alternative flame retardants to Daphnia magna** S.L. Waaijers, University of Amsterdam / Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam/IBED Institute; M. Soeter, J. Hartmann, University of Amsterdam; S. Kools, Grontmij (Aquasense); M.H. Kraak, J.R. Parsons, W. Admiraal, P. de Voogt, University of Amsterdam. Several halogenated flame retardants have been banned due to their persistence, bioaccumulation potential, toxicity (PBT) and probable environmental risk. Hence, halogen-free flame retardants (HFFR) are required and a range of new flame retardants (FR) have been proposed. However, reviewing the literature we demonstrated that the PBT properties of most alternative flame retardants are poorly characterized. Therefore, the aim of the present study was to generate toxicity data for HFFRs by performing aquatic toxicity experiments with *Daphnia magna*. To this purpose daphnids were subjected to the selected compounds in 48 h immobility tests, based on OECD guideline 202. For each compound, first the concentration that equals water saturation (water solubility, Sw) was tested. Second, if an effect was observed at Sw, a dilution

range was prepared (4 concentrations per compound) and tested to determine the EC<sub>50</sub>. In addition, chronic toxicity experiments were performed, based on OECD guideline 211. The alternative flame retardants studied included six organic phosphates (aluminium diethyl phosphinate (ALPI), bisphenol a bis(diphenyl phosphate) (BDP), dihydro oxa phosphaphenanthrene (DOPO), melamine polyphosphate (MPP), resorcinol bis(diphenyl phosphate) (RDP), triphenyl phosphate (TPP)) and six inorganic compounds (aluminium trihydroxide (ATH), ammonium polyphosphate (APP), antimony trioxide (ATO), magnesium hydroxide (Mg(OH)<sub>2</sub>), zinc hydroxy stannate (ZHS) and zinc stannate (ZS)). Tetrabromobisphenol a (TBBPA) was tested as well, as a reference compound for halogenated flame retardants. All exposure concentrations are measured using ICP-OES, except for BDP, RDP, TPP & TBBPA, for which analysis is in progress. The brominated flame retardant exerted the highest toxicity during this study (EC<sub>50</sub> 50 = 1-10 mg/L). All other tested compounds showed low acute toxicity to *Daphnia magna* (EC<sub>50</sub> >10 mg/L, or EC<sub>0</sub> >Sw). Therefore, ALPI, BDP, DOPO, MPP, RDP, ATH, APP, Mg(OH)<sub>2</sub>, ZHS and ZS are considered here to be the most promising HFFRs. Chronic toxicity experiments currently in progress will reveal whether their toxicity will increase upon prolonged exposure. Our results contribute to the evaluation of the environmental safety of these HFFRs, and hence to their potential as alternatives for the halogenated flame retardants.

**113 Safety/toxicity assessment of ceria (a model engineered nanomaterial)** R. Yokel, University of Kentucky / Pharmaceutical Sciences; S. Hardas, A. Butterfield, R. Sultana, University of Kentucky / Chemistry; M. Dan, University of Kentucky / Pharmaceutical Sciences; J. Unrine, University of Kentucky; U. Graham, University of Kentucky / Center for Applied Energy Research; R. MacPhail, US EPA / Neurotoxicology Division; M. Tseng, University of Louisville / Anatomical Sciences and Neurobiology; P. Wu, E. Grulke, University of Kentucky / Chemical and Materials Engineering. Ceria engineered nanomaterial (ENM) is a catalyst, used in diesel fuel with potential in energy storage, and is an abrasive used in chemical-mechanical polishing. The long-term objective of this project is to investigate nanoceria physical-chemical properties that influence its distribution, biopersistence, and effects after introduction into the vascular system of the rat. To enable maximal understanding of the physical-chemical properties of the studied ENM, in-house synthesized, extensively characterized, citrate-coated, 5, 15, 30, and 55 nm cubic/polyhedral ceria and a ceria nanorod were intravenously infused into rats terminated 1 h to 90 days later. Cerium was quantified by ICP-MS in blood, plasma and blood cells; brain; peripheral tissues; urine and feces. Multiple oxidative stress markers were assessed. Ceria ENM distribution and cellular accumulation and histological changes were studied using light and electron microscopy. Valence of ceria ENM as prepared and *in situ* were determined using electron energy loss spectroscopy. Less than 1% of a 30 nm ceria dose was eliminated in feces and urine within 14 days, of which 98% was in feces. Five nm ceria clearance from blood was slower than the 15, 30, or 55 nm ceria ENM. Nanoceria increased in blood within a few h after its administration and in the liver and spleen from 1 h to 30 days, suggesting re-distribution from (an)other site(s), which might have been association with the vascular luminal wall. Ceria ENM accumulated in the mononuclear phagocyte system from which it was not significantly cleared over 90 days. Ceria ENM distribution following 5 doses that were 20% of a larger dose paralleled the larger dose, suggesting a large dose predicts the bioaccumulation of repeated small doses. Electron microscopy revealed very little ceria ENM in the brain, consistent with ICP-MS results. Initial anti-oxidant effects were temporally followed by pro-oxidant effects. Liver and spleen histopathology, including granulomas, observed 30 days after ceria ENM administration, did not abate or progress over 90 days. The surface valence of the ceria ENM, rich in Ce (III), did not significantly change after 30 days *in situ*. Nanoceria biopersistence, associated with toxicity, is consistent with the concern that slow clearance of insoluble nanomaterials may be result in adverse responses. Supported by US EPA STAR Grant Number RD-833772.

**114 Speciation and transformations of platinum in environmental materials** M.M. Shafer, University of Wisconsin-Madison / Environmental Chemistry & Technology, University of Wisconsin-Madison / Environmental Chemistry & Technology Dept.; J.J. Schauer, University of Wisconsin / Environmental Chemistry & Technology. Our research addresses three major questions: (a) what are the primary sources and environmental receptors of platinum and nano-sized platinum? (b) what are the chemical forms of

platinum introduced into the environment from current and potential major sources? and (c) how does the speciation of platinum change within specific environmental reservoirs after release? Our focus is on aerosol-mediated emissions, transport, and exposure in non-occupational settings. Emissions from vehicles are being addressed using roadside aerosol sampling and a synoptic program of roadway dust sampling. Engine dyno experiments were conducted to evaluate platinum emissions from platinum-cerium based fuel-borne catalysts (FBC). Concentrations and chemical speciation of platinum in particulate and "soluble" phases of these samples was determined with a suite of analytical tools. sXAS was applied to solid phases. "Soluble" species, as defined with physiological relevant fluid extractions including Gamble's Saline and Alveolar Macrophage Vacuole Fluid, are characterized for particle size (ultrafiltration), and charge (IC). The presence of the particularly toxic chloroplatinate species is being probed using an HPLC-IC-ICPMS method. Platinum species transformation will be evaluated in controlled laboratory experiments with both environmental and model samples. Road dust and road-side aerosol samples from cities across the country (including Atlanta, Denver, Los Angeles, Milwaukee) exhibit elevated levels of total platinum (200–800 ng/g). Significant (8–23% of total) soluble pools of platinum, with measurable anionic character, were measured in these vehicle emission receptor samples. Our sXAS studies of aerosol emissions (PM) from diesel engines burning a Pt/Ce-based FBC reveal a large fraction of oxidized platinum. Spectral fitting suggests that a platinum(IV)oxide is the dominant oxidized platinum species in the engine PM. Similarly, a substantial component of the platinum pool in used TWCs was found to be oxidized. The majority of the primary emissions of platinum from diesel engines burning a Pt-FBC was present in fine and ultra-fine particle-size fractions. We have advanced the analytical methodology for separation and detection of hexa- and tetra-chloroplatinate to achieve quantification limits an order-of-magnitude better than reported in the literature.

**115 Environmental Behavior and Bioavailability of Ag and CeO<sub>2</sub> Nanoparticles: surface functionalization and interaction with natural organic substances** J.M. Unrine, University of Kentucky, University of Kentucky / Department of Plant and Soil Sciences, University of Kentucky / Department of Plant & Soil Sciences, University of Kentucky / Savannah River Ecology Laboratory, University of Kentucky / Department of Plant and Soil Sciences, University of Georgia / Savannah River Ecology Laboratory; E. Oostveen, B. Collin, University of Kentucky; O.V. Tsyusko, University of Kentucky / Department of Plant & Soil Sciences; U. Graham, University of Kentucky / Center for Applied Energy Research; D.A. Butterfield, University of Kentucky / Department of Chemistry; P.M. Bertsch, University of Kentucky / Department of Plant and Soil Sciences. The objective of this project is to investigate the role of nanoparticle surface chemistry and environmental modifications of nanoparticle surfaces in determining their aggregation, deposition and dissolution in environmental matrices, as well as bioavailability and toxicity to a model organism (*Caenorhabditis elegans*). We have synthesized CeO<sub>2</sub> nanoparticles (NPs) with a mean geometric diameter of 4 nm and a 10 kDa dextran coating (DEX). This coating was then functionalized to confer either a net positive charge (diethylaminoethyl dextran; DEAE), or a negative charge (carboxymethyl dextran; CM). The DEX-CeO<sub>2</sub> NPs are amphoteric and have a point of zero net charge (ZPC) of around 7, while the CM dextran coated particles display a net negative charge over a wide pH range and the DEAE particles have a net positive charge over a wide pH range. We are examining the environmental behavior of these particles, including interactions with natural organic matter (NOM), as well as their bioavailability and toxicity and how toxicity and bioavailability are modified by NOM. We observe clear changes in surface chemistry in exposure media such as moderately hard reconstituted water for the DEX CeO<sub>2</sub> NPs but not the DEAE CeO<sub>2</sub> NPs. Similarly, the ZPC of the DEX particles is shifted by up to 2 pH units upon interaction with NOM, but the ZPC of the DEAE particles is relatively unaffected. The positively charged DEAE CeO<sub>2</sub> NPs are far more toxic to *C. elegans* than the CM CeO<sub>2</sub> NPs which are more toxic than the neutral DEX CeO<sub>2</sub> NPs. These differences seem to be attributed to differences in bioavailability. Both the DEX and DEAE coated particles are mostly oxidized as prepared, with some Ce (III) on the surface of the particles. Upon interaction with *C. elegans*, the particles are reduced and contain up to 80% Ce (III). This suggests that reduction of Ce coupled with oxidation of biomolecules as a possible mechanism of toxicity. We intend to use redox proteomics and real-time PCR to help elucidate these mechanisms. In a separate study, we examined the effects of exudates released from aquatic plants (*Potamogeton*

*diversifolius* and *Egeria densa*) on the aggregation and dissolution of Ag NPs with either polyvinylpyrrolidone (PVP) or gum arabic (GA) coatings. The exudates oxidized and dissolved the GA Ag NPs, but stabilized and prevented aggregation of the PVP Ag NPs.

**116 Impact of Nanosilver and Silver Ions on Methanogenesis and Methane Production from Municipal Solid Waste** Y. Yang, S. Gajraj, University of Missouri / Civil and Environmental Engineering; J. Wall, University of Missouri / Biochemistry; Z. Hu, University of Missouri / Civil and Environmental Engineering. Silver nanoparticles (AgNPs, nanosilver) released from industrial activities and consumer products may be disposed directly or indirectly in sanitary landfills. To determine the impact of AgNPs on anaerobic digestion of landfill waste, municipal solid waste (MSW) was loaded in identical landfill bioreactors (9 L volume each) and exposed to AgNPs (average particle size = 21 nm) or silver ions. The landfill anaerobic digestion was carried out for more than 200 days, during which time the cumulative biogas production was recorded automatically and the chemical property changes of leachates were analyzed. There was no significant difference in the cumulative methane volume or methane production rate between the silver ions treated group and the control group. There was also no significant difference between the groups of control and 1 mg AgNPs/kg. However, landfill solids exposed to AgNPs at 10 mg/kg resulted in the reduced biogas production, the accumulation of volatile fatty acids (including acetic acid), and the prolonged period of low leachate pH (between 5 and 6). This was accompanied by higher average total Ag concentration of  $3.9 \pm 0.1$  mg/L in the leachates as compared to  $0.2 \pm 0.2$  and  $1.3 \pm 0.1$  mg/L for the groups of control and the bioreactor treated with 10 mg Ag<sup>+</sup>/kg, respectively. Quantitative PCR targeting 16S rRNA genes of methanogens indicated a slower methanogen growth rate in the bioreactor treated with 10 mg AgNPs/kg. The results suggest that at the concentration of 10 mg/kg, silver ions have minimal impact on landfill methane production. Nanosilver is more toxic than its counterpart resulting in reduced methane production and methanogenic assemblages, likely because of higher silver concentration available in the leachate due to the slow or minimal nanosilver dissolution under landfill operations.

**117 Photochemical and Fungal Transformations of Carbon Nanotubes in the Environment** C.T. Jafvert, S. BeigzadehMilani, Purdue University / School of Civil Engineering; D.H. Fairbrother, J.L. Bitter, Johns Hopkins University / Department of Chemistry; T.R. Filley, T. Berry, C. Gibson, Purdue University / Department of Earth and Atmospheric Sciences. Transformations of carbon nanotubes (CNTs) in the environment are likely to be dominated by abiotic oxidative and extracellular microbial processes. Consequently, we are investigating photochemical and fungal mediated transformations of CNTs, both individually and sequentially. Types of CNTs investigated include pristine (unfunctionalized) single-walled carbon nanotubes (SWCNT) from Carbon Solutions (AP and P2) and from SouthWest Nano Technologies (SG-65); and functionalized single-walled nanotubes from Carbon Solutions (P3 and P7). Also studied are SG-65 nanotubes and multi-walled nanotubes from NanoLab Inc that have been functionalized by acid treatment and further purified to remove metal catalysts (used in their preparation). Initial results indicate the recalcitrance of unfunctionalized SWCNTs to both solar light (after weeks) and fungal reactions. When suspended in water and exposed to solar spectrum light, both carboxylated and PEGylated SWCNTs produce reactive oxygen species (ROS). Singlet oxygen and superoxide anion have been detected from these two SWCNTs. Fungal species, *Trametes versicolor* and *Gloeophyllum trabeum* are currently being investigated for toxicity responses to the suite of CNTs in this study and show impeded growth in culture media when exposed to some unpurified CNTs. Because reaction may lead to further oxidation of carboxyl carbon, the rate of CO<sub>2</sub> evolution is being assessed in both sunlight irradiated samples and CNT preparations exposed to white and brown rot-type wood decay fungi. As a result of exposure to 254 nm light (a positive control for potential product identification), flocculation was observed for oxidized MWCNTs and SWNTs over a range of pH values (4-10), although their ability to resist aggregation was enhanced as the pH and the degree of CNT surface oxygen increased. The rate of photo-induced aggregation was found to depend linearly on the photon flux. Collectively, these observations are consistent with the idea that photo-decarboxylation of the oxidized CNTs is responsible for the effects of UV-irradiation. This hypothesis is currently being tested by using XPS in conjunction with

chemical derivatization to assay the change in oxygen concentration and functional group distributions induced by photolysis in both the UVC and solar regions.

**118 TiO<sub>2</sub> Nanoparticle Exposure and Illumination During Zebrafish Development: Mortality at Parts per Billion Concentrations** W. Heide-man, University of Wisconsin / School of Pharmacy; O. Bar-Ilan, University of Wisconsin / Division of Pharmaceutical Sciences; R. Peterson, J. Pedersen, H. Robert, University of Wisconsin. Titanium dioxide nanoparticles (TiO<sub>2</sub>NPs) can be activated by photons to produce reactive oxygen species (ROS). Exposure to TiO<sub>2</sub>NPs and illumination has the potential to produce cumulative cellular damage. To test this, we exposed zebrafish (*Danio rerio*) to two commercial TiO<sub>2</sub>NP preparations at concentrations ranging from 0.01 to 10,000 ng/ml over a 23-day period. This short period spans all of embryogenesis, larval development, and metamorphosis into the juvenile/adult body plan. During this exposure, some groups of exposed fish were also illuminated with a metal halide lamp that simulates solar irradiation below the surface of shallow water. TiO<sub>2</sub>NP exposure produced significant mortality at 1 ng/ml. As expected, this toxicity was photo-dependent. The LC<sub>50</sub> values for the two TiO<sub>2</sub>NP preparations were 14 ng/mL (95% CI: 0-400), and 268 ng/mL (95% CI: 50-2803). Toxicity included stunted growth, delayed metamorphosis, malformations, organ pathology, and DNA damage. TiO<sub>2</sub>NPs were found in the gills and gut, and elsewhere. Toxic responses were observed in gills, liver, and skin—where exposure to TiO<sub>2</sub>NPs is highest. The two preparations differed in particle diameter ( $12.1 \pm 3.7$  nm and  $23.3 \pm 9.8$  nm), but produced aggregates in the 1  $\mu$ m range, and both were taken up to approximately the same extent, in a dose-dependent manner. Illuminated particles produced a time- and dose-dependent increase in 8-hydroxy-2'-deoxyguanosine DNA adducts, consistent with cumulative ROS damage. Zebrafish take up TiO<sub>2</sub>NPs from the aqueous environment even at low ng/ml concentrations, and these particles, when illuminated in the violet-near UV range produce cumulative toxicity.

**119 Transformation and Fate of Nanomaterials During Wastewater Treatment and Incineration** L.C. Marr, Virginia Tech / Civil and Environmental Engineering; A. Pruden, Virginia Tech / Via Department of Civil and Environmental Engineering, Virginia Tech / Civil & Environmental Engineering; E. Vejerano, Y. Ma, A.L. Holder, Virginia Tech / Civil and Environmental Engineering. Disposal is the final step in the product life cycle, and understanding how waste treatment processes might modify nanomaterials is critical to predicting their fate in the environment. The overall objective of this research is to characterize the transformation and fate of engineered nanomaterials and byproducts during biological wastewater treatment and incineration. We have assessed the response of a nitrifying wastewater treatment system to nanosilver and titanium dioxide. The majority of the nanomaterials partitioned to the sludge in lab-scale sequencing batch reactors. Results of RT-qPCR indicated that nitrite-oxidizing bacteria were significantly reduced in reactors containing nanosilver compared those containing ionic silver and the control. The expression of specific tetracycline and sulfonamide antibiotic resistance genes did not change in response to the addition of nanosilver or ionic silver. We have characterized the microbial community through high-throughput pyrosequencing and used the Comet Assay to assess toxicity of the effluent. Incineration was simulated through combustion of waste samples spiked with 0.1%, 1%, and 10% by weight ceria, C<sub>60</sub>-fullerene, nickel oxide, silver, or titania in a muffle furnace. The presence of nanomaterials in the waste stream either enhanced or reduced emissions of polycyclic aromatic hydrocarbons (PAH), depending on the type of waste and the specific PAH. The most abundant PAH species found in the exhaust were those containing 2-3 rings, and their yields depended on the concentration of nanomaterials in the waste. Phenanthrene, fluorene, and anthracene were the dominant PAH species at nanomaterial concentrations of 0.1%, 1%, and 10%, respectively. Nanomaterials in the waste resulted in increased emissions of some of the 4-6 ring PAHs: benzo(k)fluoranthene, pyrene, and chrysene. The total PAH yields for the samples containing nanomaterials were ~6 times higher, on average, than for samples containing the nanomaterials' bulk counterparts, suggesting that the high specific surface area of the nanomaterials affects PAH formation. The shift in emissions occurred mainly in the 2-3 ring PAHs and not in the larger ones. Partitioning between the ash and airborne particulate matter was assessed for the metallic nanoparticles. At most, 3% of the nanomaterials were found in particulate matter.

**120 Fate and behaviour of silver nanoparticles in aquatic systems** J. Lead, University of Birmingham / School of Geography, Earth and Environmental Scien. Silver nanoparticles are one of the most used nanoparticles types due to anti-bacterial properties and such usage inevitably leads to environmental discharge. However, both the nature and extent of silver nanoparticle exposure and hazard are poorly understood. This talk will particularly focus on the potential environmental transformations of nanoparticles, related to aggregation, oxidation, dissolution and the formation of nanoscale coatings of natural organic macromolecules (NOM). These processes will be examined in relation to nanoparticle properties (size, capping agent) and environmental conditions (concentration and nature of NOM, pH, ionic strength, presence of specific ions). Speculations on potential timescales and ultimate fates of the nanoparticles will be given.

**121 Bioaccumulation of Emerging Contaminants in Tropical Mangrove Food Webs** B.C. Kelly, H. Zhang, F. Chen, National University of Singapore / Department of Civil and Environmental Engineering. Tropical mangroves are important ecosystems in Southeast Asia, as well as other tropical and subtropical regions of the world. These unique ecosystems provide essential habitat for numerous species of aquatic and terrestrial organisms. This paper reports results of a field study involving (i) stable nitrogen  $\delta^{15}\text{N}$  and carbon  $\delta^{13}\text{C}$  isotope analyses to assess nutrient dynamics and trophic position of mangrove organisms and (ii) trace chemical analyses to assess the bioaccumulation behavior of emerging contaminants of concern in mangrove ecosystems. Field sampling was conducted at two local mangroves in Singapore and included collection of water, sediments, suspended sediments, polychaetes, bivalves, crustaceans and fish. Stable isotopes were determined using isotope ratio mass spectrometry (IRMS). Target analytes included legacy POPs, as well as various contaminants of emerging concern including current-use pesticides (CUPs), brominated flame retardants (BFRs), synthetic musks and pharmaceuticals and personal care products (PPCPs). Following standard extraction and cleanup methods, identification and quantification of target compounds was performed using liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) or gas chromatography triple-quadrupole tandem mass spectrometry (GC-QQQ-MS/MS). Residues of PPCPs, Caffeine, Carbamazepine, Diclofenac, Diphenhydramine, Estrone (E1), Estradiol (E2), Gemfibrozil, Ibuprofen, Linuron, Naproxen, Simvastatin and Triclosan, were detected at levels of  $< 0.1$  to  $200 \text{ ng/g dry wt.}$  in sediments and  $< 0.1$  to  $20 \text{ ng/g wet wt.}$  in biota. Four synthetic musks (Celestolide, Galaxolide, Tonalide and Musk Ketone) were also commonly detected in mangrove samples. Galaxolide and Triclosan Metabolite (Methyl Triclosan) were detected at relatively high concentrations in biota ( $100$  to  $2500 \text{ ng/g lipid wt.}$ ). Observed species-specific bioaccumulation factors (BAFs), biota-sediment accumulation factors (BSAFs) and overall trophic magnification factors (TMFs) emerging contaminants were generally lower than those for legacy POPs. Bioaccumulation metrics of many emerging contaminants were lower than anticipated based on physical-chemical properties (e.g., chemical  $K_{OW}$  and  $K_{OA}$ ), indicating many of these compounds are likely metabolized in mangrove organisms.

**122 Derivation of critical body burdens to assess the potential risks of perfluorinated compounds to aquatic organisms** J. Newsted, Cardno Entrix, Cardno ENTRIX, Inc.. Perfluoroalkyl compounds (PFCs) are synthetic fluorinated organic compounds that can be released to the environment during manufacturing processes, from commercial products and applications, or indirectly via oxidation of precursor molecules containing perfluoroalkyl chains. While PFCs have received increased attention in monitoring programs, the assessment of the potential risks PFCs pose to aquatic organisms are still being investigated. The tissue residue approach (TRA) provides a framework for analyzing aquatic toxicity in terms of mode of action and tissue residue concentrations and was applied to perfluorooctane sulfonate (PFOS), PFC that has been extensively studied in laboratory and field studies. Using acute and chronic toxicity data from invertebrate and fish studies, critical body burdens were derived using several methods. In the first method, an assumption of steady state conditions was used along with bioaccumulation factors and whole body critical tissue levels were calculated using LC10 and LC50 values from freshwater organisms. Critical body burdens ranged from  $0.15$  to greater than  $60 \text{ mmol/kg ww}$  while tissue values based on MATC values ranged from  $0.03$  to  $13 \text{ mmol/kg ww}$ . Given the uncertainty related to the assumption of steady state conditions for acute and subacute exposures, a second analysis was conducted using

pharmacokinetic models in several aquatic organisms. In one example, a kinetically derived tissue residue value in bluegill was  $0.24 \text{ mmol/kg}$ . In a third approach, measured tissue values from toxicity study conducted with bluegill had a tissue value of  $0.47 \text{ mmol/kg}$ . While a critical body burdens for aquatic organisms can be derived for PFOS, the presence of significant data gaps introduce great amounts of uncertainty that at this time are difficult to address due to a clear understanding of the mechanisms of accumulation of PFOS into biota. However, given these constraints, this work presents an approach that can be used to further define critical body burdens for aquatic organisms. Finally, the results of a hazard assessment will be presented that compares the PFOS critical body burden values to PFOS concentrations in fish tissues collected from North America and other global locations.

**123 Dynamics of uptake and elimination of  $17\alpha$ -ethinylestradiol in male goldfish (*Carassius auratus*)** A. Alansari, University of Ottawa / Biology; J.M. Doyle, V.M. Trudeau, J.M. Blais, University of Ottawa. To determine the uptake and elimination kinetics of  $17\alpha$ -ethinylestradiol (EE2), goldfish (*Carassius auratus*) were exposed to EE2 via two different routes: water ( $150 \text{ ng/L}$ , nominal) for  $72 \text{ h}$  and food ( $250 \text{ ng/g}$ , nominal) for  $120 \text{ h}$ . Whole tissue EE2 levels revealed a rapid uptake of EE2 in goldfish, and reached  $8.43 \text{ ng/g}$  ( $\pm 1.22$ , Standard deviation, dry weight) after the first hour of exposure with an uptake rate constant ( $k_1$ ) of  $45 \text{ h}^{-1}$ . The elimination rate constant ( $k_2$ ) was  $0.0786 \text{ h}^{-1}$ . In the feeding experiment, EE2 concentrations increased rapidly, reaching an average of  $1.4 \text{ ng/g}$  after  $3 \text{ h}$  following the first dietary exposure with estimated assimilation efficiency ( $\alpha$ ) of  $0.106$ . An average of  $(2.66 \pm 0.87 \text{ ng/g, } n=8)$  was determined in the  $24$ – $72 \text{ h}$  samples, whereas EE2 concentrations in fish were below our method detection limits ( $0.67 \text{ ng/g}$ ) for all samples after  $72 \text{ h}$ . The calculated EE2 bioconcentration factor (BCF) for the water exposure was  $377$ . A good fit was observed between the experimental and modeled data. The modeling was critical to predict the extent by which EE2 bioaccumulation would occur at variable environmental concentrations. Our data suggested that EE2 can be rapidly taken up by fish via gill absorption and gastrointestinal absorption. To our knowledge, this was the first report to describe EE2 uptake and elimination dynamics, as well as providing important data to model EE2 kinetics following both water and dietary exposures in goldfish. Funded by NSERC-Canada and King Abdulaziz University, Saudi Arabia.

**124 Histopathological changes and bioaccumulation of platinum group metals by native Hudson River aquatic organism, *Orconectes virilis*** M. Wren, T. DesMarais, Marist College; Z. Gagnon, Marist College / School of Science. Platinum Group Metals (PGM), such as platinum (Pt), palladium (Pd), and rhodium (Rh), are of increasing concern due to rising anthropogenic input to aquatic systems. Most of United States' PGM consumption goes towards manufacturing catalytic converters. Current research demonstrates catalytic converter emissions' solubility in water and reactivity in exposed biota. Hudson River crayfish are at risk of PGM exposure as areas near the river become more densely populated and the number of automobiles increases. Crayfish have been recognized for their ability to absorb and deposit metals in their gills and exoskeleton, warranting them as an effective experimental model for metal accumulation. In this study, PGMs' effects on bioaccumulation and histopathological changes were studied using *Orconectes virilis*, a native species of the Hudson River, as a model. Raw Hudson River water was used to recreate the interactions seen between PGMs and existing chemicals polluting the water body. Organisms were exposed to varying experimental levels of water-soluble PGM salts for ten days. Experimental treatments were established:  $0.0$ ,  $1.0$ ,  $5.0$ ,  $10.0 \text{ ppm Pt}^{(IV)}$  and a PGM Mix ( $1.0 \text{ ppm Pt}^{(IV)}$ ,  $\text{Rh}^{(III)}$ ,  $\text{Pd}^{(II)}$  each). A Solar AA spectrometer in graphite furnace mode (GFAAS) was used to measure concentrations of metals in samples of exoskeleton, muscle, and liver. SPSS statistical package was used to determine differences in accumulation of Pt and Rh in crayfish tissue. Statistically significant bioaccumulation of Pt and Rh was observed in all organs, with highest concentrations found in exoskeletal tissue,  $1,856.6 \text{ } \mu\text{g}/0.1 \text{ g dw}$  in  $5 \text{ ppm}$  exposure and  $476.2 \text{ } \mu\text{g}/0.1 \text{ g dw}$  Rh in PGM mix exposure. Pt concentrations dropped significantly at  $10 \text{ ppm}$  Pt, suggesting that severe structural damage to the tissue disabled significant retention of the substrate. Paraffin sections,  $6 \text{ } \mu\text{m}$  thick, were prepared in eosin-hematoxylin stain and examined for histological abnormalities within liver and exoskeletal tissue. Inclusion bodies and hyalinization were observed in exposed liver tissue. Pathology in hepatocyte structure, such as hyper-segmentation of vacuoles and swelling of the vascular channels, were

also observed. Visible bands of the exocuticle and a lighter stain suggests demineralization in exposed exoskeletal tissue. Bioaccumulation and cellular abnormalities seen in exposed aquatic organisms raise concern of PGM biomagnification within the food chain.

**125 Internal concentrations of polychlorinated dibenzo-p-dioxins in the reporter gene assay CAFLUX for activation of the arylhydrocarbon receptor** B.I. Escher, Entox, The University of Queensland / National Research Centre for Environmental Toxicology; B. Mewburn, Entox, The University of Queensland; M.S. Denison, University of California, Davis / Department of Environmental Toxicology; J.L. Hermens, IRAS, Utrecht University. Persistent organic pollutants are ubiquitous environmental contaminants and pose health risks. Cell-based bioassays could be cost-efficient and ethical alternatives to animal testing in chemical risk assessment. However, hydrophobic organic chemicals may appear less potent than they really are because their bioavailability is reduced by sorption to growth medium and vials. In the present study we use the CAFLUX assay, CAFLUX assay uses a recombinant rat hepatoma (H4IIE) cell line containing a stably transfected AhR-inducible green fluorescent protein reporter plasmid. The CAFLUX is specific for chemicals binding to the aryl hydrocarbon receptor and detects chemicals with a dioxin-like activity. For a series of polychlorinated dibenzo-p-dioxins we have assessed bioavailability and partitioning between medium components and cells and demonstrate how the partitioning affects the cellular concentrations with 95% to more than 99% of the chemicals sorbed to medium components thus reducing the sensitivity of the assay. We also demonstrate how to overcome this limitation with a novel dosing technique where the polychlorinated dibenzo-p-dioxins are desorbed from a polymer. Depletion of free concentration by cells and medium components is replenished from polymer reservoir, thus keeping the aqueous and cellular concentrations constant over the duration of the experiment. While this approach is more precise than dosing by solvent spiking, it has the disadvantage that larger amounts of sample are needed due to the larger medium volume and the additional PDMS reservoir. Similar to PDMS, the proteins in the medium can keep the concentrations constant over the duration of the experiment and this might suffice for practical applications of environmental samples.

**126 Occurrence of Currently Used Pesticides in Tissues of Non-Target Organisms** K.L. Smalling, K.M. Kuivila, U.S. Geological Survey. A wide variety of pesticides are applied to agricultural and urban areas throughout the United States and are transported off-site either dissolved in water, bound to sediments, or by aerial drift during application. The effects of these current-use pesticides on aquatic ecosystem health are not well understood. Pesticide residues in tissues of non-target organisms demonstrate exposure and may serve as a metric that can be linked to biological endpoints. Studies of legacy pollutants have shown that tissue concentrations are potentially a better surrogate for characterizing toxicity to non-target organisms than traditional toxicity tests using external exposure concentrations (water, sediment, diet). Relatively little data are available on the occurrence of current-use pesticides in non-target organisms, and thus, linkages between tissue concentration and toxicological endpoints are rarely established for these compounds. To better assess potential ecosystem effects, the first step is to characterize pesticide exposure to aquatic organisms of concern by directly measuring concentrations in tissue. Because organisms are typically exposed to complex mixtures of pesticides, a relatively recent method was developed to measure approximately 100 pesticides and degradates in tissue (either whole body or individual organs). The most statistically significant approach to correlate pesticide exposure and effects is to measure both tissue concentration and biological endpoints (lethal and/or sublethal effects) in individual organisms (rather than composite samples). For this reason, the analytical method was optimized for maximum sensitivity to allow for the analysis of currently used pesticides in single organisms or organs. A variety of tissues, including fish, frogs, sand crabs, crab embryos, and insect larvae, from sites across the United States were analyzed for current-use pesticides. Results indicate that organophosphate and pyrethroid insecticides, conazole and strobilurin fungicides, and a variety of herbicides are present at measurable concentrations in tissues from a variety of organisms residing in substantially different habitats. Future studies will include collaborative efforts between chemists, toxicologists, and ecologists to link observed tissue pesticide concentrations to aquatic ecosystem health.

**127 Uptake and trophic transfer of perchlorate in a simulated northern pike and threespine stickleback food web** C. Furin, University of Alaska Anchorage / Dept. of Biological Sciences; F.A. von Hippel, University of Alaska Anchorage / Department of Biological Sciences; B. Hagedorn, University of Alaska, Anchorage / Environment and Natural Resources Institute; T. O'Hara, University of Alaska Fairbanks / Institute of Arctic Biology. The uptake and trophic transfer of contaminants in aquatic food webs is a major concern. This study addresses the ability of the environmental contaminant perchlorate, a highly water-soluble endocrine disruptor, to 1) biomagnify (food) and/or bioconcentrate (water), or not; and 2) assesses tissue concentrations for each route alone and both routes combined. We investigated how different routes of exposure (food and/or water) affect tissue concentrations by exposing threespine stickleback (*Gasterosteus aculeatus*) to perchlorate and then feeding them to northern pike (*Esox lucius*) housed in different water concentrations. Perchlorate exposure to the pike were through contaminated water (49 day exposure at either 10 ppm or 100 ppm) and/or food (14 day exposure to stickleback prey previously held in water at either 10 ppm or 100 ppm). We found that both water and food significantly contribute to tissue concentrations as compared to controls, but that, as expected, perchlorate does not biomagnify. Contaminated food contributed to pike tissue concentration in the control and 10 ppm water treatments but did not in the 100 ppm water treatment. These results demonstrate that assessing the combined route of exposures (food and water) is important to consider when evaluating uptake and tissue concentrations of perchlorate in fish.

**128 Emerging and Legacy Contaminants in the Foodweb in the Lower Columbia River – USGS Conhab Project** E.B. Nilsen, USGS Oregon Water Science Center / OWSC; D. Alvarez, T. Counihan, W. Cranor, J. Hardiman, J. Jenkins, M. Mesa, J. Morace, R. Patino, S. Cranor, L. Torres, I. Waite, S. Zaugg, USGS. An interdisciplinary study, USGS Columbia River Contaminants and Habitat Characterization (ConHab) project investigates transport pathways, chemical fate and effects of polybrominated diphenyl ethers (PBDEs) and other endocrine disrupting chemicals (EDCs) in aquatic media and the foodweb in the lower Columbia River. Polar organic chemical integrative samplers (POCIS) and semipermeable membrane devices (SPMDs) were co-deployed at each of 10 sites in 2008 to provide a measure of the dissolved concentrations of select PBDEs, chlorinated pesticides, and other EDCs. PBDE-47 was the most prevalent of the PBDEs detected. Numerous organochlorine pesticides, both banned and current-use, were measured at each site including hexachlorobenzene, pentachloroanisole, dichlorodiphenyltrichloroethane (DDT) and its degradates, chlorpyrifos, endosulfan, and the endosulfan degradation products. EDCs commonly detected included a series of polycyclic aromatic hydrocarbons (PAHs), fragrances (galaxolide), pesticides (chlorpyrifos and atrazine), plasticizers (phthalates), and flame retardants (phosphates). The site near Columbia City tended to have the highest concentrations of contaminants in the Lower Columbia River. In 2009 and 2010 passive samplers were deployed, resident largescale suckers (*Catostomus macrocheilus*) and surface bed sediments were collected at three of the original sites representing a gradient of exposure based on 2008 results. Brain, fillet, liver, stomach, and gonad tissues were analyzed. Chemical concentrations were highest in livers, followed by brain, stomach, gonad, and lastly, fillet. Concentrations of halogenated compounds in tissue samples ranged from 1 wet tissue. PBDEs, organochlorine pesticides, DDT and its degradates, and polychlorinated biphenyls (PCBs) were detected at all sites in nearly all organs tested. PBDE congeners most frequently detected and at the highest concentrations were PBDE-47 > PBDE-100 > PBDE-154 > PBDE-153. Concentrations in tissues and in sediments increased moving downstream from Skamania to Columbia City to Longview. Preliminary biomarker results indicate that fish at the downstream sites experience greater stress relative to the upstream site based on gonad, kidney, spleen, and liver histopathology. These results support the hypothesis that contaminant concentrations in the environment correlate to bioaccumulation in the foodweb.

**129 Analytical Considerations for the Determination of Petroleum Biomarkers** M.J. Benotti, Battelle / Analytical and Environmental Chemistry; R. Lizotte, K. McInerney, J. Thorn, Battelle. Petroleum biomarkers are a structurally diverse class of hydrocarbons found crude oils representing diagenetic transformation products of biomolecules. The relative distribution of individual biomarkers can provide information about the source or formation conditions of a particular oil and can be used to fingerprint the

material in environmental forensic applications. This talk will include 1) a summary of the analytical considerations necessary to maximize analytical sensitivity; 2) an illustration of the approach to chemical fingerprinting and source or formation conditions; and 3) a discussion of the future of petroleum biomarker analyses. Gas chromatography mass spectrometry (GC-MS) techniques have been used for several decades to measure concentrations of biomarkers in oil and sediment. However, because petroleum biomarkers are present in relatively low concentrations (compared to other classes of hydrocarbons like saturated hydrocarbons or polycyclic aromatic hydrocarbons), increasing the sensitivity of the GC-MS may require silica-gel cleanup to remove the aromatic fraction or molecular sieve cleanup to remove n-alkanes. Using a large dataset of crude oils and refined products, examples of chemical fingerprinting and the determination of source or formation conditions will be presented. Examples will include information that can be determined from individual compounds and common diagnostic ratios. Lastly, the talk will explore the future of petroleum biomarker analyses, including the potential applications for different types of detectors such as GC tandem mass spectrometry (GC-MS/MS), GC quadrupole time-of-flight mass spectrometry (GC-QToF-MS) and comprehensive GC time-of-flight mass spectrometry (GC×GC-ToF-MS).

### 130 CERCLA Well 12A, Tacoma, WA Contaminated Soil Excavation

**Case Study** R.A. Weiss, Seattle District US Army Corps of Engineers / Environmental Engineering and Technology Section; M. Michalsen, U.S. Army Corps of Engineers / Environmental Engineering & Technology Section; K. Kunas, M. Scarsella, Seattle District US Army Corps of Engineers; A. Franz, D. Giardrone, CDM Smith; M. Roberts, J. Harris, KEMRON Environmental Services, Inc.. The Well 12A Superfund Site in Tacoma, Washington is a former oil recycling facility where off-site migration of chlorinated solvent-contaminated groundwater has impacted the City of Tacoma Well 12A drinking water well. Additional site soil and groundwater contaminants include polychlorinated biphenyls (PCBs), other volatile organic compounds (VOCs), metals and dense non aqueous phase liquid (DNAPL). Reduced pump and treat system effectiveness resulted in a 2009 Record of Decision (ROD) Amendment, which specified a combination of soil excavation, in situ thermal remediation and enhanced anaerobic bioremediation to reduce groundwater contaminant mass leaving the site by 90%. The excavation component of the remedial action included removal of highly contaminated "filtercake" fill material, a 14,000 gallon underground storage tank, and related tank waste material. Two 50' x 50' excavation areas were selected from numerous sampling investigations used to model contamination greater than 1000 µg/kg VOCs in shallow soil (0-5 ft bellow ground surface [bgs]). Given the well characterized nature and small excavation area, direct dig and haul disposal was planned to accelerate the excavation process. However, the excavation complexity and project schedule were impacted from elevated soil contamination levels encountered (>3,000 µg/kg VOCs) and oily soil extending to 15 ft bgs in the direction of an on-site building which required geotechnical stabilization. On-site treatment using lime-activated persulfate was implemented to meet LDR disposal requirements and allowed landfill disposal versus incineration. On-site treatment ultimately decreased disposal travel distance by 1260 miles per trip and decreased the total excavation cost by ~ \$1,000,000. This case study will present lessons learned and information on how the conceptual site model developed from numerous extensive sampling events still allowed for major discrepancies in the overall magnitude and extent of site contamination. In addition, sampling methodologies used during excavation to characterize on-site treatment will be described along with sampling techniques used to characterize waste for final disposal. Excavation activities were completed by KEMRON Environmental Services, Inc. (KEMRON) on contract to US-ACE Seattle District, who was tasked with implementing the three remedial action components by EPA Region 10 through an Interagency Agreement.

### 131 Improved Separation of Complex Polycyclic Aromatic Hydrocarbon Mixtures Using Novel Column Combinations in GC×GC/ToF-MS

C. Manzano, Oregon State University / Department of Chemistry; E. Hoh, San Diego State University / Graduate School of Public Health; S. Simonich, Oregon State University / Depts. of Chemistry and Environmental & Molecular Toxicology. Complex mixtures of polycyclic aromatic hydrocarbons (PAHs) are difficult to resolve because of the high degree of overlap in compound vapor pressures, boiling points and mass spectral fragmentation patterns. The objective of this research was to improve the separation of complex PAH mixtures (97 different PAHs, including parent, alkyl-,

nitro-, oxy-, thio-, chloro-, bromo-, and high molecular weight PAHs) using GC×GC/ToF-MS by maximizing the orthogonality of different GC column combinations and improving the separation of PAHs from the sample matrix interferences, and unresolved complex mixtures (UCM) usually present in complex environmental samples. Four different combinations of non-polar, polar, liquid crystal and nano-stationary phase columns were tested. Each column combination was optimized and evaluated for orthogonality using a method based on conditional entropy that considers the quantitative peak distribution in the entire two-dimensional space. The highest chromatographic resolution, lowest synergety and highest orthogonality were achieved with column combination "C", consisting in a 10m × 0.15mm × 0.10µm LC-50 liquid crystal column in the first dimension and a 1.2m × 0.10mm × 0.10µm NSP-35 nano-stationary phase column in the second dimension. Environmental samples where then analyzed for complex mixtures of PAHs using column combination "C", including an atmospheric particulate matter with diameter < 2.5µm (PM<sub>2.5</sub>) sample from Beijing, China, a soil sample from St. Maries Creosote Superfund Site, and a sediment sample from the Portland Harbor Superfund Site. Column combination "C" resulted in low interference from UCM and thus better chromatographic separation and identification of PAHs. In addition, the use of this column combination in GC×GC/ToF-MS resulted in significantly shorter analysis times (176 min) for complex PAH mixtures compared to four different one-dimensional GC-methods that would be needed in order to complete the analysis of a complex PAH mixture containing parent, alkyl-, nitro-, oxy-, thio-, chloro-, bromo-, and high molecular weight PAHs using a one-dimensional GC/MS, for a total run time of 257 min, as well as potentially reduced sample preparation time.

### 132 On-line SPE coupled to LC MS/MS for sensitive analysis of multiple PPCPs in Water: Benefits versus off-line extraction and Large Volume Injection (LVI)

T. Anumol, S. Merel, S. Snyder, University of Arizona / Chemical & Environmental Engineering. With the development of advanced technologies for the treatment of Trace Organic Contaminants (TrOCs) and the synergistic effects of low doses of these compounds presently unknown, the need for analytical measurement of these compounds at very low levels in water and sewage has become paramount. The traditional method to achieve sensitivity and low levels of measurement has been to use off-line solid phase extraction (SPE) either manually or by using an automated apparatus. However, this method requires a large sample volume, is time-consuming and labor intensive. Trace enrichment or on-line SPE eliminates all these difficulties while providing sample clean-up and reduces interferences which large volume injection (LVI) cannot do. In this study, A trace enrichment cartridge (on-line) setup is compared to off-line spe for sensitivity. A single method for the analysis of over 20 pharmaceuticals and personal care products (PPCPs) using on-line spe coupled to an Agilent 6460 LC MS/MS will be shown and the results will be compared against off-line spe across different water matrixes. Critical parameters like sample volume, life of cartridge and elution solvents will also be discussed. The results of this study indicate that online spe when performed correctly offers significant benefits in time and cost while also offering extremely good sensitivity for low level TrOC detection in water.

### 133 Pyrethroid Analytical Methods for Wastewater Monitoring: An Intercomparison Exercise to Determine Suitability of Methods and Reporting Limits

J.C. Markle, Coalition for Urban/Rural Environmental Stewardship; B.H. van Buuren, Van Buuren Consulting, LLC; A.C. Barefoot, Du Pont Crop Protection / Crop Protection Products. Pesticides containing pyrethroid active ingredients have become a highly requested parameter group for low-level chemical analysis in water monitoring programs. This poses a problem to project managers, as there are no standardized methods or commercially available certified reference materials for these analyses. In addition, laboratories may vary in their instrumentation, levels of sensitivity, and techniques for extraction, clean-up, and analysis. In response to the 2006 California DPR data re-evaluation, the Pyrethroid Working Group and Tri-TAC, representing Publicly Owned Treatment Works (POTWs), developed a monitoring project for eight pyrethroids in influent, effluent and biosolids. During the project design phase, an intercomparison exercise was conducted to test the comparability of pyrethroid results from several laboratories, identify areas for method modification, and establish project reporting limits. The intercomparison exercise used real-world matrices and a process that would replicate the monitoring project's design. Two POTWs supplied samples to three participating laboratories. Each

laboratory then ran three analytical replicates of each sample in conjunction with their standard quality control samples. This generated 144 results for each of the effluent, influent, and biosolids matrices – a total of 432 data points. Laboratory reporting limits ranged from 0.5 ng/L in the effluent to 182 ng/g in the biosolids. Based on the relative standard deviations of these results, project management identified ten potential improvements to the study design – including method modifications for the biosolids matrix, and laboratory use of a stable isotope internal standards. The intercomparison allowed project managers to optimize methods, reporting limits, quality control requirements, and logistics prior to sample collection. Limitations were addressed preventatively, rather than via costly resampling and reanalysis. Intercomparisons are a useful and cost-effective tool when applied to parameter groups that are not supported through standardized methods and certified reference materials.

**134 Spatial and Temporal Mapping of Organic Contaminants Using Equilibrium Passive Samplers** P. Vlahos, University of Connecticut / Departments of Marine Sciences and Chemistry; D. Cady, Y. Son, University of Connecticut. One of the greatest challenges in the study of the fate and transport of organic contaminants is the need for long term, synoptic data. Here we present a spatial and temporally resolved time series for Long Island Sound's coastal marine waters based on 8 stations over July 2011 to July 2012. The time series uses ethylene vinyl acetate based, thin film equilibrium passive samplers that yield a quantitative measure of organic compound concentrations in water over a wide range of solubilities (Log Kow between 1.5 to 8). Samplers were deployed in triplicate for at least two weeks at each station and replaced upon retrieval. Samplers were then mailed or delivered back to the University of Connecticut where they were solvent extracted and analyzed by GCMS. Initial time series focused on polycyclic aromatic hydrocarbons (PAHs) and currently used pesticides though extracts were also archived for additional compound classes including polybrominated diphenyl ethers and phthalates. Precision at each deployment was within 20% and detection limits were in the ng/L to pg/L range for the current configuration though this may be improved by increasing the sampler surface area. Results have been embedded into Google Earth in order to illustrate the spatial and temporal advantages of this approach.

**135 An Incremental Sampling Methodology (ISM) Approach for the Characterization of Intertidal Sediment for Use in a Human Health Risk Assessment** S. McGroddy, B. Bergquist, Windward Environmental LLC. Incremental Sampling Methodology (ISM) is a structured composite sampling and processing protocol that was developed for the characterization of soil, in which samples from numerous increments (i.e., incremental samples) within areas designated as decision units are collected, combined, and analyzed in order to provide a robust estimate of the mean contaminant concentrations within the decision unit. The use of this methodology requires the identification of decision units consistent with the site conceptual site model and a protocol for deriving appropriate statistical values from the data prior to data collection. We present the use of ISM as a case study to characterize the intertidal sediment of the East Waterway in Seattle, Washington for use in the assessment of risk to humans from direct contact with sediment as a result of clamming and habitat restoration. The decision unit for human exposures was the intertidal area throughout the entire waterway. In order to develop exposure metrics such as 95<sup>th</sup> upper confidence limits on mean values, 3 replicate ISM samples were created from 96 incremental samples were collected from throughout the East Waterway, with 32 unique incremental samples for each replicate ISM sample. For most of the contaminants of concern, the variance among the three replicates was low. However, the results for polycyclic aromatic hydrocarbons (PAHs) had a high variance. Within the single exposure unit, 11 intertidal areas were created from which archived incremental samples were used to create composites for each area, which provided additional spatial information for the purpose of developing remedial alternatives. Advantages of this methodology for sampling intertidal sediment are the representativeness of mean concentrations because they are based on contributions from a large number of locations and the reduced analytical costs. Disadvantages include limitations in spatial distribution information within the decision units, and relatively increased field costs. Collecting replicate incremental samples and archiving them can enable further analyses to provide additional spatial distribution for contaminants of particular concern.

**136 Community engagement in sampling: benefits and tradeoffs using passive samplers deployed by volunteers to survey organic pollutants across an estuary** V.P. Sacks, ENVIRON / Graduate School of Oceanography, University of Rhode Island; R. Lohmann, Graduate School of Oceanography, University of Rhode Island. In recent years, passive samplers have made sampling hydrophobic organic contaminants in water and porewater easy and reliable. An advantage to using passive samplers is a comparative decrease in sample contamination issues typically associated with traditional “active” water sampling. Moreover, passive samplers are particularly easy to deploy, and persons unfamiliar can be appropriately trained on their deployment and retrieval. In this study, a group of citizen volunteers deployed passive samplers to survey organic contaminant concentrations. As part of a larger project, this element of the study helped to educate the community on the concepts of organic pollution and involve them in the science of their environment. A workshop was held to educate our volunteers and distribute sampling materials (polyethylene passive samplers, gloves, etc.). Volunteers each deployed a sampler near their homes across the Narragansett Bay (NB) watershed, thereby greatly expanding the geographic scope of our study. Of 32 samplers distributed, 25 were recovered and analyzed for the emerging contaminants alkylphenols (APs), triclosans, polybrominated diphenyl ethers (PBDEs), and legacy pesticides (OCPs). Concentrations of APs were found at about 2-3 orders of magnitude lower than their respective EC<sub>50</sub> values. Triclosan, which was undetected in NB water and porewater in a concurrent study, was detected in the volunteer sampling locations upriver near Providence, RI. Methyl triclosan, a derivative was consistently detected throughout the watershed. PBDEs 28, 47, 49, 99, and 100 were consistently found in the hundreds of fg L<sup>-1</sup> range, and PBDEs 8, 15, 153, and 154 were detected at similar concentrations in a few samples. Nine OCPs were detected in >85% of the samplers analyzed. In this presentation, we will discuss the tradeoffs and benefits of working with volunteers in this sampling effort, discuss advantages of this type of sampler, and present spatial concentrations of a variety of chemicals. Data from our volunteer deployment are compared to data from a deployment by trained scientists involved in the larger study. This study focused on involving the community to collect data for our study. By doing so, we provided community involvement, obtained useful data, and provided lower-cost sampling over a wider area than otherwise possible. We will present data quality considerations and lessons learned in this talk.

**137 Pathway-Based Analysis of Fish Transcriptomics Data Along Effluent Gradients in Minnesota Rivers** J. Berninger, Baylor University / Department of Environmental Science; D. Martinovic, University of Saint Thomas, University of St. Thomas / Dept. of Biology, U.S. EPA, Mid-Continent Ecology Division / Mid-Continent Ecology Division, University of St. Thomas / Biology, University of Saint Thomas / Biology; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA. As part of a larger effort to assess the health of streams and rivers influenced by municipal effluents in Minnesota, fathead minnows (*Pimephales promelas*; FHM) were exposed to ambient surface waters from three locations. The locations were generally representative of the state: urban – Rochester, agricultural – Hutchinson; rural/forested – Ely. Fish were exposed in aerated mobile exposure units supplied with water from upstream, at, or downstream of a wastewater treatment plant (WWTP) outfall. While multiple endpoints were evaluated, this study focuses on FHM female ovary transcriptomics following a 4 day exposure. Comparing between treatment groups (upstream, downstream, at effluent) within each location, the number of significantly differentially expressed genes (DEGs) were highest in Rochester (5847), than Hutchinson (1295) and Ely (867). Among the DEGs, hierarchical clustering and PCA showed distinct separation of the upstream, downstream, and effluent treatments at each location. Gene Set Enrichment Analysis (GSEA) showed the overall number of gene sets enriched followed the same pattern as the differential expression, with highest enrichment in Rochester and lowest in Ely. Comparing along the effluent gradient, different patterns were observed at each site. There were, however, a few gene sets that showed consistent responses to the effluent gradient across all three locations. Enrichment moving upstream was seen in two gene sets putatively linked with the promotion of oocyte maturation, (through gene sets associated with cyclin B and cathepsin D). Another gene set, a putative inhibitor of oocyte maturation (through a TGFB1 associated

gene set), exhibited enrichment along the downstream gradient at all locations. Given the substantial differences in land use, human population, and pollutant chemistry the consistent impact on oocyte maturation-related gene sets suggests an emerging trend across effluent gradients. In general, results from female FHM ovary transcriptomics follow a similar pattern to those of the companion analytical chemistry and studies with male FHM livers (transcriptomics and metabolomics). This study demonstrates the potential utility of transcriptomics for effects-based monitoring efforts. The contents of this abstract neither constitute nor reflect official US EPA policy.

**138 Phenanthrene induced transcriptional responses in the female fathead minnow (*Pimephales promelas*) liver** J.R. Loughery, A. Mercer, K. Kidd, C. Martyniuk, University of New Brunswick / Biology. Phenanthrene (PHEN), a polycyclic aromatic hydrocarbon (PAH), is commonly found in the aquatic environment due to natural and anthropogenic causes. PHEN has been shown to induce oxidative stress in teleosts but recent studies suggest it may also be an endocrine disrupting substance. Female fathead minnows (FHM; *Pimephales promelas*) were exposed for up to 72 hrs to waterborne PHEN at target concentrations of 0, 50 and 500 ppb (environmentally relevant) and a high concentration of 5000 ppb. Fish were sacrificed after 24, 48 and 72 hrs. Body, liver and gonad weights were recorded and livers frozen for gene expression analyses. A dose-response microarray analysis was conducted on 48 hr liver tissues on an 8x15K FHM microarray. Relative to control tissue, there were 1235, 907 and 2568 differentially regulated transcripts in 50, 500, and 5000 ppb, respectively. Of these genes, 228 were common between concentrations. A total of 1201 genes displayed significant variation when the concentrations were compared. Some of the significantly different gene transcripts were related to reproductive processes, including genes involved in zona pellucida glycoproteins (oocyte membrane proteins), and estrogen receptor binding proteins (estrogen receptor  $\alpha$  transcription activity). Gene set enrichment analysis of livers from fish exposed to 5000 ppb yielded 100 significant gene ontologies (GO). GO terms with a significant median fold change of -1.5 or less were involved in immune system function and lipid storage. GO terms with a significant median fold change of 1.5 or greater were involved in DNA replication or neuron contraction and guidance. This study demonstrates that a short-term exposure to PHEN induces transcript changes associated with reproduction and pathways associated with the immune system, DNA replication and meiosis, and lipid metabolism.

**139 Effects of cadmium and nickel on cellular antioxidants and gene transcription levels in yellow perch under chronic laboratory exposure conditions** M.A. Defo, B. Bougas, INRS / INRS-ETE; E. Normandeau, Université Laval / Biology; L. Bernatchez, Université Laval / Département de Biologie; P.G. Campbell, INRS-Eau, Terre et Environnement / INRS-ETE, INRS / Centre Eau Terre Environnement; P. Couture, INRS / Centre Eau Terre Environnement, INRS / Centre Eau, Terre et Environnement. The transcriptional response of one thousand genes to metal contamination was investigated using a cDNA microarray on adult yellow perch (*Perca flavescens*) exposed in the laboratory to cadmium (0  $\mu\text{g/L}$ , 0.8  $\mu\text{g/L}$  and 8  $\mu\text{g/L}$ ) and nickel (0  $\mu\text{g/L}$ , 60  $\mu\text{g/L}$  and 600  $\mu\text{g/L}$ ) for 6 weeks. At the end of exposure, although kidney cadmium and nickel concentrations were significantly different among the exposed groups, differences in transcription level were detected only at the highest concentration, where a total of 106 genes were differently expressed for both metals. Among these, 2 genes involved in cell oxidative stress were of particular interest: the transcription level of catalase (*cat*) was increased whereas that of microsomal glutathione S-transferase 1 (*mgst1*) decreased with the level of metal contamination. We propose that the transcription level of oxidative stress-related genes can be a good indicator of cadmium and nickel exposure. Coupled with field validation, these findings will orient future physiological and biochemical studies aimed at identifying mechanisms of metal toxicity in fish under chronic exposure conditions.

**140 Genetic pathways underlying the immediate and lifespan impacts of a developmental exposure to the endocrine disrupting herbicide atrazine** G. Weber, Purdue University / School of Health Sciences; S. Peterson, S. Lewis, Purdue University; T.L. Lin, Purdue University / Comparative Pathobiology; M. Sepulveda, Purdue University / Forestry and Natural Resources; J. Freeman, Purdue University / School of Health Sciences. There is a growing body of evidence which indicates continual exposure to endocrine disruptors over the lifespan of an individual or during increased

sensitivity windows (such as development) substantially elevates the risk to develop multiple types of diseases. Atrazine, an herbicide commonly applied to agricultural areas throughout the Midwest and a common contaminant of potable water supplies, is implicated as an endocrine disruptor and potential carcinogen. The specific adverse health effects associated with atrazine exposure and the underlying molecular mechanisms of these effects are not well defined. In an effort to delineate the mechanisms of atrazine toxicity, we exposed zebrafish embryos to environmentally relevant concentrations of atrazine shortly after fertilization through 72 hours post fertilization (hpf). Transcriptomic profiles immediately following the embryonic atrazine exposure were obtained and subsequent analyses identified an enrichment of genes with altered expression patterns that are involved in neuroendocrine development and function, cell cycle regulation and carcinogenesis. A subset of individuals was permitted to mature under normal conditions to evaluate the persistent effects of developmental exposure to atrazine in these adults and in unexposed subsequent generations. A significant difference in the number of pairs that successfully bred in one of the atrazine treatment groups coupled with a distinct altered reproductive morphological phenotype in ~10% of female adult zebrafish was observed indicating a persistent lifespan effect of the developmental atrazine exposure. These females were substantially larger in size, particularly in the area of the ovaries. Furthermore, gene ontology analysis from microarrays performed on adult female zebrafish brains that were developmentally exposed showed enrichment for genes involved in neuroendocrine system function and carcinogenesis. The reproductive alterations observed in a subset of females along with decreased mating success and altered transcriptomic profiles provide support to the endocrine disrupting effects of this herbicide and warrant further investigation. Current efforts are aimed at assessing the transgenerational effects of this developmental atrazine exposure in subsequent unexposed generations by focusing on epigenetic regulatory processes and targets that may be altered in response to atrazine exposure.

**141 Effects of Disperse Yellow 7 in *Silurana tropicalis* Gene Network Analysis** V.S. Langlois, Royal Military College of Canada / Chemistry & Chemical Engineering; J. Mathieu-Denoncourt, Royal Military College of Canada; C.J. Martyniuk, University of New Brunswick / Dept. of Biology/ Canadian Rivers Institute, University of New Brunswick / Biology; S.R. de Solla, Environment Canada / Science and Technology Branch. Dyes used in fabric and leather industry are being released into Canadian ecosystems. Recent studies have demonstrated that dyes made of azo compounds are toxic to biota, which is explained by their toxic metabolites (e.g., aromatic amines) produced. The metabolites of azo compounds interact with hydrophobic surfaces of cell membranes and expand them which impede normal cellular functions. It has been suggested that this process leads to cell death due to improper ion balance. Currently, it is estimated that between 10 and 15% of azo dyes are released in the environment as effluent. A recent study conducted by our laboratory has demonstrated that the azo dye Disperse Yellow 7 (DY7) induced cellular stress and interfered with androgen biosynthesis in early tadpole development. The aim of this study was to evaluate gene networks altered by azo compounds in amphibians using ecotoxicogenomic approaches. Larvae of the frog *Silurana tropicalis* (Western clawed frog) were exposed to sediment spiked with up to 887 ppm DY7. Larvae were exposed from Nieuwkoop-Faber developmental stage 12 to 46. At exposure completion, RNA was isolated from whole larvae and quality was ascertained using bioanalyzer analysis. Our custom Agilent 4 X 44 K microarray for *S. tropicalis* was used to investigate gene regulatory networks. Four control and four treated biological samples were investigated. Following exposures, heat shock protein (hsp) 70 and 90 mRNA levels increased by 2.5 and 2.4 fold, respectively, suggesting a response to cellular stress, DY7 also affected the androgen-related genes *ar* and *srd5a2*. This study presents the transcriptional regulatory pathways affected by DY7 in *S. tropicalis* early development.

**142 Effect of Glyphosate on the Genomic DNA of African Snail, *Archachatina marginata*** A.C. Udebuani, Federal University of Technology / Dept. of Biotechnology; I.N. Onwurah, University of Nigeria / Dept of Biochemistry, University of Nigeria, Nsukka / Department of Biochemistry, University of Nigeria / Biochemistry, University of Nigeria. The study of the effects of contaminants of emerging concern such as glyphosate on non-target organisms such as African snail (*Archachatina marginata*), with emphasis on the genomic DNA profile, is of great toxicological importance in terms of risk assessment. Until relatively recently, genetic effects were

largely inferred from observations of genotype. With the ability to perform DNA sequencing and use of PCR, it has become possible to determine genetic variations occasioned by environmental toxicants through the science of Genomics. *Archachatina marginata's* nature and way of life offers it an excellent model animal for the study of the sensitivity of some terrestrial animals to environmental stress induced by chemical pesticides such as glyphosate. In this study, the African giant snail was exposed to soil samples spiked with different concentrations of glyphosate for several weeks and their genomic DNA extracted and subjected to electrophoresis. Amplification of the various DNA bands was carried out using an OMnE-PCR System programming. Our result shows that the AP-PCR genotypic profile with oligonucleotide prima OPA (gaaacgggtg) on DNA of *Archachatina marginata* exposed to glyphosate for a period of 7 days gave varying number of fragments with different amplification bands, corresponding to different molecular weights or sizes. Similarly in comparing the length of time of exposure to glyphosate, it was observed that newer DNA fragments with higher intensity and larger molecular sizes were obtained from DNA amplification as against the control that remained the same, except for the unique band (100-400bp) that was observed in all the snails (exposed and unexposed). It can be inferred from this study that since glyphosate caused increased number of DNA fragments and significantly varying molecular sizes in the African giant snail after an exposure, it has the potential mutagenicity that could induce genotoxicity on non target organisms.

**143 Looking for biomarkers of Hg exposure by transcriptome analysis in the aquatic plant *Elodea nuttallii*** N. Regier, University of Geneva; C. Cosio, Geneva University, Geneva University / Forel Institute. To gain insight into the impact of metal contamination on ecosystems, the potential of various tests on metal accumulating organisms is explored. Rooted macrophytes are well-suited to be used in ecotoxicological tests because they are exposed to both water and sediments. *Elodea nuttallii* is a rooted macrophyte native to Northern America, but as a neophyte, has spread throughout the world. It is able to accumulate large amounts of metals, including Hg and Cd, and is therefore a good candidate for the aim of this study. In the present work we used transcriptome analysis (RNA-seq) of *Elodea nuttallii* to identify biomarkers of Hg exposure. RNA-seq yielded a total number of 63'596 contigs. A total of 27'669 sequences could be assigned to at least one GO term. We also used the functional catalogue of MIPS to identify which biological functions were affected by Hg and Cd exposure. In brief, these results can be interpreted such that *E. nuttallii* responded to the treatments by a change in energy metabolism caused by the inhibition of photosynthesis, and an adaptation of homeostasis networks to control accumulation of Hg. We identified transcripts regulated in a dose-dependent manner in response to Hg and Cd. By applying these criteria, we found a total number of 212 differentially expressed genes in response to Cd, and 170 genes in response to Hg. We further performed a global expression analysis using the Nanostring nCounter for this subset of genes to evaluate whether gene expression observed in metal-specific treatments was able to predict metal exposure in a complex environment. We found two main clusters: samples exposed to high ( $\mu\text{g/L}$  range) and low ( $\text{ng/L}$  range) metal concentrations, suggesting that more genes would be needed to discriminate between the different metals. Samples exposed in the field and to natural contaminated sediments clustered well with samples exposed to low metal concentrations under laboratory conditions. Plants exposed to darkness, cold or salinity also showed a response, although different from the metal exposed samples. Genes identified in the laboratory after exposure to high concentrations were successfully used as biomarkers of Hg exposure in the field in a complex environment and resulted more sensitive than other endpoints. Data suggest that a genomic approach could be used to develop water and sediment quality tests with unsequenced organisms and confirmed the interest of rooted macrophytes for this aim.

**144 Whole genome data and its potential use in the omics-based researches of the self-fertilizing fish, *Kryptolebias marmoratus*** J. Lee, Hanyang University / Dept of Chemistry, Hanyang University Graduate School / Dept of Chemistry; J. Rhee, Hanyang University. Genome resources of certain organisms may offer several advantages for a better understanding of diverse areas of biological patterns and functioning. The omics platform makes useful approaches possible for the study of organs and entire organisms. These approaches can be applied as powerful screening tools for whole genome, proteome, and metabolome profiling, and can also be utilized to understand molecular changes in response to internal and/or

external stimuli. This methodology has been already successfully applied to the model fish species such as zebrafish and medaka in diverse research areas such as basic physiology, developmental biology, genetics, and environmental biology. To develop *K. marmoratus* as another model species that has unique characters and research merits, we obtained the whole genome data from *K. marmoratus*, and address here how we can use such data to obtain genome resource-based molecular mechanistic findings. Here, we review the current developmental status of genome information of *K. marmoratus* to provide a start line for omics approaches. We evaluate the potentials and applications of integrated-omics platforms for future studies, particularly in environmental science, developmental biology, and cancer science. We conclude that *K. marmoratus* whole genome information will allow us to better understand molecular functions of genes, proteins, and metabolites that are involved in diverse biological functions in this species. Each omics platform and particularly combined technologies making effective use of bioinformatics will provide a powerful tool for hypothesis-driven investigations and discovery-driven discussions on diverse aspects of this species and probably of fish and vertebrates in general.

**145 A Mesoscale Total Dissolved Solids Quantity and Quality Study Integrating Responses of Multiple Biological Components in Small Stream Communities** C. Nietch, U.S. EPA, Office of Research and Development, National Risk Management Laboratory / Water Supply Water Resources Division, U.S. Environmental Protection Agency / Water Supply Water Resources Division, U.S. EPA / Water Supply Water Resources Div; J. Lazorchak, United States Environmental Protection Agency / Ecological Exposure Research Division; B. Johnson, U.S. EPA / Ecosystems Research Branch; D. Brown, U.S. EPA / Water Supply and Water Resources Division; B. Ramakrishnan, Shaw Environmental Inc. / EPA Experimental Stream Facility; H. Rogers, Student Services Contractor; P. Weaver, The McConnell Group, c/o U.S. EPA; S. Decelles, The McConnell Group c/o U.S. EPA; D. Macke, US EPA / ORD; K. Daniels, US EPA / Water Supply and Water Resources Div; J. Allen, U.S. EPA / Office of Research and Development, U.S. EPA / ORD; K. Patnode, USFWS / Pennsylvania Field Office. A 42-day dosing test with ions comprising an excess TDS was run using mesocosms colonized with natural stream water fed continuously. In gridded gravel beds biota from microbes through macroinvertebrates are measured and interact in a manner realistic of stream riffle/run ecology. Single species assays were run in-parallel using the equivalent mesocosm matrices. Although the species assemblage and background water chemistries of the mesocosms may not translate to certain field locations, the intent was to study the potential change in the ecologies of community interactions. Paired with the single-species assays the approach provides community context to standard toxicological tests. The excess TDS was comprised of  $\text{Cl}^-$ ,  $\text{Na}^+$ , and  $\text{Ca}^{2+}$ , which are the primary ions making-up produced waters of Central Appalachian shale brines. The realized TDS concentrations were 247, 370, 590, 742, 1288, 2066, 3615, and 6963 ( $\text{mg/L}$ ). Targets were based on mixing-models from fifty Pennsylvania oil and gas wastewater permits and estimated low flows of their receiving streams. An increasing trend in periphytic algal biomass happened across doses higher than 590  $\text{mg/L}$ . Visible differences in algal community structure occurred after 742  $\text{mg/L}$  including a shift to a high percentage of red alga (*Compsopogon*) coverage, increased density of long-chain diatom filaments, and a decrease in cyanobacteria colonies. These changes coincided with community changes that were significant after the 1288  $\text{mg/L}$  dose for macroinvertebrates colonizing the mesocosms. Chironomids and Elmidae were the primary larval insects. They responded oppositely to the excess TDS with a respective increase and decrease in doses higher than 2066  $\text{mg/L}$ . EPT taxa (only 3% of individuals) generally decreased with increasing TDS. Polycentropid caddisfly nets were absent in the two highest doses. Worms and crustaceans exhibited negative dose-responses, while snails appeared unaffected. Interpreting the single-species exposures were more straightforward. They suggested significant (LC50) lethality near the 2066  $\text{mg/L}$  TDS dose for two species of mussels and daphnids, while a mayfly exhibited higher sensitivity. All endpoints considered, the data suggested that a chronic dose of greater than 590  $\text{mg/L}$  could start to alter the producers in streams, while varied responses in the consumers have significant community-wide consequence at exposures greater than 1288  $\text{mg/L}$  and when the TDS is dominated by  $\text{Cl}^-$ ,  $\text{Na}^+$ , and  $\text{Ca}^{2+}$  ions.

**146 An Overview on EPA's Research on Potential Impacts from Hydraulic Fracturing on Drinking Water Resources** C.A. Impellitteri, US EPA / Water Supply and Water Resources Division, US EPA / Environmental

Engineer; J. Briskin, U.S. EPA OAA / OSP. The United States Environmental Protection agency has undertaken research to examine the potential effects of hydraulic fracturing (HF) on drinking water resources. The research encompasses the total water cycle as it is used in hydraulic fracturing; from water procurement for HF operations to water treatment and disposal. The research will also provide information on potential impacts from HF operations on groundwater and surface water sources. This presentation will provide a basic overview on water issues related to hydraulic fracturing in the United States. The presentation will also summarize EPA's research plan and an update of progress on efforts such as: field case studies, water consumption, water quality monitoring and water/wastewater treatment research. A summary of the current cross-agency plans for future environmental HF research will also be presented.

**147 Aquatic macroinvertebrate communities across a gradient of natural gas activity in streams** S. Entekin, University of Central Arkansas / Biology; N. Jensen, A. Musto, J. Kelso, University of Central Arkansas; B. Austin, M. Evans-White, University of Arkansas; C. Gallipeau, The Nature Conservancy; B. Haggard, University of Arkansas; E. Inlander, The Nature Conservancy; L. Massey, University of Arkansas. Advances in drilling and extraction of natural gas have resulted in rapid expansion of wells and associated infrastructure in shale basins across the US. Rate of gas well installation in the Fayetteville Shale of north-central Arkansas has been 774 wells per year since 2005 with more planned. Rapid and concentrated activity and wells placed close to streams increases potential for negative effects to aquatic biological communities. We quantified a suite of water quality metrics at storm and base flow including trace element concentrations, conductivity, and suspended sediments from autumn 2009 to autumn 2011. Macroinvertebrates were quantified across the same study sites in spring 2010 and spring 2011. We predicted higher concentrations of suspended sediment, conductivity, and trace elements in catchments with more gas well activity and a concurrent decline in macroinvertebrate density, diversity, and some species traits. Pearson correlations were used to explore relationships among gas activity, sediment and trace elements, and macroinvertebrates across the gradient of gas activity represented by the study sites. Turbidity during storms was positively related to gas well activity during six of seven storms, organic sediment was positively related to gas activity in two of seven storms, and inorganic sediment was positively related to gas activity in four of seven storms. In 2010, macroinvertebrate density was positively related to gas activity ( $r=0.85$ ,  $p=0.002$ ) and diversity was negatively related to suspended inorganic sediment concentration ( $r=-0.98$ ,  $p<0.001$ ). In 2011, most trace elements (e.g., Al, Pb, Ni) and conductivity were positively related to gas well densities ( $r>0.6$ ,  $p<0.05$ ). Multivoltine macroinvertebrate taxa were positively related to inorganic sediment concentrations ( $p=0.007$ ,  $r=0.71$ ) and diversity declined with fine organic matter ( $p=0.02$ ,  $r=-0.68$ ). Few community-level metrics were related to trace element concentrations, although two mayfly taxa (*Caenis* and *Baetis*) tolerant to sedimentation were strongly positively related to gas well density and an increase in nickel and lead concentrations ( $p<0.05$ ,  $r>0.7$ ).

**148 Impact of natural gas wells on periphyton and metabolism in streams in north central Arkansas** B. Austin, University of Arkansas Fayetteville / Department of Biological Sciences; K. Brick, University of Arkansas Fayetteville; M. Evans-White, University of Arkansas Fayetteville / Department of Biological Sciences; S. Entekin, University of Central Arkansas / Biology; E. Inlander, C. Gallipeau, The Nature Conservancy. Recovery of natural gas has increased significantly in recent years. Construction of natural gas wells (NGWs) increases the potential for sediment erosion into streams, which could negatively influence periphyton communities. The goal of this study was to determine if increasing NGWs within catchments negatively impact stream periphyton biomass and metabolism. Ten streams with varying catchment densities of NGWs (0-3.2 wells/km<sup>2</sup>) were sampled during winter and spring of 2010 and 2011 to examine the effects of NGWs on periphyton and metabolism. Two cobbles from three riffles and three pools were collected within each stream to quantify periphyton biomass in the form of chlorophyll *a* (chl *a*) and ash-free dry mass (AFDM). Whole stream metabolism was estimated from diel curves of dissolved oxygen at a single station, within each stream over a three day period. In addition, dissolved nutrients, turbidity, and light transmittance were measured across sites and land use variables were quantified for each catchment using ArcMap. We used multiple linear regressions to examine effects of NGWs, well density, land use, and water quality on periphyton

and metabolism response variables. Chlorophyll *a* was positively related to the number of wells in a catchment during both winter sampling events (2010  $r^2=0.79$ ,  $p<0.01$ ; 2011  $r^2=0.57$ ,  $p=0.01$ ). Gross primary production (GPP) was positively related to well density during spring 2010 and winter 2011 sample periods ( $r^2=0.46$ ,  $p=0.05$ ;  $r^2=0.83$ ,  $p=0.01$  respectively). Nutrients and light transmittance were not positively related to chlorophyll *a* or GPP. Therefore, NGW effects on additional environmental factors, such as on densities or biomass of grazing macroinvertebrates, might explain the positive effect of NGWs on stream periphyton and GPP. Our findings suggest that increases in primary production may result from NGW development in catchments. Periphyton and primary production metrics may be useful indicators of NGW impacts on streams.

**149 Marine shales are a source of selenium to aquatic and terrestrial food webs in a watershed being developed for energy** T.S. Schmidt, US Geological Survey / Water Resources Div, USGS / Water Resources Div; R.E. Wolf, U.S. Geological Survey; C.A. Stricker, C.R. Bern, M.L. Clark, J.M. Holloway, R.R. McDougal, USGS. Some energy development in Muddy Creek, WY, occurs on marine shales. These shales are natural sources of selenium (Se) that, when disturbed, can mobilize Se into streams. We assessed Se dynamics in soil, sediment, water, and aquatic (damselfly larvae) and riparian (spiders and adult damselflies) food webs at 9 sites to develop baselines and assess risks to wildlife prior to expansion of oil and gas development. Different shale formations contribute varied Se concentrations to stream sediment and water. Sediments control the concentration of Se in dissolved and particulate phases and partitioning of Se from dissolved to particulate phases was exceptional ( $k_d = 3000$ ). Sediment controls on Se bio-availability to the aquatic and terrestrial food web were observed via strong negative relations between Se concentrations in damselfly (Lestidae and Coenagrionidae,  $r^2=0.87$ ) larvae and spiders (*Tegrynatha*,  $r^2=0.68$ ). Adult damselfly Se concentrations showed no trend with Se in larvae, soil, water, or sediment. Se concentrations in emergent aquatic insects were higher than those in terrestrial arthropods suggesting that spider exposure to Se was via aquatic prey. Ecosystem-scale modeling of Se exposure demonstrated substantial risks to aquatic and terrestrial wildlife via aquatic sources and potentially even greater risks to birds if emergent aquatic insects and spiders were considered as prey items. We conclude damselfly larvae and riparian spiders are good indicators of aquatic and terrestrial exposure, respectively, to Se derived from marine shales and that risks to terrestrial wildlife might be underestimated if pathways of exposure that link aquatic and terrestrial food webs are not considered.

**150 Relationship Between Mountaintop Mining Activities and Macroinvertebrate Communities in Streams in Southwestern West Virginia** S.P. Canton, GEI Consultants, Inc. / Ecological Division; N. Burbank, G. DeJong, J. Lynch, GEI Consultants, Inc.. Recently, the relationship between mountaintop removal coal mining/valley fill (CM/VF) activities and macroinvertebrate communities in Appalachian streams has been considered. CM/VF is thought to elevate concentrations and levels of certain stressors, including sulfate and conductivity, which is in turn thought to negatively affect macroinvertebrate communities in streams that drain CM/VF operations. The purpose of this study was to evaluate the ecological impacts of CM/VF activities on macroinvertebrate communities in streams draining valley fills. We sampled the benthic macroinvertebrate populations at multiple sites in 12 streams in southwestern West Virginia, including 9 streams that drain valley fills and 3 reference streams with no upstream mining. We analyzed the relationship between certain macroinvertebrate community metrics, including number of taxa; number of Ephemeroptera, Plecoptera, and Trichoptera taxa; percent Ephemeroptera individuals; and West Virginia Stream Condition Index (WVSCI) score, and measures of watershed disturbance, such as mining influence (e.g., percent of upstream area mined), conductivity, and sulfate concentrations. We found that the macroinvertebrate community metrics generally indicated less ideal conditions with increasing amounts of mining, conductivity, and sulfate, but these trends were not always strong or statistically significant. Previous analyses of these data indicated that a combination of ionic chemistry, soil characteristics, substrate characteristics, and channel features related to erosion were influential in determining the structure of macroinvertebrate communities. Given the results of the current and prior studies, the effect of CM/VF activities on macroinvertebrate communities appears to be related to a complex combination of multiple factors that may be related to watershed disturbance, changes in water chemistry, and variation in habitat quality.

**151 The Dangers of “Proofiness” in the Evaluation of Mountaintop Removal Coal Mining Impacts** C. Stahl, U.S. EPA Region III, U.S. Environmental Protection Agency, Region III / Environmental Assessment and Innovation Division, U.S. EPA Region III / Environmental Assessment and Innovation Division, U.S. EPA Region III / Air Protection Division; A. Cimorelli, U.S. Environmental Protection Agency, Region III; J. Babendreier, U.S. Environmental Protection Agency / Office of Research and Development; J. Kremer, U.S. Environmental Protection Agency, Region III / Environmental Assessment and Innovation Division. Assessment of ecological and human health impacts from coal mining in West Virginia presents challenges for agencies responsible for permitting and evaluating those impacts. These challenges include correctly identifying, locating and diagnosing stressor sources and understanding the resulting impacts when observations are presented only in the integrated ecosystem. This presentation discusses the need for caution when determining the appropriateness of data and scientific tools particularly when making controversial environmental assessments. Some commonly used existing techniques and approaches evaluating the environmental and public health impacts of anthropogenic activities such as mountaintop removal coal mining will be discussed, such as the use of land cover data, regression models, sampling, monitoring and census data, and decision support tools. “Proofiness” (paraphrased from Seife’s book of the same name) is the use or misuse of mathematical arguments to arrive at misleading conclusions. Environmental assessments typically use many kinds of data and scientific tools, where the need for caution introduces uncertainty. Furthermore, combining information in these environmental assessments uses values, which introduces additional uncertainty. This presentation also discusses the need for better understanding of the role of uncertainty and values, which can be improved through the use of uncertainty analyses and decision analytic techniques. Scientists have always warned and been warned about the appropriate selection and application of techniques such as statistics and models. Scientists drawn into the high level of controversy and community urgency can fail to adequately articulate the caveats and constraints of these kinds of assessments. Therefore, additional vigilance is required when performing impact assessments, particularly when there are controversial activities being evaluated. Disclaimer: Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

**152 Potential Risks to Ecological Receptors Posed by Hydraulic Fracking** S. Jones, Conestoga-Rovers & Associates / Ecologist. As the practice of hydraulic fracking becomes a more widely used method for extracting natural gas from underground sources, the concerns for risk to human health and the environment are likewise increasing. To date, the vast majority of the attention from environmental and conservation groups and regulators has been directed at risk to human health due to introduction of known carcinogens into groundwater systems. Conversely, relatively little attention has been directed at potential risks to ecological receptors. Although ecological receptors are not generally not directly exposed to groundwater, exposure to chemicals and abiotic media in fracking fluids may ultimately occur through the migration and transport to streams, lakes, and wetlands. In this presentation, the framework for ecological risk assessment will be used to objectively assess the potential to risk to aquatic, semi aquatic, and terrestrial receptors posed by fracking. The assessment will identify the types of chemicals and media typically used in fracking, the mechanisms of fate and transport of fracking chemicals in groundwater, migration pathways, exposure routes, exposure points. The mechanisms of ecotoxicity and availability of ecological benchmarks for fracking chemicals will also be addressed.

**153 You Intentionally Put Pesticides in Water? The Role, Fate and Risk of Aquatic Herbicide Use** M. Blankinship, Blankinship & Associates, Inc. Currently, there are 10 herbicides registered for use in California to control aquatic vegetation. These herbicides are intentionally applied to water to control submersed, emergent, and floating weeds and algae in ponds, lakes, irrigation canals, drinking water reservoirs and flood control channels. An overview of the role, fate and human and ecological risk that the use of these herbicides pose will be presented.

**154 Occurrence of glyphosate and acidic herbicides in select urban rivers and streams in Canada, 2007** N.E. Glozier, J. Struger, Environment Canada; A. Cessna, Agriculture and Agri-Food Canada; M. Gledhill,

M. Rondeau, W. Ernst, M. Sekela, S. Cagampan, E. Sverko, C. Murphy, J. Murray, D.B. Donald, Environment Canada. Public and scientific concern has grown over the last decade in Canada over the cosmetic use of pesticides in urban centres. With this in mind a national survey was designed to monitor eight commonly used herbicides in urban rivers and streams across Canada. Samples were collected monthly on one of two pre-determined dates from April to September, 2007 from 19 sites within 16 watersheds, including 15 sites downstream of urban lands and 4 non urban sites. Additional samples were also collected approximately three times from each watershed after precipitation events. The herbicides 2,4-D, mecoprop, dicamba, glyphosate and its major metabolite AMPA were most frequently detected. Using either herbicide concentrations upstream/downstream of urban centres or bromoxynil and clopyralid as indicators of agricultural inputs of herbicides to streams, it was clear that environmental concentrations of these herbicides downstream of urban areas were linked to urban pesticide use in Canada. Herbicide concentrations were greater during or after significant rainfall events, however, none of the herbicide concentrations measured in these samples exceeded existing Canadian Water Quality Guidelines for the protection of aquatic life. This is the first time a national survey of pesticides in urban rivers has been carried out in a consistent fashion across Canada. Concentrations of 2,4-D, mecoprop, dicamba, glyphosate and AMPA were linked to urban use and frequently detected in all geographic areas. Geographical differences in concentration suggested differences in herbicide usage or stream connectivity rather than overall indicators of urban land use. Some jurisdictions in Canada have recently restricted cosmetic use of pesticides and future studies should be able to determine whether such restrictions will lead to reduced pesticide concentrations in these surface waters.

**155 Wash-off potential of a urban use herbicide from concrete surfaces: potential contributor to urban pesticide contamination** J.H. Myers,

University of Melbourne / CAPIM; V.J. Pettigrove, The University of Melbourne / CAPIM; G. Rose, P. Zhang, A. Bui, Department of Primary Industries / Future Farming Systems Research Division. Monitoring studies are showing prevalent contamination of urban waterways with pesticides, and this contamination is being linked with urban use. The finding of almost ubiquitous contamination of urban systems by herbicides in areas such as Melbourne, Australia, is of particular concern due to the acute toxicity related to these chemicals. Recent surveys by CAPIM consistently reported triazine herbicides as dominant contaminants in Melbourne’s waterways (up to 4.45µg/L). In Australia, the triazine herbicides atrazine and simazine are the second most widely used herbicides (6000 tonnes annually), with over 4000 registered uses. Impervious surfaces, such as concrete in driveways and paths are considered sources of herbicide contamination in urban areas. While transport and fate of insecticides from hard surfaces has had attention, very little is known about herbicide transport from hard surfaces. To the best of the authors’ knowledge this is the first investigation of triazine herbicide transport from hard surfaces. In the present study a simple method was used to evaluate pesticide wash-off potential from concrete surfaces. Two types of commercially available pavers, smooth and rough aggregate, were treated with an off-the-shelf product containing simazine as the active ingredient. Treatment was according to label directions. The dependence of washable simazine residues in run-off was evaluated on time exposed to outdoor conditions prior to a wash event and repeated washing events. After application to the pavers, washable fractions of simazine rapidly decreased for both paver types. Wash-off potential was greatest 1hr after pesticide application, with simazine concentrations in run-off reduced by ½ that of 1hr concentrations after 2d. These concentrations remained stable for repeated washings up to 90d (continuing) and for exposure to outdoor conditions of 14d prior to a wash event. Smooth pavers showed a high concentration of simazine to be washed off during the first washing (1330µg/L), compared to that off rough aggregate (835µg/L). As time exposed to outdoor conditions prior to washing increased, or with repeated washings, simazine concentrations in run-off were higher for rough aggregate pavers (average 485µg/L compared to 420µg/L). Results from this study indicate that simazine residues remain on concrete and are available for contaminating runoff for months after application.

**156 Importance of loose particles in pesticide runoff from urban concrete surfaces** J. Gan, University of California Riverside; W. Jiang, California Environmental Protection Agency / Department of Environmental Sciences, University of California, Riverside / graduate student, University

of California, Riverside / Environmental Sciences. Hardscape surfaces such as concrete are an important component of urban environments, including residential areas. Insecticides used for structural and landscape pest control, including pyrethroids and fipronil, may be applied directly onto these surfaces, or deposited indirectly via application drift, and water or wind-aided transport. Runoff of pesticide residues from urban hardscapes has been often suspected as the main route by which pesticides enter urban waterways. However, the mechanisms underlying such off-site movement are not well understood. We have carried out several studies and established that loose particles, including soil particles and likely small fragments from cement disintegration, are the main carrier of pesticides in urban surface runoff. Most of the pyrethroids in runoff water from concrete surfaces receiving treatment of various formulations were associated with particles  $> 0.7 \mu\text{m}$ . In addition, dust samples collected randomly from a total of 40 single homes showed the constant presence of a wide range of insecticides and their metabolites on driveways, sidewalks and streets. The levels of pesticides appearing in runoff water and the residues found on sponge swipes were closely correlated, further validating the role of loose particles while simultaneously providing an easy prediction tool. Our findings suggest that to minimize pesticide contamination of urban surface waters, a key is to control offsite movement of loose particles on hardscapes.

**157 Impervious Surfaces as a Potential Source of Biologically Active Pesticide Degradates in Urban Runoff** W. Jiang, California Environmental Protection Agency / Department of Environmental Sciences, University of California, Riverside / graduate student, University of California, Riverside / Environmental Sciences; J. Gan, University of California Riverside. Impervious surfaces such as concrete are identified as an important source of pesticide contamination in urban runoff. However, the occurrence of their degradation intermediates in runoff water has not been studied, especially for the contaminated surfaces after extended environmental exposure. We studied the degradation of two commonly used insecticides, permethrin and fipronil, on concrete and assessed the potential of their biologically active degradates to contaminate surface runoff water. Permethrin degradate 3-phenoxybenzoic acid (3-PBA) and three fipronil degradates (i.e. desulfinyl, sulfide and sulfone) appeared in the runoff water 1 d after pesticide treatment, and they were consistently found in subsequent runoff within 3 months of summer conditions. 3-PBA concentrations were consistently above  $100 \mu\text{g/L}$ , and the runoff half-lives of fipronil degradates were 1.3-2.2 times of parent fipronil. 3-PBA is a common degradate of several pyrethroids and has endocrine disruption activity. The three fipronil degradates have longer environmental persistence than fipronil, and have comparable or greater acute toxicities to arthropods. After 20 d, the concentrations of 3-PBA and total fipronil degradates became higher than their respective parent compounds, indicating the importance to include them in monitoring studies and regulations for urban water protection. Over 70 % of fipronil degradates and 3-PBA were found in the dissolved phase of runoff water, indicating their potential for long-distance transport and bioavailability.

**158 Important Pathways and Effect of Application Practices on Residential Runoff of Pyrethroids** R.L. Jones, Bayer CropScience; P.C. Davidson, C.M. Harbourt, Waterborne Environmental, Inc.; P. Hendley, Syngenta Crop Protection, LLC. Runoff studies to determine the major pathways for transport of pyrethroids applied to suburban residences were conducted at a full scale test facility in central California. Six replicate house lots were typical of front lawns and house fronts of California residential developments and consisted of stucco walls, garage doors, driveways, and residential lawn irrigation sprinkler systems. Each of the six lots also included a rainfall simulator to generate artificial rainfall events. Different pyrethroids were applied to five surfaces—driveway, garage door and adjacent walls, lawn, lawn perimeter (grass near the house walls), and house walls. The volume of runoff water from each house lot was measured, sampled, and analyzed to determine the amount of mass lost from each surface. Applications to three of the house lots were made using the application practices typically used prior to recent label changes, while applications were made to the other three house lots according to the revised application procedures. Results from the house lots using the historic application procedures showed that losses of the compounds applied to the driveway and garage door (including the adjacent walls) were more than 99.5 percent of total runoff losses. The highest losses were associated with significant rainfall events rather than lawn irrigation events. However, runoff losses were 50 times less using the revised application procedures recently specified on pyrethroid labels.

**159 Development and Validation of an Approach for Modeling Pyrethroid Residues in Urban Streams** M.F. Winchell, Stone Environmental, Inc. / Senior GIS Specialist, Stone Environmental, Inc. / Senior Environmental Modeler / GIS Specialist; S.H. Jackson, BASF Corporation; B.N. Toth, J.P. Hanzas, Stone Environmental, Inc.; G.C. Mitchell, FMC Corporation. Pyrethroid insecticides have been detected in urban waterways throughout California and other regions. Modeling pyrethroid environmental fate in a residential setting can help us to better understand the sources, transport pathways, and mitigation strategies for reducing environmental concentrations of pyrethroids. Currently, there is not a standard modeling approach for estimating environmental concentrations of pesticides in an urban environment, either as part of a tiered risk assessment or for development of mitigation strategies. One modeling approach is to adapt an urban water quality model, the Storm Water Management Model (SWMM) to serve this purpose. To test the suitability of SWMM in predicting urban pesticide exposure, the model was applied to a heavily developed residential neighborhood in southern California. This neighborhood was modeled because of the data available from monitoring of pyrethroids conducted there over a several year period. One of the primary inputs to the model, the wash-off characteristics of the pyrethroid, were calibrated to observed plot-scale data for both impervious and pervious turf surfaces. A statewide survey regarding the spatial and temporal patterns of pyrethroid applications was used in structuring the SWMM model to allow realistic application variability throughout the neighborhood. Because of their direct effects on "dry weather" wash-off and storm drain residues, residential outdoor water use practices represented another important component to the model structure and parameterization. The hydrologic component of the model was calibrated to 1 years' worth of hourly flow data measured from a storm drain outfall draining the neighborhood. Pyrethroid samples from both storm and non-storm periods were used to adjust the pesticide components of the model, including application patterns and wash-off characteristics. This presentation will report on the model development, calibration results, and the potential for utilizing this modeling approach as part of a standardized risk assessment process and as a tool for evaluating the potential benefits of best management practices.

**160 Outcomes from Studies on the Transport, Fate and Ecotoxicology of Pyrethroids in Urban Settings** P. Hendley, Syngenta Crop Protection, LLC.; R.L. Jones, Bayer CropScience; M.G. Dobbs, Bayer Crop Science, Bayer CropScience / Ecotoxicology Group; A.C. Barefoot, Du Pont Crop Protection / Crop Protection Products; D. Tessier, E.I. Du Pont De Nemours And Co., Inc.; G. Mitchell, FMC Corporation; S. Jackson, BASF Corporation / Principal Scientist; N. Assaf, Valent BioSciences corporation; J. Hemiller, Amvac Chemical Corporation; K.S. Henry, Syngenta Crop Protection, Inc. / Ecological Sciences. Over the last few years, there has been considerable interest in the occurrence and potential impacts of pyrethroid insecticide residues in sediment and water samples from urban streams. In California, the Department of Pesticide Regulations (DPR) instituted a data re-evaluation on pyrethroids to help refine risk assessments and identify the sources of residues occurring in urban streams and, where necessary, potential mitigation alternatives. Since 2006, the Pyrethroid Working Group (PWG) has been developing data to address DPR's requirements in addition to conducting a wide range of related studies to improve understanding of the science underlying the transport, occurrence and potential impact of pyrethroids arising from residential uses. Laboratory-based PWG studies have included an investigation of sediment fate, acute ecotoxicology studies on *Hyalella azteca* and *Chironomus tentans* as well as continuing improvements in analytical methods. Indoor studies have examined the potential for commercial pyrethroid products to washoff from various building surfaces. Work has also been conducted in model systems and via monitoring to understand how pyrethroids behave in wastewater treatment plants. At the "real world" scale, PWG has conducted multi-year sediment monitoring and deposition area mapping programs in several urban stream systems with complementary bioassessment studies to provide ecological context. Additional water column and sediment sampling is under way in the American River. Finally, a field site has been established for conducting replicated studies to identify those transport pathways which contribute most significantly to residential pyrethroid transport (e.g. driveway treatments). Importantly, this replicated study has demonstrated how recent label changes clarifying precisely how pyrethroids may be applied to hard surfaces around homes will result in extensive reduction in off-site transport during storms. A conceptual model of pyrethroid occurrence and transport

has been developed and refined and will be the focus for explaining how these integrated PWG programs have refined our knowledge and helped to demonstrate the efficacy of some mitigation options. This paper will provide an overview of how these studies have increased understanding of pyrethroid occurrence and behavior in urban settings and have helped identify improved ways of continuing to achieve successful insect control while greatly reducing off-target transport.

**161 Anticoagulant rodenticides are pervasive contaminants of terrestrial birds of prey** J. Elliott, Environment Canada / Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada / Pacific Wildlife Research Centre, Environment Canada / Wildlife Toxicology, Environment Canada / Canadian Wildlife Service; S. Hindmarch, Environment Canada / Science and Technology; L. Wilson, Environment Canada / Canadian Wildlife Service; F. Maisonneuve, Environment Canada. Previous studies, including our own, have reported a high incidence of liver residues of commonly used second generation anticoagulant rodenticide (SGAR) compounds, in raptors, especially rodent-eating hawk and owl species. A proportion of birds tested commonly exhibit symptoms of anti-coagulant poisoning. In the present study we widened the scope of sampling to include other hawk and falcon species. Of 130 raptors analyzed using high resolution GC/MS/MS from a recent survey of birds collected over the period 2005 to 2011 from southwestern British Columbia, 94% had detectable liver residues of at least one SGAR compound. Barred and Great Horned Owls had the highest incidence of exposure and the greatest residue concentrations; however, 5 of 5 Peregrine Falcons and 5 of 5 Sharp-shinned hawks tested had residues of at least two SGAR compounds, indicating pervasive contamination of the food chains of terrestrial birds of prey. The process by which smaller avian prey of falcons and accipiter hawks are contaminated is not known. Both temporal trends and spatial patterns of SGAR contamination in relation to the degree of urbanization or intensive agricultural activity will be tested quantitatively. We will also extend a previous analysis of the relationships between liver residues of SGARs and diagnosis of anticoagulant poisoning.

**162 Anticoagulant Rodenticide Exposure and Toxicosis in Free-living Birds of Prey Presented to a Wildlife Clinic in Massachusetts, USA, 2006-2010** M. Murray, Tufts Cummings School of Veterinary Medicine / Wildlife Clinic. Mortality among birds of prey from anticoagulant rodenticide (AR) toxicosis has been documented in the United States; however, there is little information on the extent of exposure among specific populations of raptors. Moreover, information on the significance of sublethal AR tissue residues and an understanding of how tissue residues relate to toxicosis are lacking, particularly in wild birds exposed to ARs via their natural prey. The study presented here, conducted at the Tufts Cummings School of Veterinary Medicine Wildlife Clinic in Massachusetts, USA, had multiple aims: to document the proportion of four species of free-living birds of prey (red-tailed hawks [*Buteo jamaicensis*], barred owls [*Strix varia*], eastern screech owls [*Megascops asio*], and great horned owls [*Bubo virginianus*]) admitted to the clinic that died or were euthanized due to the severity of their presenting injuries that had AR residues in liver tissue; to identify and quantify ARs present; to evaluate potential sublethal effects of ARs; to describe ante- and post-mortem signs of toxicosis; and to associate liver AR levels with toxicosis. Of 161 birds tested, 86% were positive for liver AR residues. The second-generation AR brodifacoum was identified in 99% of positive birds. Mortality from AR toxicosis was diagnosed in 6% of birds. No sublethal effects of ARs were detected. No apparent association was found between liver AR level and signs of toxicosis, indicating that individual sensitivity to ARs may vary greatly. The results of this study demonstrate the pervasiveness of ARs, particularly brodifacoum, in the prey of the sampled population during the study period. In addition, the data presented here incorporate ante-mortem signs, post-mortem findings, and AR residue levels to present a more complete picture of the significance of liver residue levels in raptors acquired via a natural route of exposure.

**163 Effects of Anticoagulants on Non-Target Species: Risk Assessments using PBPK Modeling** K. Horak, USDA NWRC; B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / USGS, USGS-Patuxent Wildlife Research Center / Beltsville Laboratory, USGS-Patuxent Wildlife Research Ctr / Beltsville Laboratory; S. Volker, USDA NWRC; J. Johnston, USDA FSIS. Rodents cause significant damage to agricultural crops throughout the world and, when accidentally introduced, these invasive species are a serious threat

in many ecosystems. Anticoagulant rodenticides have long been used to control rodent populations. Although quite efficacious at reducing rodent population size, anticoagulants can pose a risk to non-target wildlife which may be exposed through the consumption of rodents that have ingested anticoagulant bait. In order to generate reliable risk assessments for non-target wildlife, concentrations and half-life values of anticoagulants in target rodents must be accurately estimated. Moreover, a clear relationship between exposure and adverse health outcomes in non-target wildlife must be determined. In a series of studies, several exposure scenarios in wistar rats (*Rattus norvegicus*), bobwhite quail (*Colinus virginianus*), kestrels (*Falco sparverius*) and eastern screech owls (*Megascops asio*) were used to establish time-dependent distributions of the anticoagulant diphacinone in numerous tissues. These data were then used to create physiologically-based pharmacokinetic (PBPK) models for diphacinone in both target mammals and non-target avian species. Through use of these validated models, many of the factors affecting the potential exposure of non-target wildlife to anticoagulant rodenticides can be investigated. Data will be presented illustrating the use of model-generated estimates of tissue anticoagulant concentrations to predict the exposure and risks to non-target species associated with different rodent control strategies.

**164 Monitoring Anticoagulant exposure and toxicity in red foxes with fecal samples** P. Berny, Vetagro-sup, campus vétérinaire / Toxicology; M. Sage, Université de Franche-Comté / Laboratoire Chrono-environnement; I. Fourel, Vetagro-sup, campus vétérinaire / Toxicology; M. Coeurdassier, P. Giraudoux, Université de Franche-Comté / Laboratoire Chrono-environnement. In many countries, the red fox (*Vulpes vulpes*) is particularly affected by secondary poisoning with anticoagulants after field control operations against water voles (*Arvicola terrestris*). There is, however, no specific method available to monitor AVK exposure in the field over large areas and no toxicological data are available concerning sensitivity of foxes to bromadiolone. The aim of this work was to compare excretion kinetics of bromadiolone in fox faeces with clinical and haemostatic effects after repeated exposure to poisoned voles. A sensitive method for the quantification of bromadiolone in fox faeces and plasma was developed, using liquid chromatography combined with mass spectrometry (LC-ESI-MS). The LOD was 0.9 µg/kg and 0.15 µg/L, and the LOQ was 3.0 µg/kg and 0.5 µg/L, in faeces and in plasma, respectively. Captive foxes were fed for 2 or 5 days with water voles spiked with bromadiolone at concentrations close to those measured in the field. Faeces and blood were collected for bromadiolone determination, and blood-clotting tests were performed. After euthanasia (D28), a complete necropsy was performed, and liver samples were analyzed for bromadiolone. Residues were detected in faeces 15 hours after the first exposure. They increased dramatically during the exposure period and then gradually decreased, but remained detectable for at least 26 days after the last exposure. Bromadiolone residues in plasma showed a similar pattern but were no longer detectable 7 to 24 days after the last exposure. Two foxes presented very severe external haemorrhages, requiring the administration of the antidote vitamin-K1. Persistence of AVK residues was also monitored in fecal samples and found to decrease slowly (half-life > 1 month). Bromadiolone residues in faeces and their relationships with exposure and other markers will be discussed. These findings provide a basis for programs aiming to monitor the exposure of wild fox populations to bromadiolone (or potentially other second generation AVK) using non-invasive methods based on standard sampling and analysis of residues in faeces.

**165 Rodenticide Residues in the Environment following a Rodent Eradication Operation on Palmyra Atoll** W. Pitt, USDA APHIS Wildlife Services National Wildlife Research Center / Hawaii Field Station; A. Berentsen, J. Eisemann, S. Volker, USDA APHIS Wildlife Services National Wildlife Research Center; G. Howald, A. Wegmann, Island Conservation. We monitored an application of Brodifacoum 25W Conservation in an attempt to eradicate rats from Palmyra Atoll. Brodifacoum 25W Conservation was aerially broadcast twice over the entire atoll, with target application rates of 80 kg/ha and 75 kg/ha, respectively. These application rates were more than 4 and 8 times, respectively, the application rates typically allowed by EPA under this label. In addition, a supplemental hand broadcast application occurred over a 10 ha area in the on Cooper Island (at a rate of 71.6 kg/ha) in response to a live rat capture. We monitored bait fate, treatment efficacy, and residues in the environment. We systematically checked rodenticide residue levels in hermit crabs, fiddler crabs, geckos, ants, cockroaches, fish, sea water, fresh water, and soil prior to and several

periods up to 30 days after the application of bait. We also opportunistically collected all dead animals found on the atoll and tested them for rodenticide residues. Bait was spread throughout the terrestrial areas of the atoll at the target application rate, but significant quantities of bait also entered the marine environment at distances at least as far as 7m from the shore. We collected 81 potential non-target samples representing 14 species of birds, fish, reptiles and invertebrates for residue analysis. We were able to document the movement of brodifacoum through the environment in primary, secondary and perhaps even tertiary exposure pathways. Levels of brodifacoum were detected in nearly every environmental compartment analyzed. However, given the magnitude of the application we are not surprised by these levels. Our data suggest that even in a short one-month period, brodifacoum residues had begun declining in some biological samples.

**166 Island restoration and the anticoagulant rodenticides: An unholy alliance?** G. Howald, Island Conservation; C. Gill, Coastal Conservation. Islands occupy approximately three percent of the earth's surface but provide key habitat for 15-20% of all plant, reptile and bird species. Approximately 50% of confirmed extinctions have been island species and most of these extinctions were the result of invasive species. One of the most significant are introduced rats, which are responsible for 40-60% of all bird and reptile extinctions. Rodents have been introduced onto 82% of the world's islands which not only negatively affect native plant and wildlife species, but also human health, economies and ecosystem services provided by intact systems. Fortunately for native species, introduced rodents can be removed from islands and ecosystems can recover. This conservation measure is now considered to be one of society's most powerful tools for preventing extinctions and restoring island ecosystems. Over 400 rodent eradication have been completed worldwide, most with the use of the second generation anticoagulant brodifacoum. Brodifacoum has high oral toxicity to rodents, often only requiring a single feeding to achieve mortality. However, it is also highly toxic to other mammals and birds, posing an unwanted hazard to non-target wildlife. Conservation practitioners must seek ways to avoid negatively impacting native biological resources whenever practical. However, with most invasive vertebrate eradications, the potential for eradication success must be balanced by risks to individual non-target wildlife. Although both sides of this balancing equation are important, the need to maximize the chances of eradication success is particularly acute and some non-target mortality (sub-population level impact) may prove unavoidable as long as these individual negative effects can be outweighed by the expected beneficial effects of rat eradication (e.g. recovery of native species and ecosystems). Conversely, a failed eradication attempt resulting from prioritizing a desire to avoid or minimize non-target impacts above all else will provide few conservation returns in the long term because surviving invasive rodents will reproduce at high rates and quickly reoccupy vacant territories throughout the island. Furthermore, a failed eradication attempt will still put individuals of non-target species at risk with no measurable improvements to the species of interest, or the ecosystem as a whole.

**167 Investigating the Risk of Secondary Rodenticide Poisoning to Owls Inhabiting and Foraging in Urban Landscapes of the Lower Mainland, British Columbia** S. Hindmarch, Environment Canada / Science and Technology; J. Elliott, Environment Canada / Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada / Pacific Wildlife Research Centre, Environment Canada / Wildlife Toxicology, Environment Canada / Canadian Wildlife Service. Anticoagulant rodenticides are widely used to control pest rodents, but poisoning of non-target wildlife has been linked to these practices, including secondary poisoning of birds of prey, particularly owls. In this study, we investigate whether Barred owls (*Strix varia*), Great-horned owls (*Bubo virginianus*) and/or Barn owls (*Tyto alba*) inhabiting and foraging in predominantly urban landscapes of the Lower Mainland, British Columbia are at risk of consuming rodenticide-laden prey, such as rats and house mice. By conducting a pellet study, we found that urban Barred owls had the largest proportion of rats in their diet, with some individuals' diet consisting primarily of rats. Urban Great-horned owl pellets were also comprised mainly of rats, but there was a clear shift towards alternative prey base when urbanization within home ranges decreased. Field voles (*Microtus townsendi*) were the main prey item for Barn owls, regardless of the amount of urbanization within their home range. For all three species, consumption of rats and house mice appears to coincide with increased urbanization within home ranges. The shift in the diet of owls living in urbanized areas may potentially lead to an increased risk of secondary

rodenticide poisoning. Radio telemetry was deployed to further investigate which landscape features urban Barn owls select as foraging habitat and whether they forage in proximity to buildings where rodenticide is applied. Urban Barn owls were found to predominantly forage in grass strips along highway interchanges and verges, and untended grass patches within the city. The majority of foraging was done within 100 m of commercial buildings where rodenticide had been applied. These findings will be discussed in conjunction with previous research done on rodenticide residues found in the livers of deceased owls and the current and historic sales of rodenticides in the Lower Mainland, BC.

**168 Mitigating risk of rodenticides to nontarget wildlife – potential options and unintended consequences** A. Fairbrother, Exponent / EcoSciences, Exponent, Inc. / EcoSciences; A. Kaiser, S. Kane Driscoll, R. Tinsworth, Exponent. Recent studies of liver concentrations indicate that nontarget wildlife, especially owls and hawks, are being exposed to anticoagulant rodenticides. It is desirable to reduce this exposure and potential risk even though the consequences of these exposures are difficult to predict because diagnostic tissue concentrations are not available and necropsy findings of diffuse hemorrhage need careful interpretation. Risk mitigation can occur through the use of less toxic products or by placing fewer baits in locations frequented by nontarget wildlife. Replacing second generation anticoagulants (e.g., brodifacoum or bromadiolone) with first generation products (e.g., warfarin or chlorophacinone) may not reduce risk to all nontarget species because subacute toxicity from repeated exposures would remain high and the development of resistance in rodents to the first generation products may result in increased body burdens. Replacing anticoagulant rodenticides with the neurotoxin bromethalin may increase risk to nontarget species (including children and pets) because bromethalin poisoning is difficult to diagnose (exposure results in nonspecific neurological signs and minimally diagnostic postmortem brain lesions), is difficult to measure in tissue due to extremely rapid photodegradation, has a high bioaccumulation potential, and has no known antidote (in contrast with anticoagulant exposures, which are treatable with Vitamin K). Restricting consumer use of anticoagulants will not significantly decrease wildlife exposure if continual bait placements around commercial establishments, in public parks, or around agricultural buildings (feedlots, chicken houses, etc.) by licensed pest control operators are not also curtailed. Effective strategies for reducing risk to nontarget wildlife may include increasing public awareness of the unintended consequence of rodenticide misuse, providing additional and appropriate training of licensed pest control operators emphasizing implementation of as-needed bait placements, and improving sanitation. Since there is currently no evidence that anticoagulant rodenticides are causing population declines in urban wildlife, it is imperative to take sufficient time to appropriately assess the relative risk of alternative products and approaches in order to select and implement an effective risk mitigation strategy.

**169 Derivation of congener-specific dioxin and furan soil to earthworm bioaccumulation factors** M. Buonanduci, ARCADIS; P. Anderson, Ohio EPA. The uptake of dioxins and furans from soil by earthworms is often a critical assumption and primary risk driver in terrestrial ecological risk assessments as well as the development of cleanup levels and screening benchmarks. We reviewed and summarized all published literature on earthworm uptake of dioxins and furans. Un-normalized and lipid-organic carbon normalized soil to earthworm bioaccumulation factors (BAFs) for 2,3,7,8-tetrachlorodibenzo(p) dioxin (2,3,7,8-TCDD) and the other sixteen 2,3,7,8 substituted congeners were estimated and compared across studies. In cases where the authors themselves did not calculate a BAF, but sufficient information was provided, a BAF was calculated using the data presented in the paper. The review finds that most, but not all, 2,3,7,8 substituted congeners are taken up at a lower rate than 2,3,7,8-TCDD and, therefore, that the BAF for 2,3,7,8-TCDD cannot be applied to the other congeners or the 2,3,7,8-TCDD toxic equivalent concentration in soil. We develop bioaccumulation equivalency factors (BEFs) to account for differences in uptake between congeners. An example of their recommended application is provided. Our review also found that the earthworm bioaccumulation model for 2,3,7,8-TCDD developed by Sample et al. (1998), which is frequently applied in ecological risk assessments and the development of screening benchmarks, is an outlier and overestimates uptake by more than 10-fold.

**170 The influence of soil type on the toxicity of silver to soil microbial processes** K. Langdon, CSIRO / M. McLaughlin, CSIRO / Land & Water, University of Adelaide / School of Agriculture, food and wine, CSIRO / Advanced Materials Transformational Capability Platform, Land & Water; J. Kirby, CSIRO / Advanced Materials Transformational Capability Platform, Land & Water; G. Merrington, WCA Environment Ltd / NCEHS. Silver (Ag) has been shown to exhibit extensive antimicrobial properties, which has led to its increased use in many consumer products, mainly in the form of Ag-nanoparticles. In comparison to many other metals, there is currently little known about the environmental behaviour and potential risks associated with Ag in soils. Although Ag in its ionic form ( $\text{Ag}^+$ ) has been shown to exhibit ecotoxicological properties, it is likely that interactions with the soil matrix will result in variations in Ag bioavailability and toxicity, similar to that seen for other metals. This study examined the toxicity of Ag to the soil microbial nitrification process and assessed the influence that varying soil properties may have on this measure of toxicity. Toxicity testing was conducted in seven soils that showed a wide range of physico-chemical properties, including pH ( $\text{CaCl}_2$ ) (4.6 – 8.0), organic carbon (0.9 – 12%), clay content (1.4 – 60%) and cation exchange capacity (5.3 – 42  $\text{cmol}^+/\text{kg}$ ). Soluble Ag was added to the soils as  $\text{AgNO}_3$  for all toxicity tests, as this provided the most available form of Ag in the soils ( $\text{Ag}^+$ ). Toxicity testing was conducted on soils both leached and unleached, which is the approach used to account for the effects normally observed as a result of spiking soils with soluble metal salts (i.e. increased electrical conductivity and decreased soil pH). The results from this study produced  $\text{EC}_{50}$  values (concentrations corresponding to a 50% effect or inhibition) in the low mg Ag/kg concentration range. However, these toxicity values varied over approximately two orders of magnitude, indicating that there is a strong influence of soil properties on the toxicity of Ag in soils. The results suggest soil organic carbon plays the greatest role in decreasing the toxicity and bioavailability of Ag in soils. Additional toxicity testing with a wider range of organisms is required to confirm these results. The results from this study can be incorporated in the development of Ag-specific terrestrial toxicity relationships, which can be used to predict toxicity in a range of soils, therefore, assisting in the environmental risk assessment of Ag.

**171 Environmental bioavailability of lead in metal-rich granules produced by the earthworm *Eisenia fetida*** R. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; S. Brasfield, M. Ansley, US Army Engineer Research and Development Center; J.G. Coleman, US Army Engineer Research and Development Center, US Research and Development Center / Environmental Laboratory, US Army Engineer Research and Development Center / Research Biologist, US Research and Development Center / Research Biologist; J. Seiter, U.S. Army Corps of Engineers / Research Physical Scientist; R. Jones, 2US Army Engineer Research and Development Center; S.R. Bowman, The Ohio State University / Evolution, Ecology, and Organismal Biology, The Ohio State University / Department of Evolution, Ecology, and Organismal Biology, The Ohio State University; M. Vasko-Bennett, Ohio State University. Lead (Pb) is the most common metal contaminant found in the soils of small-arms ranges of US military installations. Currently, risk assessors often assume that Pb is 100% bioavailable for ecological receptors, even though research has shown the modification of Pb bioavailability and toxicity by soil physicochemical characteristics and metabolism by organisms. Many terrestrial invertebrates are capable of rendering Pb toxicologically inactive through the formation of metal rich granules (MRGs). While Pb in MRGs is not considered bioavailable via trophic transfer, little is known regarding the fate of MRGs in the terrestrial environment once released from exposed organisms. The current research characterizes the microstructure of MRGs formed by the earthworm, *Eisenia fetida* and determines the potential for the microbial degradation and remobilization of Pb previously sequestered in MRGs. If liberated by bacterial degradation, sequestered Pb may become bioavailable to invertebrates and their predators. The direct bioavailability of Pb in MRGs to oligochaetes in soil will also be examined. Earthworms were exposed to soils spiked with 4,000 mg/kg Pb for a six-week period and fractionated utilizing differential centrifugation and digestion to separate whole-animal tissue from MRGs to obtain sufficient MRGs for amending soils for microbe and oligochaete exposures. Once extracted, MRG composition and concentration was analyzed utilizing synchrotron-based analysis at Argonne National Laboratories (Argonne, IL). Synchrotron imaging provided multi-channel analyzer (MCA) plots which revealed localized MRG hotspots within the samples, not only confirming the presence of Pb,

but also the binding of additional metals such as zinc and iron. Additionally, synchrotron techniques were utilized on cross-sections of earthworms to determine the presence and concentration of Pb across a gradient of dermal and gut tissue. MCA plots of cross sections revealed a wide dispersion of Pb inside the gut wall, suggesting the presence of unbound Pb in addition to MRG formation. The results of the exposure of microbes and oligochaetes to Pb in MRGs will be discussed.

**172 Derivation of a Tier 2 site-specific remedial objective for Bromacil, a soil sterilant** G.L. Stephenson, Stantec Consulting Ltd. / Environmental Management, Stantec Consulting Ltd. / Environmental Remediation Services, Stantec Consulting / Environmental Toxicology & Remediation; R.A. Angell, E.J. Shrive, Stantec Consulting / Environmental Toxicology & Remediation; K. Bessie, EBA, A Tetra Tech Company / Soil Science; A. Burk, Cenovus Energy. Site-specific soil standards for chemicals are derived to be protective of organisms under specific exposure conditions. Climate change directly and indirectly influences the prevailing environmental conditions such that natural processes are altered (e.g., rates of microbial degradation, adsorption, and bioavailability of chemicals). As a result, chemicals in soil could be more (or less) persistent or bioavailable. Bromacil, a synthetic herbicide, was used in Alberta as a soil sterilant to control vegetation on facilities associated with the oil and gas industry. The rates and frequency of applications, the nature of the chemical, and the increasingly arid conditions in some areas have resulted in concentrations that persist in soil despite the fact that the chemical can be degraded by microbial organisms. These persistent concentrations of Bromacil in soil have the potential to migrate off site and adversely affect crop production or contaminate ground and surface waters. Therefore, the semi-arid lands with persistent Bromacil concentrations in soil require remediation. In Alberta (and many other jurisdictions), there is no soil quality standard for Bromacil to protect ecological receptors exposed as a result of direct contact with contaminated soil. During the decommissioning of a site, concentrations of Bromacil were measured in soils collected across the site and the risk associated with these exposure concentrations was considered unacceptable for ecological receptors. An ecotoxicity assessment with a battery of test methods and species was conducted with both a fine-textured and coarse-textured soil using chemically spiked site soils. Subsequently, species sensitivity distributions of the toxicity data ( $\text{IC}_{25}$ s) were used to derive a site-specific remedial objective (SSRO) for Bromacil in soils for the direct contact exposure pathway. The SSRO was based on the 25<sup>th</sup> percentile of the distribution of inhibiting concentrations ( $\text{IC}_{25}$ s) for plant and soil invertebrate species and plant species alone. Because the sensitivities of the plant species were much greater than those for soil invertebrate species, the recommended SSRO for the eco-contact exposure pathway was based on the SSD for plant species only.

**173 Arctic mites and nitrifiers: should these drive our remediation clean up standards** S.D. Siciliano, A. Schafer, University of Saskatchewan / Toxicology Group; J. Princz, Environment Canada / Ecotoxicology and Wildlife Health Division; J. Owjori, University of Saskatchewan. The derivation of site-specific remedial objectives is a key component of any remediation plan. For many sites, human receptors are not routinely present and thus, ecological receptors or off site migration, drives clean-up standards. We have developed a new invertebrate toxicity test species, oribatid mites, as well as validated a biogeochemical toxicity test: potential nitrification which can be used to set ecologically based clean up standards. Both of these new tests have been compared to standard toxicity tests and found to compare well. In addition, we have modified the mite and biogeochemical toxicity tests to allow rapid, on-site assessments of toxicity. The goal of these modifications is to allow front-line personnel to rapidly (< 24 hr) assess the toxicity of a soil sample and thereby provide guidance for clean up efforts. However, both of these tests suffer from limitations in their use. Specifically, oribatid mites are sensitive to organic matter content, and in some cases, nitrification inhibition may not be a relevant endpoint for the ecosystem. I will discuss the current state of polar region soil toxicity testing, how it applies to remediation designs, and what I think are some reasonable next steps to allow us to develop ecoregion specific remedial objectives.

**174 A new processing pipeline and policy framework to incorporate pyrotag sequencing results into soil toxicity testing and assessments in Polar Regions** S.D. Siciliano, University of Saskatchewan / Toxicology Group; J. van Dorst, B. Ferrari, University of New South Wales; K. Mengersen, Queensland University of Technology; J. McKinley, B.

Raymond, C. King, I. Snape, Australian Antarctic Division. Risk assessment of soil sites in Polar Regions are dominated by microbial activities because on many of these sites there are no higher animals or vascular plants. Traditional soil activity toxicity testing, such as respiration or nitrification, are sensitive indicators of change. Further, the application of molecular approaches such as Quantitative PCR is clearly within our current paradigm of how sites should be assessed for toxic impacts. However new technologies, specifically massively-parallel sequencing efforts, such as the Ion Torrent or 454 platforms, provide new opportunities into how a site can be assessed and characterized. Here, we present our view of how the results from these sequencing technologies can be processed and interpreted. Specifically, we will outline the processing pipeline developed in R to handle these datasets as well as the policy framework necessary to incorporate these results into a risk assessment. Finally, using an 18 month chronic exposure study to diesel pollution, we will provide an example of how this new pipeline and framework compares to traditional approaches to soil toxicity assessment.

**175 Earthworm responses to petroleum hydrocarbons in aged field contaminated soil using both traditional ecotoxicity endpoints and  $^1\text{H}$  NMR metabolomics** M. Whitfield Aslund, Intrinsik Environmental Sciences Inc., University of Toronto; G.L. Stephenson, Stantec Consulting Ltd. / Environmental Management, Stantec Consulting Ltd. / Environmental Remediation Services, Stantec Consulting / Environmental Toxicology & Remediation; M.J. Simpson, University of Toronto / Department of Physical and Environmental Sciences.

$^1\text{H}$  NMR metabolomics was used to examine the metabolic profile of earthworms exposed to petroleum hydrocarbons (PHCs) in soil. Significant relationships were observed between the earthworm metabolic profile (collected after two or 14 days of exposure) and soil properties including soil PHC concentration, suggesting that earthworms responded to PHC contamination at a metabolic level. Since the ecological relevance of metabolomic responses is currently poorly understood, soils were also evaluated using more traditional earthworm ecotoxicological endpoints. Although not acutely toxic to earthworms (average survival  $\geq 90\%$ ), some soils impaired reproduction endpoints by  $>50\%$  compared to the field control soil. Further comparisons by partial least squares regression revealed a significant relationship between these reproduction endpoints (collected after 63 days) and earthworm metabolomic data (collected after only two or 14 days), which suggests it may be possible to develop metabolomics as a rapid tool to predict chronic toxicity of PHCs in soil to earthworms.

**176 Risk Assessment of petroleum hydrocarbon contamination in soil.**

**II. Toxicity of conventional and renewable fuels to three test species** V. Malk,

University of Helsinki / Palmenia Centre for Continuing Education; E. Barreto Tejera, Autonomous University of Madrid / Department of Biology; O. Penttinen, University of Helsinki / Department of Environmental Sciences. Oil and fuel spills are among the most extensive and environmentally damaging pollution in Finland and other Nordic countries, but only limited data on the ecotoxicology of petroleum hydrocarbons exist. Petroleum products, such as diesel fuel and gasoline, are complex mixtures of compounds when their toxicity depends on composition of fuel and joint effect of harmful constituents. Composition of new environmentally friendly products such as biodiesel and ethanol based gasoline can be expected to have different toxicity profile when compared to conventional gasoline and diesel. Oil products exist in soil pores as non-aqueous phase liquids (NAPL) which is challenge for ecotoxicity testing. Organisms may be affected by oil as a result of physical fouling or by exposing to toxic compounds. For determining effects of toxic compounds alone, water soluble fractions (WSF) of fuels need to be used in ecotoxicity testing. In this study, ecotoxicological effects of conventional gasoline and diesel, as well as RE85 gasoline and renewable NExBTL diesel in soil were determined by exposing earthworms (*Eisenia fetida*) during 14 days in a laboratory. Acute toxicity of water soluble fractions of different fuels was determined by exposing water fleas (*Daphnia magna*) and luminescent bacteria (*Vibrio fischeri*). WSFs were generated by mixing one part of fuel to four parts of water by 22-24 hours. NExBTL had lower percentage proportion of heavy hydrocarbon fractions (C21-C40) and PAH compounds in test soil when compared to conventional diesel. EC50 value for diesel was 1600 mg/kg while for NExBTL toxicity was not detected at concentration of 5000 mg/kg. The co-solvency effect of ethanol increased the solubility of BTEX compounds and short chained PHCs (C5-C10) in the RE85 WSF solution. EC50 for *Vibrio fischeri* in RE85 and gasoline exposure was approximately 1800 mg/l and 8300 mg/l.

*Vibrio fischeri* was considerably less sensitive for PHC compounds than *Daphnia magna*.

**177 Modeling Mercury Distribution in the Sarasota Bay Ecosystem using SERAFM and Stable Isotope Ratio of Nitrogen ( $\delta^{15}\text{N}$ )** Y. Hong,

Johns Hopkins University / Geography and Environmental Engineering, Johns Hopkins University; E. Rifkin, National Aquarium Baltimore; E. Bouwer, Johns Hopkins University / Geography and Environmental Engineering. Mercury (Hg) transport and transformation and Hg bioaccumulation in the Sarasota Bay ecosystem are investigated using the Spreadsheet-based Ecological Risk Assessment for the Fate of Mercury (SERAFM). The mercury biomagnification from the foodchain base to the blood of Sarasota Bay resident bottlenose dolphins is modeled using a linear relationship between logarithmic Hg concentrations and stable isotope ratio of nitrogen ( $\delta^{15}\text{N}$ ) in biota. By combining and using the two models, the Hg sources of the bay are identified and the strategies to lower the reported methylmercury (MMHg) levels in the blood of resident bottlenose dolphins are investigated. The model is calibrated with field data collected by the authors in the Sarasota Bay during the summer of 2011. The combined model successfully related atmospheric total mercury (THg) deposition to the Hg concentrations in the overlying water, sediment, various shellfish and finfish species, and in the blood of resident bottlenose dolphins. The model showed that the THg loading to the bay is about  $7.6 \text{ kg yr}^{-1}$ . The Hg runoff from impervious areas in the watershed and the THg atmospheric direct deposition to the waterbody were the two major Hg sources to the bay occupying 46% and 31% of the THg loadings, respectively. To lower the average MMHg concentrations in the blood of resident bottlenose dolphins from  $570$  to  $150 \text{ ng g}^{-1}$  (the reference value observed in the bottlenose dolphins of Charleston, SC), the THg loadings may need to be reduced by 74% from  $7.6$  to  $2.0 \text{ kg yr}^{-1}$ . The reduction can be achieved by lowering the THg atmospheric deposition from  $20.6$  (value of 2010) to  $3.0 \mu\text{g m}^{-2} \text{ yr}^{-1}$ . If appropriate watershed implementation plans could reduce the Hg runoff from the impervious surface by 50%, then the current THg loading to the bay can be decreased by 26% from  $7.8$  to  $5.8 \text{ kg yr}^{-1}$ . Under such condition, the reduction of atmospheric THg deposition to  $4.5 \mu\text{g m}^{-2} \text{ yr}^{-1}$  is required to lower the Hg blood levels in the Sarasota resident bottlenose dolphins to the value observed in Charleston, SC. The increasing population in the Sarasota Bay watershed is likely to increase the Hg runoff from impervious areas, so appropriate storm water management together with the reduction of Hg atmospheric deposition may be required to reduce the Hg levels in the bay ecosystem.

**178 Seasonal and annual trends in forage fish mercury concentrations,**

**San Francisco Bay** B.K Greenfield, University of California, Berkeley, University of California, Berkeley / Berkeley Center for Green Chemistry; A.R. Melwani, R.M. Allen, San Francisco Estuary Institute; D.G. Slotton, S.M. Ayers, University of California – Davis / Department of Environmental Science and Policy; K.H. Harrold, University of North Carolina / Environmental Sciences and Engineering; K. Ridolfi, LimnoTech; M.B. Sandheinrich, University of Wisconsin – La Crosse / River Studies Center, University of Wisconsin – La Crosse / Department of Biology. Monitoring of mercury (Hg) in San Francisco Bay forage fish has revealed relatively elevated concentrations throughout the Bay ecosystem. As a result, potential short and long-term changes in Hg exposure and bioaccumulation have been of interest among Hg researchers. In 2005, the Regional Monitoring Program for Water Quality in San Francisco Bay began monitoring Bay forage fish to indicate temporal patterns in bioaccumulation. Interannual variation and long-term trends were determined by monitoring Hg bioaccumulation during September – November, for topmelt and Mississippi silverside at six sites, over a six year sampling period (2005 – 2010). Seasonal variation was characterized for arrow goby (*Clevelandia ios*) at one site and topmelt at four sites during 2008 – 2010. Statistical model evaluation indicated both seasonal and interannual variation to be present. Seasonal patterns accounted for 30 – 60% of the total variation in arrow goby and topmelt Hg concentrations. Arrow goby exhibited a consistent seasonal pattern from 2008 – 2010, with lowest concentrations observed in March or April, and highest concentrations in July or September. In contrast, topmelt concentrations tended to peak in late winter or early spring. The seasonal patterns were not correlated with changes in body size, but may relate to seasonal shifts in abiotic concentrations in the contrasting habitats of the two species. In general, strong directional trends for Hg in forage fish were not apparent over the study duration. For both species, the variability explained

by year was relatively low compared to sampling station, suggesting that interannual variation is not a strong influence on Hg concentrations. Topsmelt (*Atherinops affinis*) exhibited a significant increase in Alviso Slough from 2005 to 2010 that was not observed at other locations, which may relate to ongoing habitat restoration in adjacent salt ponds. Although fish Hg has shown long-term declines in some ecosystems around the world, San Francisco Bay forage fish did not decline over the six year monitoring period examined.

**179 Hg bioaccumulation in shoots of the macrophyte *Elodea nuttallii* happens through copper transporters** N. Regier, University of Geneva; C. Cosio, Geneva University, Geneva University / Forel Institute. Previous studies suggest that macrophytes might participate in bioaccumulation and biomagnification of toxic mercury (Hg) in aquatic environment. Hg bioaccumulation and uptake mechanisms in macrophytes need therefore to be studied. Amongst several macrophytes collected in an Hg contaminated reservoir in Romania, *Elodea nuttallii* showed a high organic and inorganic Hg accumulation and was then further studied in the laboratory. *Elodea nuttallii* is a rooted submerged aquatic macrophyte native of North America, which occurs as aggressive invader worldwide in temperate areas. It is often found in metal contaminated sites in freshwater environments. Hg tolerance and accumulation of this plant was also high in the microcosm. Basipetal transport of inorganic Hg was predominant, whereas acropetal transport of methyl-Hg was observed with apparently negligible methylation or demethylation *in planta*. In addition methyl-Hg proportion as total Hg was increased in rhizospheric sediments. Hg concentrations were higher in roots>leaves>stems and in top>middle>bottom of shoots. In shoots, more than 60% Hg was found intracellularly where it is believed to be highly available to predators. Accumulation of inorganic and methyl-Hg in shoots was highly reduced by cold, death and by competition with Cu<sup>+</sup> for inorganic Hg. Hg in *E. nuttallii* shoots seems to mainly originate from the water column, but methyl-Hg was produced in rhizosphere and can also be remobilized from the sediments driving in part its entry in the food web. At the cellular level, uptake of Hg into the cell sap of shoots was linked to the metabolism, in particular to copper transporters. In summary, our results revealed that shoots of *E. nuttallii* are extremely tolerant to Hg and show huge bioaccumulation ability. Based on densities previously reported in the field by other authors (350-2800 g DW m<sup>-3</sup>) and concentration of Hg found in Babeni reservoir, it can be estimated that 0.7 to 5.6 mg Hg m<sup>-3</sup> could be accumulated in these plants. This amount is likely to return to water and sediments at the end of the growing season when plants decay. Moreover, the Hg uptake by shoots might be an important pathway of Hg from the water to organisms feeding on the macrophytes. In conclusion, these plants should probably be removed in contaminated sites.

**180 Bottom-up nutrient and top-down fish impacts on mercury flux from aquatic ecosystems** M.M Chumchal, T. Jones, R. Drenner, Texas Christian University / Biology department; W.H. Nowlin, Texas State University / Department of Biology; G. Timmins, Texas State University / Biology department. Methyl mercury (MeHg) is one of the most hazardous toxins in the environment, adversely affecting the health of wildlife and humans. Recent studies have demonstrated that aquatic insects biotransport MeHg and other contaminants to terrestrial consumers, but the factors that regulate the flux of MeHg out of aquatic ecosystems via emergent insects have not been studied. We used experimental mesocosms to test the hypothesis that insect emergence and the associated flux of MeHg from aquatic to terrestrial ecosystems is affected by both bottom-up nutrient effects and top-down fish consumer effects. In the present study, nutrient addition led to an increase in Hg flux primarily by enhancing the biomass of emerging insects whose tissues were contaminated with MeHg, while fish decreased Hg flux primarily by reducing the biomass of emerging insects. Further, we found that these factors are interdependent such that the effects of nutrients are more pronounced when fish are absent and the effects of fish are more pronounced when nutrients concentrations are high. The present study is the first to demonstrate that the flux of Hg from aquatic to terrestrial ecosystems is strongly enhanced by bottom-up nutrient effects and diminished by top-down consumer effects.

**181 Spatial and temporal variations in fish mercury concentrations in Grand Lake, Oklahoma, USA** L.A. Schaidt, Harvard School of Public Health / Department of Environmental Health; Z. Dong, Harvard School of Public Health / Environmental Health; R.A. Lynch, University

of Oklahoma Health Sciences Center / Occupational and Environmental Health; S. Ziara, Grand River Dam Authority; J.P. Shine, Harvard School of Public Health / Department of Environmental Health. Exposure to methylmercury (MeHg) through fish consumption is a public health concern, with thousands of fish consumption advisories in the U.S. Coal-fired power plants are the primary anthropogenic sources of atmospheric mercury (Hg) emissions and freshwater bodies near these plants may contain elevated Hg in sediments and biota. This study is based at Grand Lake, northeastern Oklahoma, a reservoir located within 100 km of six coal-fired power plants. As part of a community-based participatory research project to evaluate MeHg exposure among residents who consume local fish, we measured Hg concentrations in commonly-consumed fish throughout the watershed, evaluated food web dynamics using  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  and tested for spatial and temporal variations in Hg concentrations in prey fish and plankton. This project addresses community concerns about Hg exposure through consumption of local fish and involved local agencies and recreational fishermen in the collection of fish. Total Hg was measured in 700 filet samples representing 23 types of commonly-consumed fish. In general, Hg concentrations were below the U.S. EPA tissue residue criterion of 0.3  $\mu\text{g g}^{-1}$  MeHg, with the exception of several flathead catfish, drum and largemouth bass. While Hg concentrations were generally higher as  $\delta^{15}\text{N}$  increased, elevated Hg in some flathead catfish could not be explained by  $\delta^{15}\text{N}$ , suggesting they derive their dietary Hg from a different food web. Hg concentrations were correlated with fish length for some types of fish, but showed no length dependence in other types. While differences in Hg concentrations were not observed in higher trophic level fish among different parts of the watershed, fish at lower trophic levels may more closely reflect spatial and temporal variations in MeHg production. Samples of prey fish (minnow, brook silver-side), young mid- and high-level consumers (largemouth bass, sunfish) and plankton (53  $\mu\text{m}$ , 163  $\mu\text{m}$ , 363  $\mu\text{m}$ ) were collected monthly throughout spring and summer from two locations in Grand Lake (an upstream location with primarily riverine conditions and a downstream location with primarily lacustrine conditions) and from one location in Lake Hudson, another reservoir immediately downstream of Grand Lake. Samples were analyzed for total Hg,  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ , and a subset was also tested for MeHg. These results provide insight into the extent that Hg concentrations in fish reflect localized variations in MeHg production.

**182 Environmental factors controlling mercury methylation in low productivity sediments** P. Schierz, university of Texas at Austin / Department of Civil and Environmental Engineering, Duke University / Pratt School of Engineering, Duke University / Civil and Environmental Engineering, university of Texas at Austin / Department of Civil, Architectural and Environmental Engineer, The University of Texas at Austin / Center for Research in Water Resources; P. Bireta, J.S. Grundy, L.E. Katz, The University of Texas at Austin / Civil, Architectural and Environmental Engineering Department-EWRE; D.D. Reible, The University of Texas-Austin, University of Texas / Environmental and Water Resources, The University of Texas at Austin / Dept. of Civil & Environmental Eng.. Mercury is a pollutant of global concern. In sediment environments, inorganic mercury can be transformed to methylmercury, the most dangerous form, by sulfate and/or iron reducing bacteria. Strongly reducing, organic rich sediments typically exhibit maximum methylation at the transition between iron reduction and sulfate reduction. The purpose of this study is to evaluate mercury methylation behavior in low productivity, deep water sediments and to identify key controlling factors. Here we define low productivity sediments as sediments low in labile organic matter that exhibit low sediment oxygen demand and are only mildly reduced with limited or minimal sulfate reduction. Sediment batch slurry experiments were performed with marine, mercury contaminated sediment under different geochemical conditions initiated by different amendments such as Fe<sup>2+</sup>, sulfate and lactate. The slurry experiments with no amendments as well as iron and sulfate amendment were characterized by mildly reduced conditions reflected in low sulfate reduction (as indicated by acid volatile sulfides, AVS) after 78 days. Slow accumulation of AVS indicated continued slow reduction and reflected the low productivity of the sediment. The addition of an electron donor (lactate) stimulated microbial activity in the sediment slurries, increased reduction (fully reduced conditions) and methylation. However, this does not reflect field site conditions. Results identify labile organic carbon as the limiting factor for mercury methylation under field site conditions. Mesocosms studies (overflow cells) were also performed to explore representative field conditions (density, vertical redox gradient) using voltammetry, DGT (diffusive gradient in thin

films) pore water analysis to characterize geochemical parameters, mercury availability and net methyl mercury production. Results of these laboratory studies were compared to the analysis of field cores (both frozen and refrigerated) to verify reproduction of field conditions. The limited reduction in the sediments resulted in low methylmercury concentrations (< 0.1% of mercury in porewater). The observed MeHg levels are consistent with observations in the raw sediment from the site, indicating that the experimental systems are representative of site conditions and suggesting that the site poses much less risk (in terms of methylation potential) than would normally be ascribed to the observed bulk solid mercury concentrations.

### **183 Selenium:mercury interactions in aquatic systems receiving anthropogenic inputs of mercury and selenium**

**A.R. Stewart**, U.S. Geological Survey / Water Resources Division; **D. Krabbenhoft**, J. DeWild, C. Thompson, U.S. Geological Survey. Global fish consumption advisories to protect humans against mercury (Hg) toxicity are at odds with the positive nutritional benefits of consuming fish for their high quality protein and omega-3 fatty acids. This conflict has led to discussions within regulatory and scientific communities about strategies for reducing Hg exposures in nature and mitigating its toxic effects, including the role of selenium (Se). Some studies suggest that when Se is present in molar quantities greater than Hg Se may reduce the bioaccumulation of Hg and protect against Hg toxicity at a physiological level. Yet understanding of specific mechanisms controlling molar Se:Hg ratios in nature are far from clear. Interactions between the elements may be occurring at geochemical, physiological and ecological levels. Here, we present results on Se-Hg interactions at two different ecological settings (San Francisco Bay, CA; and Goose Lake, MI), but share a common condition of being distinctly contaminated by mining and/or agricultural practices. In San Francisco Bay we evaluated the bioaccumulation of Hg and Se in top predator fish. Molar Se:Hg ratios in fish muscle tissue ranged from 3-29 in adult white sturgeon muscle, 3-15 in juvenile striped bass, and 1-6 in adult striped bass. Variation in Se:Hg molar ratios among individuals and developmental stage appeared to be related to their foraging location relative to Se sources in San Francisco Bay. These results indicate that while all predators analyzed in the study had molar Se:Hg > 1 some ratios did approach 1 and all varied widely within and among species in an estuarine environment with spatially variable sources of Se and Hg. At Goose Lake, field studies were designed to evaluate whether antagonistic Se-Hg interactions would limit Hg availability for methylation, and subsequent incorporation into the aquatic food web. Our results show that there was very little apparent inhibition effect of Se on methylation of ambient Hg or tracer-level amendments of  $^{202}\text{Hg}$  used for quantifying methylation. However, while methylmercury was clearly produced, unlike most aquatic ecosystems, very little was passed up the food chain beyond the primary producer level, resulting in very low Hg levels at higher trophic levels. These studies indicate that interactions between Se and Hg are complex and that further research on processes controlling bioaccumulation across a range of Hg and Se exposure levels and environmental settings is warranted.

### **184 Bioenergetic effects of food web simplification on mercury biomagnification in northern pike (*Esox lucius*) in southern Alberta, Canada**

**L. Brinkmann**, University of Lethbridge; **J. Rasmussen**, University of Lethbridge / Department of Biological Sciences. In the past, studies on mercury contamination in reservoirs have focused on the pulse in baseline levels following inundation and ensuing responses in resident biota. Considerably less is known about the trophodynamic and bioenergetic effects on mercury biomagnification in communities responding to the lotic-lentic transition. Absence of key taxa or functional groups in aquatic communities can lead to food web simplification and inefficient energy transfer between lower trophic levels and top predators. Low growth efficiency, or bioenergetic bottleneck effects, may be reflected in stunted growth of species exploited by humans, recreationally or commercially. Growth efficiency of fish is also a key determinant in the biomagnification of contaminants such as mercury, in that it affects the accumulation of body tissue for a given amount of contaminant assimilated during feeding. This study investigates mercury biomagnification in relation to growth characteristics of northern pike in lakes and reservoirs of semi-arid southern Alberta, Canada. These systems differ in their forage fish community, in that zooplanktivorous lake whitefish, an important link between pelagic and littoral food webs, are either present (LKWH+) or absent (LKWH-). In LKWH- systems diets of northern pike consist predominantly of invertebrates (amphipods and leeches), despite the presence of other potential forage fish species. In LKWH+ systems lake whitefish is a

major constituent in the diet of northern pike. Stable isotope analysis ( $\delta^{15}\text{N}$ ) shows that food chains are shorter in LKWH- systems, placing northern pike at lower trophic position compared with LKWH+ systems. Based on previous work we expect flattened growth trajectories of northern pike in LKWH- systems, reflecting lower growth efficiency, relative to LKWH+ systems. We hypothesize that achieving saturation on an invertebrate diet imparts significant activity costs on large pike and therefore reduces growth efficiency of pike in these systems. In conjunction with reduced growth efficiency we expect to find greater mercury biomagnification factors of pike from their invertebrate diet. In the greater context bioenergetic constraints resulting from food web simplification may compound the risk of mercury contamination in fish following construction of new reservoirs. We propose that community structure, trophodynamics and bioenergetics be addressed in the planning of reservoir projects.

### **185 Using macrobenthic community structure to identify stressors in Southern California estuaries, bays, and harbors**

**D. Gillett**, J.A. Ranasinghe, M. Satula, Southern California Coastal Water Research Project; **D. Cadien**, County Sanitation Districts of Los Angeles County; **K. Schiff**, Southern California Coastal Water Research Project. Macrobenthic community structure is a commonly used measure to assess general environmental condition in marine and freshwater habitats. When degraded conditions are detected, it then becomes necessary to identify the cause(s) leading to the impact. Compared to assessments however, there has been comparatively minimal progress towards the development of macrobenthic-based tools for the diagnosis of individual stressors that lead to degraded condition. Eutrophication and chemical contaminants are the most pervasive stressors impacting the quality of estuaries and coastal oceans around the world. Though they are often the product of different anthropogenic activities, little work has been done to develop approaches to monitoring/assessment that differentiate between the two. Our goal was to develop practical tools that use macrobenthic community structure to help diagnose the major stressor(s) impacting the sediments and overlying waters of the estuaries and coastal ocean of the Southern California Bight. We developed suites of potential indicator taxa from 4 years of regional monitoring data and tested their ability to predict sediment eutrophication (elevated TOC and TN) or chemical contamination (e.g., metals, organics, pesticides). In preliminary analyses, several taxa show promise. They are being tested for independence from natural gradients and will be validated against a new, naive dataset. Eventually, macrobenthic community metrics developed from these indicator taxa could be included in the state of California's coastal and estuarine monitoring tools. These additions should provide valuable stressor insights that could be used in causal assessments of locations with degraded benthic communities.

### **186 Stressor identification analysis in a small salmon-spawning watershed in the Sacramento Valley**

**B.S. Washburn**, OEHA/Cal EPA / Ecotoxicology Program; **K.A. Pulsipher**, Ecotoxicology Program / Office of Environmental Health Hazard Assessment; **W.G. Wieland**, Ecotoxicology Program / Office of Environmental Health Hazard Assessment. The Stressor Identification (SI) methodology, based on principles of eco-epidemiology, was used to pinpoint the cause(s) of the decline in fall-run chinook salmon in a HUC 10 watershed northeast of Sacramento. The SI process involves listing candidate stressors, analyzing data from the case and from other situations, and characterizing causes based on a set of criteria. The dataset used for the analysis was collected from ten different sites in the watershed over a period of 6 years. Due to the complexity of salmon's life cycle, benthic macroinvertebrates (BMI) were used as a surrogate assessment endpoint. Relationships between water quality, physical habitat, land use characteristics, and BMI metrics were analyzed. We developed a scoring system to evaluate data from the watershed as well as data from elsewhere. Over fifty possible stressors were evaluated. Most were eliminated because they failed to meet basic criteria; a dozen were advanced for detailed analysis. The percent silt, sand, and fine gravel was most closely linked to the decline in the abundance and diversity of BMIs, with a total score of 44 out of a possible 55. A variety of physical habitat and conventional water quality parameters were weakly correlated with BMI metrics. The percent impervious cover in the 100 ft. buffer in the stream network was the landscape factor most closely linked to poor BMI metrics. Conversely, the percent open space within a 100 ft. buffer in the stream network was strongly linked with healthier BMI populations. The results of the analysis will be used to prepare a watershed indicator report.

**187 Satellite Image Analysis to Assist Remedial Action Decisions**

W. Stiteler, Arcadis U.S., Inc.; C. Meyer, A. Thatcher, ARCADIS. Soil remediation is necessary in areas of high contamination, but in many cases remediating an area may do more harm than good to existing vegetation, particularly in arid areas. This study presents the results of an analysis of land cover type and health using satellite remote sensing. The study area consists of over 40,000 acres, making intensive sampling of vegetation health through ground sampling impractical. Ikonos satellite imagery of the area, consisting of information in the visible and near-infrared portions of the electromagnetic spectrum, was used to classify the quality of rangeland and wildlife habitat using three metrics. This information was used to target areas for remediation from within an estimate of areas of high contamination based on geostatistical analysis. The first metric, rangeland condition for cattle, was assessed using a maximum likelihood classification of the imagery, trained with a set of ground samples. The second metric, vegetative cover for wildlife was estimated with a model using a vegetative index calculated for each Ikonos pixel, calibrated with field visits. The third metric, wildlife habitat quality, was found to correlate with species richness. This was assessed with the mean and variance of the vegetation index across a twenty-five square meter area, which provided a measurement of both vegetative cover and heterogeneity. Another maximum likelihood classifier was used on this aggregate index data and trained using field measurements at a similar spatial scale to determine which areas had acceptable habitat quality. Accuracy from ground sampling was 70% for rangeland condition, 80% for vegetative cover, and 74% for species richness assessments. Areas with cover and species richness meeting 60% of that of reference areas, and rangeland sites in fair or good condition are likely to not need remediation.

**188 Using Receiver Operating Characteristic Analysis To Characterize Stressor-Response Relationships for Causal Analysis in Ecological Risk Assessment**

D.B. McLaughlin, National Council for Air & Stream Improvement / Northern Regional Center, National Council for Air & Stream Improvement / Western Michigan University. The analysis of field-derived stressor-response data plays a key role in building evidence to support conclusions regarding the presence of a causal link between a potential stressor variable and a biological or ecological response of interest. Several data analysis methods are widely available for describing a stressor-response relationship and its associated uncertainty. For example, USEPA's Causal Analysis/Diagnosis Decision Information System (CADDIS) website includes information on regression analysis, classification and regression tree analysis, conditional probability analysis, propensity score analysis, and others. Receiver operating characteristics (ROC) analysis is one relatively simple data analysis approach that, while not new to ecological research, appears to be under-utilized in causal assessment. More commonly used in medical diagnosis, machine learning, and other fields, ROC analysis quantifies the strength of relationships between true and indicated or predicted conditions (e.g. the presence or absence of disease based on the results of a diagnostic test). Applied to ecological risk assessment, ROC analysis can be used to identify a level or range of stressor necessary to maintain a desired ecological condition, and to characterize the uncertainty in predictions of ecosystem state based on levels of a stressor. One advantage of ROC analysis over other methods is its comprehensive quantitation of false positive, false negative, positive predictive, and negative predictive errors when comparing the predictive performance of alternative candidate models of ecosystem or biological condition. In addition, characterizing model performance in these terms can be more meaningful to decision-makers and affected stakeholders than mean square error, regression  $r^2$ , or other terms from more common statistical procedures. In turn, the overall strength of evidence supporting the presence of a causal relationship can be more transparent to a broad audience. Software for conducting ROC analysis is available using the open source R statistical package. In this presentation, important elements of ROC analysis will be presented along with examples using field-derived stressor-response data in which ROC results are compared with results from conditional probability analysis and linear regression.

**189 A Bayesian network approach for causal inferences in pesticide risk assessment and management** J.F. Carriger, Jr., U.S. EPA, U.S. EPA / Gulf Ecology Division; M.G. Barron, US EPA / Gulf Ecology Division. Pesticide risk assessment and management must balance societal benefits and ecosystem protection, based on quantified risks and the strength of the causal linkages between uses of the pesticide and socioeconomic and ecological endpoints of concern. A Bayesian network (BN) is a graphical representation

of the joint probability distribution over a set of discrete random variables and provide a mathematical approach for assessing causality. A BN can represent the best available knowledge of causal dependencies between variables important to risk management such as the influence of application events on contaminant exposure. Capabilities, advantages, and disadvantages of BNs to enhance assessments of causality in pesticide risk assessment and management are demonstrated through a model development process. The process focuses on the incorporation of domain knowledge to represent and evaluate cause-consequence relationships between system variables and endpoints, and the integration of non-causal factors important to a risk problem such as measurement uncertainty, definitional interactions, and reconciliation of independent models. For the causal linkages, conditional and marginal probabilities in the BN represent the strength of evidence on causal associations and permit the incorporation of a wide range of statistical model output and expertise. The model building process illuminates the potential for BNs to facilitate the identification of new management options, improve risk communication, assimilate competing hypotheses, and enhance public participation in risk management tasks. Some of these features of BNs are exhibited in a case study of lampricide risks and benefits in Great Lakes region. The example BN will demonstrate predictive reasoning on the efficacy and potential risks to non-target organisms from several uses and diagnostic reasoning for updating beliefs on potential causes from observed effects.

**190 A Causal Analysis of Mercury Impacts to Invertebrates in a High-Gradient Freshwater Stream**

J.R. Flanders, URS Corporation, URS; G. Long, URS; W.H. Clements, Colorado State University / Fish, Wildlife and Conservation Biology, Colorado State University, Colorado State University / Fish, Wildlife and Conservation Biology; R.G. Stahl, DuPont Company / Corporate Remediation Department, DuPont Company / Corporate Remediation Group, DuPont Company / DuPont Corporate Remediation Group. Mercury (Hg) is a persistent bioaccumulative contaminant that may present potential ecological risk to wildlife on a regional basis, but the effect of direct contact exposure to aquatic invertebrates is difficult to gauge due to high stochasticity in invertebrate communities, variation in species sensitivity, and multiple potential stressors. A causal analysis of invertebrate community exposure to Hg in the South River, VA, which has high Hg concentrations in surface water, sediment and biota relative to other regional watersheds was conducted between 2006 and 2011. The causal analysis used empirical field data and *in situ* experiments (e.g., benthic colonization and *in situ* microcosm approaches), laboratory toxicity tests (sediment quality triad), statistical modeling, and data from other systems to determine potential impacts to invertebrate communities. Field experimental data indicated that the relative composition of functional feeding groups and major classes or orders of invertebrates were not substantially different between study sites and pooled reference areas, and that there were no observed population- or community-level differences between study sites and reference areas. A comprehensive multivariate statistical analysis of invertebrate community, physical habitat and water chemistry and quality data revealed that invertebrate abundance and species richness were determined by a complex interaction between physicochemical variables, substrate composition and Hg; only one taxon had Hg concentration as a primary explanatory variable. Sediment quality triad data revealed that there was no toxicity or effects on the invertebrate community at concentrations up to 18.9 µg/g total Hg (THg) or 102 ng/g methylmercury (MeHg). An evaluation of data from other freshwater sites from the SEDTOX database revealed no association with toxicity at sites with concentrations ranging up to 949 mg/g THg. The findings of these lines of evidence were further supported by sediment pore water analyses, which indicated that concentrations of THg and MeHg in sediment pore water samples from the South River were not consistent with concentrations associated with adverse effects to invertebrates in aqueous toxicity tests reported in the literature. The conclusion of the causal analysis is that although invertebrates themselves may contribute to the mercury uptake by other organisms, there is little if any direct risk to invertebrates in the South River.

**191 Causal Assessment of Biological Impairment in a Low Gradient Coastal California River: The Salinas River** S. Hagerthey, S. Norton, U.S. Environmental Protection Agency / National Center for Environmental Assessment. Biological impairment of California perennial streams is defined by a region specific benthic macroinvertebrate index of biological integrity (B-IBI) score. For the central coast, the southern California coastal IBI (SoCal B-IBI) is used, with values less than or equal to 39 being categorized

as "poor" and deemed as not meeting the biological objective. In 2006, biological assessment of four sites along the middle and lower Salinas River, Monterey County, had scores below the SoCal B-IBI impairment value of 39. The lower river sites had scores of 14 and 19 and were categorized as "very poor". In contrast, the low gradient middle river sites had scores greater than 24 and were considered "poor". We conducted a causal assessment that utilizes a pragmatic approach based on the U.S. Environmental Protection Agency's Stressor Identification Protocol ([www.epa.gov/caddis](http://www.epa.gov/caddis)) to identify the likely cause of the "very poor" IBI scores. Stakeholders assisted in identifying seven potential candidate causes. These were changes or alterations in dissolved oxygen, pesticides, metals, nutrients, ionic strength, flow, sediments, and physical habitat. A conceptual diagram and narrative were constructed for each candidate cause to link with potential sources and effects. Evidence from the case (i.e., data specific to the river) and from elsewhere (i.e., not specific to the river) were weighed against comparator sites to develop a "strength of evidence" score for each candidate cause. Scores were then used to identify the probable cause(s). Preliminary scoring suggested that dissolved oxygen and ionic strength were not the likely impairment causes. Pesticides, metals, nutrients, flow, sediments, and physical habitat could not be ruled out and were evaluated further using a weight of evidence approach. The advantages of conducting a causal assessment when biological objectives are not met are that it is scientifically defensible formal method, reproducible, prevents biases, may identify unexpected causal relationships, engages stakeholders and decision makers, and increases confidence that management actions will improve biological condition. **DISCLAIMER:** The views expressed in this presentation are those of the authors and do not necessarily reflect the views or policies of the U.S. Environmental Protection Agency.

**192 Leaching of Urban Biocides from Building and Construction**

**Materials: Use of LC-MS/MS for Detection in Storm Water Runoff and Wastewater** N. Stock, Trent University / Water Quality Centre; C.D. Metcalfe, Trent University / Environmental & Resource Studies, Trent University / Department of Environmental & Resource Studies. Urban biocides, particularly those used in building and construction materials that have the potential to leach to the aquatic environment during rain storm events, have recently become a class of contaminants of emerging concern. A liquid chromatography – tandem mass spectrometry (LC-MS/MS) method has been developed to analyze for three target urban biocides: Terbutryn, Mecoprop and Irgarol 1051. A series of samples including storm water runoff, wastewater, and receiving water from Southern Ontario were analyzed, and ng/L concentrations of the three target urban biocides were observed. To confirm identity of these a quadrupole – time of flight (QTOF) mass spectrometry method for accurate mass measurements and investigation of isotopes was also developed.

**193 Screening Wastewater Effluent and River Water for Emerging Micropollutants using a Multi-residue GC-MS-AIQS Database method**

M. Allinson, University of Melbourne / CAPIM; F. Shiraiishi, D. Nakajima, National Institute for Environmental Studies; G. Allinson, Department of Primary Industries, Victoria / Future Farming Systems Research Division. Urban municipal wastewaters may contain a large number of organic chemicals, some of which, when discharged to receiving waters, may prove directly toxic to organisms living therein, while others may elicit more subtle effects, including eliciting endocrine disrupting effects. Managing the effects of such contaminants ultimately requires information on effluent toxicity and chemical concentrations. Preliminary screening of samples using rapid assessment tools is an increasingly attractive prospect for treatment plant and waterways managers. Rapid screening does not preclude the innovative use of more traditional techniques, such as gas chromatography – mass spectrometry (GC-MS). Kadokami et al. (2005) developed a new method combining a mass-structure database with GC-MS (the Automated Identification and Quantification System with GC-MS Database system, or GC-MS-AIQS-DB) that can screen samples for more than 900 semi-volatile compounds, including numerous halogenated and non-halogenated hydrocarbons, polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyl compounds (PCBs), and range of pharmaceutical and personal care products (PPCPs), and pesticides. In 2007, samples of treated effluent were collected at point of discharge to the environment from 40 WWTPs located across Victoria, Australia. The wastewater treatment plant samples investigated in this study were prepared using relatively straightforward process involving solid-phase extraction, and then tested using the GC-MS-AIQS-DB method. Chemicals observed in one or more effluents included food additives (dibenzylether, 98% of the 40 effluents), various alkyl phenols (4-*t* octylphenol, 20%; bisphenol A, 13%), tyre leachates (e.g. 2(3H)-benzothiazolone, 40%), flame retardants (TBP, 68%; TCEP, 83%), antioxidants (BHT-aldehyde, 45%), insect repellents (DEET, 93%), stimulants (caffeine, 18%) and anticonvulsants (carbamazepine, 68%). Of the 451 pesticides screened, carbamate insecticides (bendiocarb, 33%, propoxur, 40%), and herbicides (simazine, 35%) were amongst the compounds observed. By using the GC-MS-AIQS-DB screen, a single analytical method can be used to cover the large number of compounds, reducing the concomitant financial implications associated with operating multiple definitive tests.

**194 Quaternary ammonium compounds as improved tracers of sewage affected particles and sediments as well as potential contaminants of emerging concern**

A.C. Doherty, Stony Brook University / School of Marine and Atmospheric Sciences, Stony Brook University / graduate student; X. Li, Connecticut Agricultural Experiment Station / Analytical Chemistry; B.J. Brownawell, Stony Brook University / School of Marine and Atmospheric Sciences, Stony Brook University / Marine Sciences Research Center. Studies of quaternary ammonium compounds (QACs) in sediments from urbanized estuaries near the New York metropolitan region indicate that they are typically present in higher abundances than classes of synthetic organic compounds. Total concentrations of 20 targeted QACs average approximately 30 µg/g in muddy sediments of Jamaica Bay, western Hempstead Bay and other areas of the Lower Hudson Basin. Owing to high sensitivity of analysis afforded by electrospray ionization mass spectrometry, a large number of QAC analytes can be very easily detected at distances up to 70 km from sewage sources. Although little studied in the field to date, elevated concentrations alone do not necessarily indicate that QACs should

be classified as CECs. These cationic surfactants merit further investigation due to the antimicrobial properties possessed by some QACs (e.g., benzalkonium compounds and shorter alkyl chain dialkyldimethylammonium compounds (DADMACs)), where concentrations in sediments are appreciably higher than the more extensively studied triclocarban, triclosan and fluoroquinolone antibiotics. It may be that strong sorption of QACs to sediments limits influence on microbial communities. Other reasons for further studies of QACs include the fact that the more abundant and hydrophobic DADMACs (fabric softeners) and the newly discovered behentrimonium compounds (hair care products) may be uniquely suited as source specific tracers of sewage affected particles and their sorbed contaminants. While the hydrophobicities of the 20 targeted QACs vary by many orders of magnitude, the persistence of QAC tracers is inferred by similarities in composition between suspended particles collected at a sewage outfall and in sediments at variable distances away, as well as studies of their persistence in sediment cores. In recent years significant attention has been paid to the application of more soluble organic wastewater contaminants as sewage source indicators, yet many chemical and microbial contaminants of concern are primarily transported associated with sediments or particulate phases. In this presentation we compare and contrast what we know about the properties and behavior of QACs with other proposed tracers of sewage derived particles, as well as illustrate applications where QACs appear to provide useful source allocation information for particle reactive contaminants such as di-ethylhexyl phthalate and brominated flame retardants.

**195 What Goes Down the Drain Eventually Reaches the River: Characterizing Emerging Contaminants in the Columbia River Basin**

J. Morace, USGS Oregon Water Science Center, US Geological Society; E.B. Nilsen, USGS Oregon Water Science Center / OWSC. Toxic contamination is a significant concern in the Columbia River Basin in Washington and Oregon. To help water managers and policy makers in decision making about future sampling efforts and toxic-reduction activities, a reconnaissance was done to assess contaminant concentrations directly contributed to the Columbia River through wastewater-treatment-plant (WWTP) effluent and stormwater runoff from adjacent urban environments and to evaluate instantaneous loadings to the Columbia River Basin from these inputs. Nine cities were selected in Oregon and Washington to provide diversity in physical setting, climate characteristics, and population density. Samples were collected from a WWTP in each city and analyzed for anthropogenic organic compounds, pharmaceuticals, PCBs, PBDEs, organochlorine or legacy compounds, currently used pesticides, mercury, and estrogenicity. Of the 210 compounds analyzed in the WWTP-effluent samples, 112 (53 percent) were detected, and the detection rate for most compound classes was greater than 80 percent. Despite the differences in location, population, treatment type, and plant size, detection frequencies were similar for many of the compounds detected among the WWTPs. By contrast, the occurrence of PAHs was sporadic, and PCBs were detected at only three WWTPs. With a better understanding of the presence of these contaminants in the environment, future work can focus on developing research to characterize the effects of these contaminants on aquatic life and prioritize toxic reduction efforts for the Columbia River Basin. One example is an interdisciplinary project designed to assess contaminants and characterize habitats in the lower Columbia River basin provides an example of this type of research. Using a foodweb approach, emerging contaminants, particularly PBDEs and endocrine-disrupting compounds, are being determined in osprey (a fish-eating raptor), the fish they eat – largescale suckers (*Catostomus macrocheilus*, a bottom-feeding fish), the water column, streambed sediment, and benthic invertebrates. Multiple fish biomarkers, including those focused on size, reproduction, and organ function, provide an assessment of the potential biological effects of these contaminants. The ultimate goal is to provide information about contaminant distributions in the system and contribute to understanding how emerging contaminants are affecting the ecosystem and the foodweb in the lower Columbia River.

**196 Pharmaceuticals and Personal Care Products (PPCPs) in a Wastewater Receiving Stream During Normal and Low Flow Conditions**

A.J. Jones, Clemson University / Institute of Environmental Toxicology, Clemson University / Institute of Environmental Toxicology; E. Carraway, Clemson University / Department of Environmental Engineering and Earth Sciences. The Reedy River, located in the piedmont of South Carolina, is a stream receiving effluent from two wastewater treatment facilities (WWTP) serving the greater metropolitan area of Greenville, SC. The work presented

here details two sample collections during a normal flow condition and a low flow condition. EDCs and NSAIDs can result in negative effects on aquatic populations at very low concentrations (ng/L, pg/L) in surface waters. Variability in pharmaceuticals and PPCPs under low flow situations has been poorly studied. Sample enrichment was accomplished with solid phase extraction (Waters Oasis HLB) and the samples were analyzed using liquid chromatography – tandem mass spectrometry (Varian 320 MS). Analytes of interest are caffeine, diphenhydramine, ibuprofen, naproxen, triclosan, estrone, 17 $\beta$ -estradiol, and 17 $\alpha$ -ethynylestradiol. The results indicate significantly higher concentrations of all analytes, with the exception of estrone, during low flow conditions. In addition, caffeine and diphenhydramine were found in the Reedy at locations upstream of the two WWTP outfalls. Generally decreasing analyte concentrations on a downstream gradient from the WWTP inputs to the stream suggest some removal mechanisms which may include sorption and degradation.

**197 A novel approach to describe the total PPCP contamination in aqueous environments** J.L. Conkle, W. Wang, J.O. Sickman, University of California Riverside / Environmental Sciences; J. Gan, University of California Riverside. There are numerous studies documenting the presence of pharmaceutical and personal care products (PPCPs) in the environment, specifically near wastewater effluent, septic discharge and large-scale agricultural operations. However, there is no general method to quantify total PPCP contamination levels of a water sample, compare effectiveness of treatment technologies or to simplify statistical analysis of complex, variable data sets within or across studies. In this presentation we propose multiple empirical equations to describe the total PPCP contamination in aqueous samples. Each equation was developed using concentrations from 21 previously published studies (with 284 total samples) on PPCPs in aquatic environment. We then applied the best-suited equation to a survey of PPCPs in surface and groundwater of Beaumont, CA. PPCP contamination was observed in surface water samples and multiple groundwater wells as a result of septic discharge, managed aquifer recharge and riverbank filtration. Index values of surface water samples downstream of a wastewater treatment plant discharge were similar to those observed in the review of literature for wastewater effluent, which is the main source of water in this tributary. Additionally, groundwater nearby this tributary reflected the level of PPCP contamination observed in the overlying surface water. Index values observed in groundwater elsewhere in the basin were lower, reflecting contamination from the state water project and septic systems. Through the examination of additional literature, we also present multiple proofs of concept to demonstrate the utility of index values to compare water treatment technologies within and across studies, the ability to compare sample collection, extraction and analytical techniques and also the ability to simplify statistical analysis of large PPCP datasets.

**198 Occurrence of pharmaceuticals and their metabolites in urban aquifers of Barcelona metropolitan area. Impact of recharge sources.** D. Barcelo, ICRA / Environmental Chemistry, ICRA / Catalan Institute for Water Research, IDAEA-CSIC / Environmental Chemistry Department, Catalan Institute for Water Research (ICRA) / Environmental Chemistry Department; R. Lopez-Serna, IDAEA-CSIC; M. Petrovic, ICRA – Catalan Institute for Water Research. Groundwater is an important resource of water supply in the world and urban aquifers are especially vulnerable to contamination by a variety of contaminants. Groundwater in urban aquifers from the Barcelona metropolitan area suffers pollution from different sources, including losses from water supply networks, leakage from sewers, direct rainfall recharge, recharged from the river Besos and seawater intrusion. Previous study showed that contaminants, such as surfactants and their degradation products (i.e. nonylphenol ethoxylates (NPEO), nonylphenol carboxylates (NPEC), nonylphenol (NP) and linear alkyl benzene sulfonates (LAS)) are present at high concentrations (mg/L level) in aquifers recharged by the river Besos showing clear dependence on the sources of recharge or/and pollution containing these substances and ground water redox conditions. Similarly groundwater in the Barcelona area was found to contain low concentrations of drugs of abuse. The highest groundwater concentrations (around 200 ng/L) and the largest number of detected compounds were found in zones recharged by a river that receives large amounts of effluents from wastewater treatment plants. This study reports on the occurrence of pharmaceuticals and their metabolites. 95 compounds belonging to different classes are analyzed in 37 urban groundwater samples collected in the city of Barcelona using optimized and validated on-line solid phase

extraction-liquid chromatography-tandem mass spectrometry (SPE-LC-MS/MS) method. A wide range of pharmaceuticals are detected being the predominant contaminants the most consumed anti-inflammatory drugs (naproxen, ibuprofen, diclofenac),  $\beta$ -blockers (metoprolol), lipid regulators (gemfibrozil) and antibiotics (azithromycin, erythromycin, ofloxacin, sulfadiazine). It is important to mention finding of several metabolites (in some cases in concentrations higher than of parent compounds), such as carbamazepine metabolites 10,11-epoxy carbamazepine, 2OH- and 3OH carbamazepine, desmethyl diazepam, N-acetyl sulfadiazine, 4OH diclofenac, 4OH propranolol and enalaprilat which shows the importance of monitoring metabolites and transformation products in order to properly assess the risk posed by pharmaceutical compounds. Acknowledgements: Authors would like to thank the Spanish Ministry of Economy and Competitiveness for its financial support through the project SCARCE (Consolider-Ingenio 2010 CSD2009-00065)

**199 Halogenated byproducts generated through wastewater treatment in secondary effluent** D.N. Bulloch, University of California Riverside / Chemistry, University of California Riverside; A. Ramkishun, University of California Riverside / Chemistry; C.K. Larive, University of California Riverside / Department of Chemistry; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; J. Armstrong, Orange County Sanitation District / Environmental Compliance & Monitoring. The study of disinfection by-products of pharmaceuticals in wastewater is an emerging field. Most by-products of known contaminants are unregulated, and may have altered physiochemical properties and toxicity profiles compared with the parent. Our previous work determined the levels of halogenated byproducts of the lipid regulator gemfibrozil as generated by primary wastewater treatment followed by chlorination, with a monochlorinated analog occurring at 166 ng/L and a monobrominated analog occurring at 50 ng/L in a final effluent grab sample. Herein this research is extended to measuring the levels of several pharmaceutical and personal care products and their halogenated analogs as potentially formed by chlorination treatment in a secondary effluent grab sample from a Southern California wastewater treatment plant. The parent compounds are the lipid regulator gemfibrozil, the analgesic salicylic acid, the surfactant 4-nonylphenol, the non-steroidal anti-inflammatory diclofenac, and the plasticizer bisphenol A, all of which have been reported in the literature to form halogenated analogs upon exposure to chlorine. In addition, the octanol-water partition coefficients of each parent compound and their halogenated analogs were determined by a microcentrifuge tube-based shake-flask protocol. Experimental partition coefficients for the halogenated analogs are compared to calculated values as generated by the US EPA's Estimation Programs Interface Suite.

**200 TINE: The fate, behavior, and ecotoxicology of manufactured nanomaterials in terrestrial ecosystems** P.M. Bertsch, University of Kentucky / Department of Plant and Soil Sciences; S. McGrath, Rothamsted Research / Soil Science Department; J.M. Unrine, University of Kentucky, University of Kentucky / Department of Plant and Soil Sciences, University of Kentucky / Department of Plant & Soil Sciences, University of Kentucky / Savannah River Ecology Laboratory, University of Kentucky / Department of Plant and Soil Sciences, University of Georgia / Savannah River Ecology Laboratory; O.V. Tsyusko, University of Kentucky / Department of Plant & Soil Sciences; N.J. Kabengi, D.M. McNear, University of Kentucky / Plant and Soil Sciences; G.V. Lowry, Carnegie Mellon University / Dept. of Civil and Env. Engineering, Center for the Environmental Implications of NanoTechnology; E. Casman, Carnegie Mellon University; M. Wiesner, Duke University / Civil and Environmental Engineering; J. Liu, Duke University; A. Neal, Rothamsted Research; B. Jefferson, R. Dorey, K. Ritz, J. Harris, S. Rocks, Cranfield University; S. Lofts, NERC Centre for Ecology & Hydrology / Shore Section; D. Spurgeon, NERC Centre for Ecology and Hydrology; C. Svendsen, Centre for Ecology & Hydrology, Monks Wood / Pollution and Ecotoxicology, NERC Centre for Ecology & Hydrology / Hails Section, NERC Centre for Ecology & Hydrology / Ecotoxicology; H. Zhang, Lancaster University. We have developed a life cycle perspective inspired conceptual model (CM) that indicates terrestrial ecosystems as a major repository for ZnO, TiO<sub>2</sub>, and Ag manufactured nanomaterials (MNMs) introduced via the land application of MNM-containing biosolids. In this project we are investigating the transport, fate, behavior, bioavailability, and effects of MNMs in (to) agroecosystems under environmentally realistic scenarios organized around three key hypotheses: Hypothesis (H1)

Surface chemistry is the primary factor influencing the fate and transport of MNMs in the terrestrial environment as well as the bioavailability and effects to biological receptors; Hypothesis (H2) Once released to the environment, pristine MNM surfaces will be modified by interactions with organic and inorganic ligands (macromolecules) or via other biogeochemical transformations (aging effects forming a-MNMs); Hypothesis (H3) Ecoreceptors will respond to interactions with pristine metal and metal oxide MNMs, a-MNMs, and/or dissolved constituent metal ions and bulk oxides by specific ecological and toxicogenomic responses that will reflect their combined effects. The overall objectives are to: O1) Compare the transport, fate, behavior, bioavailability, and effects of MNMs, a-MNMs, and/or dissolved free metals/bulk oxides to organisms with key terrestrial ecosystem functions, as well as exposure pathways involving humans; O2) Determine MNM, surface modified MNM and a-MNM interactions with important biological targets relevant to the BLM and pBRM models and relate these interactions to physicochemical properties; O3) Validate models with information generated from experiments designed to address O1 for MNMs introduced through a pilot scale Waste Water Treatment Process (WWTP) to key terrestrial ecoreceptors, including effects of MNMs on the WWTP itself; O4) Determine realistic MNM emission scenarios for Tier 1 MNMs in wastewater from the WWT pilot plant data and develop first generation Life-Cycle-Analysis-inspired Risk Assessment (LCA-RA) model components for terrestrial effects of Tier 1 MNMs and a-MNMs based on data generated in experiments designed to address O1, O2, & O3; and O5) Provide tools for in situ detection, monitoring, and characterization of pristine MNMs and a-MNMs in environmental media and biota. The key results from aging and toxicity studies will be presented.

#### **201 Chemical Weathering of Ag and ZnO Nanoparticles in the Presence of Inorganic Sulfide or Inorganic Sulfide/Phosphate Aqueous Environments**

G.V Lowry, Carnegie Mellon University / Dept. of Civil and Env. Engineering, Center for the Environmental Implications of NanoTechnology; R. Ma, Carnegie Mellon University / Civil and Environmental Engineering, Center for the Environmental Implications of NanoTechnology (CEINT); S. Rathnayake, University of Kentucky; J. Stegemeier, Carnegie Mellon University; C. Levard, Stanford University; J. Unrine, P. Bertsch, University of Kentucky. Benthic environments will be a sink for many manufactured nanomaterials (MNMs), especially for MNMs (e.g. Ag(0) and ZnO) used in health and hygiene products because they enter wastewater streams, partition to sewage sludge, and then are used as a soil amendment in agro-ecosystems. MNMs made from class B metals are likely to be readily transformed in sulfidic environments. In biosolids, competing ligands (e.g. phosphate) may further alter the speciation, and in turn alter the particle properties, e.g. solubility and toxicity potential. To assess risk we must understand these weathering reactions and identify the stable weathering products as these are what organisms will be exposed. This work, conducted as part of the Transatlantic Initiative for Nanotechnology and the Environment (TINE), determines the morphology, speciation, and properties of Ag and ZnO NPs in the presence of sulfide, and determines the speciation of ZnO NPs in the presence of the competing ligands sulfide and phosphate. Both Ag and ZnO NPs readily sulfidize upon exposure to inorganic sulfide. Partially sulfidized Ag and ZnO NPs form by using a range of metal to sulfide ratios. Partial sulfidation significantly decreases the solubility of Ag NPs but not ZnO NPs. This suggests that Ag NPs are sulfidized directly without significant dissolution, but that ZnO NPs dissolve followed by precipitation of ZnS. This is confirmed by formation of a coherent Ag-sulfide shell on Ag NPs, but a ring of 4nm ZnS particles surrounding ZnO NPs. Upon exposure to phosphate, ZnO is readily phosphorylated, but with sulfide also present they are primarily sulfidized. The factors that affect phosphorylation vs. sulfidation of ZnO in biosolids are being investigated. Overall, these studies suggest that both ZnO and Ag NPs will be readily sulfidized in biosolids where ample sulfide is present and the system is anoxic, but that the speciation of Zn in biosolids may also include Zn-phosphate (e.g. hopeite) if the redox conditions change. These studies also indicate that a range of Ag(0)/Ag<sub>2</sub>S and ZnO/ZnS ratios can be synthesized in the laboratory. These particles may be more representative of those materials found in the environment useful for subsequent toxicity testing.

#### **202 Comparison of the fate and impact of dissolved and nanoparticle metals on sewage treatment and biosolids production**

B. Jefferson, B. Martin, M. Pawlett, R. Dorey, S. Rocks, K. Ritz, J. Harris, Cranfield

University. Manufactured nanomaterials are increasingly used in consumer products with a large proportion discharged to wastewater treatment facilities leading to the potential transmission pathways into both aquatic and terrestrial ecosystems. Recent estimates suggest that up to 90% of some nanomaterials may end up in sewage highlighting the importance of a clear understanding of their fate so that effective risk assessments can be developed. Whilst there is a growing intensity of studies on the topic information related to real sewages and the ageing effects of NP residence within sewage matrices remains limited. The proposed presentation will outline current activities as part of a joint UK-US consortium investigating the fate and impact of nanoparticles in sewage biosolids. Three identical pilot sewage treatment facilities have been set up to treat real raw sewage incorporating sedimentation, activated sludge, thickening, anaerobic digestion and dewatering processes to mimic the processes most likely to be encountered. A mixture of titanium, silver and zinc nanoparticles are being dosed into both the primary sludge and the activated sludge components prior to mixing and biosolids production in anaerobic digestion and dewatering. One of the other identical lines is dosed with an equivalent concentration of dissolved metals to ascertain any NP specific effects and the final line is operated without dosing as a control. All plants are operated under standard conditions and were stabilised for three sludge ages prior to start of analysis. Comparison of the partitioning rates into the final bio-solid product revealed that in the case of titanium and zinc less total metal associated with the biosolids in the NP dosed line compared to the metal salt dosed line. In contrast, in the case of silver more of the total metal content associated to the sludge in the NP dosed line. No statistical difference between NP dosed and metal salt dosed lines could be observed in terms of organics removal, nitrification, solids destruction, biogas generation although difference in the microbial community within the NP dosed lines were apparent. Current work is fractionating the different liquid streams across the treatment lines to establish the colloidal banding of the metals and this data will also be presented.

#### **203 Effects of soil chemistry of zinc and zinc oxide NP toxicity to the earthworm *E. fetida***

S. Lofts, NERC Centre for Ecology & Hydrology / Shore Section; L. Heggelund, E. Lahive, NERC Centre for Ecology and Hydrology / Hails Section; D. Spurgeon, NERC Centre for Ecology and Hydrology; C. Svendsen, Centre for Ecology & Hydrology, Monks Wood / Pollution and Ecotoxicology, NERC Centre for Ecology & Hydrology / Hails Section, NERC Centre for Ecology & Hydrology / Ecotoxicology. Metal and metal oxide nanoparticles present a series of challenges for terrestrial ecotoxicology. Chemical transformations of the nanoparticle may modify the exposure of organisms to nanoparticles. Additionally, the chemistry of the soil itself may influence exposure, for example by promoting particle aggregation or dissolution. Within the TINE project, we aim to develop models to take account of these processes, based on sublethal exposures of zinc oxide (ZnO) and silver (Ag) particles to the earthworm *Eisenia fetida* across a range of soil types. The exposure model will account for (i) particle dissolution and consequent toxicity of the ionic metal across soil types; (ii) variation in the toxicity of undissolved nanoparticles across soil types. Initial results will be shown from earthworm exposures to ZnO nanoparticles, non-nano ZnO and ionic Zn, in a set of soils created in the laboratory by liming of an acidic heathland soil from the southern UK. Initial results show that (i) exposure to all three types of Zn result in effects on earthworm reproduction; (ii) the toxicity consistently increases with decreasing soil pH; (iii) ZnO, both nano and non-nano, is consistently less toxic on a Zn basis than ionic Zn; (iv) the toxicity in ZnO exposures cannot be solely attributed to ionic Zn formed by particle dissolution; (v) accumulation of Zn by the worms is higher in particle exposures than in ionic exposures. Taken together, these findings suggest that direct nanoparticle toxicity to earthworms does occur in soil exposures. The differences in uptake and toxicity between ZnO particles and ionic Zn suggest that (i) particles are directly taken up by earthworms; (ii) uptake does not trigger zinc elimination processes in the worm, hence the relatively high accumulation of Zn in particle exposures; (iii) on a Zn basis, particles are less toxic to worms than ionic Zn once within the tissues. We will discuss these findings in the context of developing the concepts behind the earthworm-nanoparticle exposure model.

#### **204 nanoBEE; a joint US-UK project to model exposure, bioavailability and toxicity of nanoparticles**

J. Lead, University of Birmingham / School of Geography, Earth and Environmental Science. This talk will give an overview of the nanoBEE project which aims overall to validate a set of

exposure, bioavailability and toxicity models so that they are both scientifically valid and usable by regulators and industry. After the scene setting, the synthesis of size and surface coating selected silver nanoparticles will be discussed. Finally, the presentation will focus on the behaviour of these nanoparticles in toxicology media over suitable time periods which mimic standard exposure times. Dynamic changes in particle properties such as aggregation, oxidation, dissolution and surface changes will be examined as will the effects of media modification. Changes in dose and the nature of the toxicant in media will be highlighted and related to toxicity studies under the same media conditions.

#### 205 Environmental Exposure and Toxicity of Engineered Nanomaterials

V. Colvin, Rice University; P.J. Alvarez, Rice University / Civil & Environmental Engineering; E. Contreras, H. Puppala, Rice University. In order to understand and develop models that can predict the environmental fate of nanomaterials (NMs) in the environment well characterized NMs are required. With this aim in mind our group has developed an organic synthetic approach for oleic acid stabilized silver nanocrystals without employing an additional size separation technique. The diameter of the nanocrystals can be controlled over a wide range from two to fifteen nm with narrow size distribution ( $\sigma < 15\%$ ). Facile ligand exchange of oleate with thiol functionalized methyl-poly(ethylene glycol) (mPEG-SH, MW 5KDa) transformed silver nanocrystals to hydrophilic with retention of optical properties. Further, stability of pegylated silver nanocrystals in high ionic media extends its applications to environmental studies involving complex matrices. The work presented herein will discuss our synthetic technique and the use of these NPs to understand factors that influence the stability and dissolution of Ag NPs (e.g. size, medium, etc). In addition to understanding the NMs physical and chemical properties, to fully understand the biological and environmental impacts of nanomaterials requires studies which address both sub-lethal endpoints and multigenerational effects. Here we use a nematode to examine these issues as they relate to exposure to two different types of QDs, core (CdSe) and core-shell (CdSe/ZnS), and compare the effect to those observed after cadmium salt exposures. The strong fluorescence of the core-shell quantum dots allows for the direct visualization of the materials in the digestive track within a few hours of exposure. Multiple endpoints, including both developmental and locomotive, were examined at QD exposures of low (10 mg/L Cd), medium (50 mg/L Cd), and high concentrations (100 mg/L Cd). While the core-shell QDs showed no effect on fitness (lifespan, fertility, growth, and three parameters of motility behavior), the core QDs caused acute effects similar to those found for cadmium salts. Over multiple generations, we commonly found that for lower life-cycle exposures to core quantum dots the parents response was generally a poor predictor of the effects on progeny. At the highest concentrations, however, biological effects found for the first generation were commonly similar in magnitude to those found in future generations.

#### 206 Tracing bioavailability of metal oxide nanoparticles using stable isotope labeling

T.S. Galloway, University of Exeter / Biosciences Department; S. Dogra, University of Exeter; F. Larner, Imperial College; A. Dybowska, Natural History Museum; E. Valsami Jones, University of Birmingham; M. Rehkamper, Imperial College; J. Lead, B. Stohlpe, University of Birmingham; C. Tyler, University of Exeter. Metal oxide nanomaterials have a wide range of uses in industrial applications and consumer products, and there is a pressing need for risk assessments for human and environmental health. For many metals, high background concentrations in natural systems hinder the interpretation of exposure studies at environmentally relevant exposure concentrations. Aim: To study the bioaccumulation and biological effects of ZnO nanoparticles (ZnO NPs) in a model invertebrate test species, using stable isotope tracing methods with high detection sensitivities. Methods: The amphipod *Corophium volutator* (mud shrimp) is an OECD test species and constituent of the marine food web.  $^{68}\text{ZnO}$  NPs were synthesised using wet chemistry. We exposed *C. volutator* in simple microcosms to DEG- $^{68}\text{ZnO}$  NPs (diameter 30nm), and  $^{68}\text{ZnO}$  in bulk and soluble forms for 10 days, and evaluated the partitioning of particles/ionic Zn between water column, sediment and body tissues. Coherent anti-stokes Raman spectroscopy (CARS), TEM and EDX helped establish the uptake and tissue distribution of particles *in situ*. Multiple collector ICP-MS was used to evaluate the Zn isotopic ratios in samples. Results: Our results show that uptake of  $^{68}\text{Zn}$  from particles into storage tissues of the organism is active, and appears to proceed through normal physiological processes. Comparable work with  $^{109}\text{Ag}$  is underway and we will also present our latest results with

this material. Conclusions: Our work illustrates the sensitivity of stable isotope tracking for studying nanoparticles in complex environmental settings and offers insight into the biological methods used to detoxify metal oxides and NPs *in vivo*.

#### 207 The utility of human ADME data for prioritizing the evaluation of pharmaceuticals in the environment

J. Berninger, Baylor University / Department of Environmental Science; C. LaLone, U.S. EPA; C. Russom, U.S. EPA / Mid-Continent Ecology Division; J.E. Tietge, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division. To proceed in the investigation of potential effects of pharmaceuticals in the environment, a cohesive data collection strategy is paramount. Given the lack of data for aquatic species, prioritization seems a logical starting point. Several methods have been put forward, for example using predicted persistence, bioaccumulation, and toxicity characteristics or sales data models. While these models are valid, critical prioritization strategies, they are not sufficiently comprehensive. Pharmaceuticals are biologically active, with specific physiological targets, suggesting that models built solely on physical-chemical properties and exposure potential cannot be adequate for prioritization. Given the nature of pharmaceuticals, the overall prioritization should include chronic effects and ADME (absorption, distribution, metabolism, excretion) parameters. The lack of available aquatic species data requires the development of an ADME-based prioritization model using read-across from the extensive mammalian knowledge-base. ADME data for 750 drugs were collected including: apparent volume of distribution, clearance rate, half life, protein binding, and therapeutic dose. For this initial prioritization, a probabilistic model was applied to data from each parameter, and subsequently divided into categories based on the each 10<sup>th</sup> centile. Each centile group was given a corresponding score of 1 to 10 ( $< 10^{\text{th}}=1$ ,  $10^{\text{th}}-20^{\text{th}}=2 \dots < 90^{\text{th}}=10$ ). Higher scores were based on the likelihood of increased absorption and distribution, or decreased metabolism or elimination. Scores were tallied for each individual drug and summed across all parameters. The resulting prioritized list looks quite different (with some overlap) from lists created from previous prioritization exercises. The unique pharmacokinetic nature of this list provides a basis for the development of testable hypotheses. This ADME-based list has been used to identify potential additions to analyte list for environmental sample analysis. Internally, the prioritized list has been used to focus research decisions in the process of validating an ADME read-across model. As part of the cohesive strategy moving forward, ADME prioritization should be included as a tool within the overall prioritization strategy, with the highest testing priority given to drugs which rank highly using multiple prioritization schemes. The contents of this abstract neither constitute nor reflect official US EPA policy.

#### 208 Identification of a novel androgen receptor agonist (or "androgen mimic") of environmental concern: spironolactone

C. LaLone, U.S. EPA; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory; M. Kahl, U.S. EPA / National Health and Environmental Effects Research Laboratory; E. Durhan, US EPA / Mid-Continent Ecology Division, US-EPA / Research Chemist; E. Makynen, US EPA / Mid-Continent Ecology Division; K. Jensen, U.S. EPA / National Health and Environmental Effects Research Laboratory; J. Cavallin, U.S. EPA, ORISE / National Health and Environmental Effects Research Laboratory; K. Stevens, M. Severson, US EPA; J. Berninger, Baylor University / Department of Environmental Science; S.Y. Skolness, University of Minnesota / Department of Biochemistry and Molecular Biology; J.E. Tietge, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / Mid-Continent Ecology Division; C. Russom, US EPA; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory. Spironolactone is a pharmaceutical that acts as an androgen receptor (AR) antagonist in humans to treat certain conditions such as hirsutism, various dermatologic afflictions, and female pattern hair loss. The drug is also used to treat hypertension as a diuretic. With this common usage in humans it is conceivable that spironolactone could enter aquatic environments, and indeed has been detected downstream of a pharmaceutical manufacturer.

Predictive methods to analyze human AR orthology suggest that vertebrates would be highly sensitive to chemicals that target the AR compared to invertebrate species. As a means to assess the predictive nature of molecular target orthology leading to unintended effects, 21-d reproduction studies were conducted with two fish species, *Pimephales promelas* (fathead minnow) and *Oryzias latipes* (Japanese medaka) and the invertebrate *Daphnia magna*. Spironolactone significantly reduced fecundity of medaka and fathead minnows at test concentrations of 50 and 5 µg/L, respectively, whereas *Daphnia* reproduction was not affected at 500 µg/L. Masculinization of females of both fish species was observed at 5 µg/L and 0.5 µg/L as evidenced by development of papillary complexes on medaka and tubercle formation on fathead minnows, respectively. Effects in fish occurred at concentrations below those reported in the environment. These results suggest that species with greater orthology to the human AR are susceptible to spironolactone. Further, this drug has the potential to affect reproduction in fish and should be included in environmental monitoring for contaminants of emerging concern. The contents of this abstract neither constitute nor reflect official US EPA policy.

#### 209 Assessing the ecological impacts of pharmaceuticals on invertebrates: insights from a multigenerational study on a common freshwater gastropod

**T.O. Luna**, Texas Tech University/TIEHH / Environmental Toxicology, Texas Tech University; **C.J. Salice**, Texas Tech University / Environmental Toxicology, Texas Tech University / TIEHH, Texas Tech University / Department of Environmental Toxicology. A number of pharmaceuticals have been detected in North American surface waters and are cause for toxicological concern, as some are known endocrine disruptors (EDs). EDs, in particular, can exert sublethal effects at environmentally relevant exposure concentrations in a wide range of vertebrate test species. Unfortunately, fewer studies have focused on understanding the effects of endocrine disruptors on invertebrates. Molluscs, for example, impact primary production, serve as food for small carnivores and can dominate macroinvertebrate biomass. While there are some studies on effects of pharmaceuticals on molluscs, these are limited to a few species and are generally of short duration even though many species can live a year or more. Our objective was to evaluate the effects of multigenerational exposure to commonly occurring pharmaceuticals on life history traits in the freshwater gastropod, *Physa pomilia*. *P. pomilia* was monitored during two generations of continuous exposure to 17- $\alpha$  ethynylestradiol (EE2; 1.0 µg/l, 0.1 µg/l, 0.01 µg/l, 0.0 µg/l) and fluoxetine (100 µg/l, 1.0 µg/l, 0.01 µg/l and, 0.0 µg/l). EE2 is a synthetic hormone found in birth control and fluoxetine is a selective serotonin reuptake inhibitor used as an antidepressant. EE2 significantly affected time to first reproduction, hatching success, egg mass and total egg production but the second generation showed a stronger adverse response than the first. Similarly, fluoxetine significantly affected total egg masses, total eggs, hatching success, size, time to first reproduction, and mortality but, again, the observed effects were mainly in the second generation. Furthermore, the second-generation snails exposed to fluoxetine did not display a typical, monotonic dose response which has similarly been observed by others and suggests endocrine disrupting activity. Current efforts are focused on understanding how the observed effects translate to potential impacts on the population because, in many cases, effects of pharmaceuticals are stimulatory. This population-level assessment will be conducted using a range of population modeling tools to explore and identify the ecological impacts of pharmaceutical exposures to molluscs. Overall, this research provides additional insight into the effects of pharmaceuticals on freshwater invertebrates and points to the utility of multigenerational toxicity studies.

#### 210 The effect of antimicrobial tetracycline on the different levels of biological organization of *Daphnia magna* in multi-generations

**H. Kim**, Gwangju Institute of Science & Technology / Department of Environmental Science and Engineering, Gwangju Institute of Science & Technology / School of Environmental Science and Engineering; **T. Jeong**, Gwangju Institute of Science and Technology (GIST); **S. Kim**, Gwangju Institute of Science and Technology (GIST) / Environmental Science and Engineering. The objectives of this study were to investigate the effect of tetracycline on the different levels of biological organization of *Daphnia magna* to link between genomic and higher level phenotypic stress responses under multi-generational exposure. A range of studies regarding the effect of antimicrobial compounds on non-target organism has been reported, but it has been limited to the one biological organization level such as organism level response. Little is known about the integrated responses at

different biological organization levels. Moreover, toxicity change caused by multi-generational exposure has been reported in a few studies. Using the microarray study, it is expected that biological processes and interlinked pathways in respond to chronic tetracycline exposure to non-target organism can be identified. The target compound was continuously exposed to *D. magna* over four successive generations at the sublethal concentrations including 0.01-10.0 mg/L. For each generation, life-cycle toxicity test for 21 days in static renewal system was conducted. Reproduction and somatic growth related parameters were monitored for the organism level responses and energy related parameters such as energy reserves and consumption were estimated for sub-organism level responses to target compound. The expression of *D. magna* gene is expected to be influenced by the exposure concentration of tetracycline and generation number. Also, *D. magna* genes responded to chronic tetracycline exposure can also be categorized into several functional processes in metabolism and genetic information processes. In addition, the genetic change might have a significant relationship with other biological organization levels. Finally, the integration of responses at different biological organization levels and their relationship can be evaluated using the results of microarray study and phenotypic stress responses in sub-organism, organism and population level responses.

#### 211 Toxic Effects of Anti-Inflammatory Drugs in Neotropical Fish

**J.L. Ribas**, Federal University of Paraná / Pharmacology; **C. Silva**, L.F. Andrade, G.L. Galvan, Federal University of Paraná; **M.M. Cestari**, Federal University of Paraná / Genetic; **E.d. Trindade**, Federal University of Paraná / Cell Biology; **A.R. Zampronio**, H.C. Silva de Assis, Federal University of Paraná / Pharmacology. Several discarded drugs represent health human risks. The use of toxicological data obtained in cell culture may be useful to predict the effects on organisms such as fish and mammals. This work aimed to evaluate the effects of anti-inflammatory drugs as diclofenac (DIC), ibuprofen (IBU), acetaminophen (ACE) and dexamethasone (DEX) on nitric oxide (NO) production and the genotoxic potential (comet assay) of these drugs in anterior kidney cell cultures and erythrocytes from the freshwater fish *Hoplias malabaricus*. Cells from monocytic lineage were separated from the anterior kidney placed and left to adhere for 24h. After this period, non-adherent cells were removed and the remaining cells were treated with DIC(0.2 -2000µg/L), IBU(0.1 - 1000µg/L), ACE(0.025 - 250µg/L) or DEX(0.03-300µg/L) in the presence or absence of 1ng/mL lipopolysaccharide (LPS, *E. coli* 0111:B4). NO concentration was evaluated after 24h in the supernatant of the cultures and the genotoxicity assay was performed in the resulting control cell monolayer (without LPS). The genotoxic potential of these anti-inflammatory drugs was also evaluated, at the same concentrations, in erythrocytes from peripheral blood diluted 1:10 in saline, before contact with the drugs. Data was analysed by One-Way ANOVA followed by Bonferroni's post-hoc test or Kruskal-Wallis followed by Dunns test. There was a reduction in basal NO concentration at 0.2 to 200µg/L of DIC, while for IBU a significant reduction occurred at 100 and 1000µg/L. ACE and DEX reduced significantly basal NO production in all tested concentrations. DIC, IBU, ACE and DEX inhibited LPS-induced NO production in all concentrations tested. Regarding the genotoxicity, no damage was observed in all the concentrations tested. However, genotoxic damage was found in erythrocytes at the lower concentration of ACE, DIC and IBU (0.025, 0.2 and 0.1µg/L, respectively). For DEX, this damage was only observed at 30µg/L. These results suggest that some xenobiotics such as anti-inflammatory drugs may lead to a reduction in monocytic cells activation even though immunosuppression is not their main characteristic. Additionally, the anti-inflammatory drugs tested can have a potential genotoxic effect at low concentrations, but this activity depends on the tissue evaluated. Financial support: CNPq/CAPES

#### 212 Contaminants of Emerging Concern: Contrasting Effects of Pharmaceutical and Estrogen Exposure on Larval Predator Performance

**D.C. Rearick**, St. Cloud State University; **H. Schoenfuss**, St. Cloud State University / Aquatic Toxicology Laboratory, St. Cloud State University / Department of Biological Sciences WSB-273, St. Cloud State University / Department of Biological Sciences MS-273. Contaminants of emerging concern have been linked to numerous endpoints in adult fish. Few studies have examined exposure during earlier ontogenetic stages, where recruitment to reproductive maturity is greatly attenuated by predation. Contaminant induced impairment to escape performance coupled with considerable predation during the larval stage has the potential to cause rapid population decline for short-lived species such as the fathead minnow (*Pimephales*

*promelas*). The objective of this study was to examine the influence of 17- $\beta$  estradiol (E2) at environmentally relevant concentrations (20 ng/L and 100 ng/L) on fathead minnow escape performance. We used a pharmaceutical mixture to contrast consequences between the two contaminant classes. Two assays quantified larval response for individuals exposed 21-days post-hatch using 50% daily static renewal. To measure variation among innate escape behavior, performance elicited by a vibrational stimulus was captured using a high-speed camera (1000 frames/sec). Video data were digitized (ImageJ) to quantify body length (BL in mm), latency (msec), velocity (BL/msec), and total escape performance (BL/msec). To determine whether any decline in escape performance resulted in greater cohort mortality under predation, a predator (bluegill sunfish – *Lepomis macrochirus*) was introduced into an arena containing both contaminate exposed and control larvae. Predation was permitted until approximately half the prey remained. Treatment groups were randomized for staining using SE-Mark for post-predation larval differentiation. E2 exposure increased latency to response ( $p < 0.0001$ ), decreased velocity ( $p < 0.0001$ ), and diminished total escape response ( $p < 0.0001$ ). Survival was higher for control larvae ( $p < 0.0001$ ) with the mean percent ( $\pm 1$  SD) equal to  $55 \pm 13\%$ . No difference was found between E2 concentrations in either assay (Survival low:  $45 \pm 0.14\%$ ; high:  $44 \pm 0.12\%$ ). In contrast, pharmaceutical exposure had no influence on survival ( $p = 0.3$ ), suggesting variation exists among emerging contaminants of concern. Reduction in larval escape performance and survival is suggestive of a mechanism potentially influential to populations. Population modeling may provide foundational insight to understanding the influence of endocrine active compounds during early ontogenetic stages. Funding provided by LCCMR.

### 213 Dose dependent adverse outcomes correlated with specific genomic profiles in fathead minnows upon low-dose exposures to the pharmaceutical fluoxetine

**R. Klaper**, University of Wisconsin-Milwaukee / School of Freshwater Sciences, University of Wisconsin-Milwaukee / Great Lakes Water Institute; J. Weinberger, University of Wisconsin-Milwaukee / School of Freshwater Sciences; J.P. Crago, Great Lakes WATER Institute, University of Wisconsin-Milwaukee, / Student. Pharmaceuticals and personal care products (PPCP) have been found in surface waters globally but at low concentrations. These compounds are not acutely toxic but as they are designed to be bioactive at small concentrations they could have potential impacts on fish and other organisms. Fluoxetine, a selective serotonin reuptake inhibitor is one of the more commonly found compounds in freshwater systems but the impacts of this compound at low concentrations is poorly understood. Previous studies have shown an impact on feeding at relatively high concentrations but have not tested relevant environmental exposures. We tested the effects of low-level exposures of fluoxetine on the reproduction, behavior, and global gene expression patterns in the brain of the toxicological model species *Pimephales promelas* (fathead minnow) for a 4 week chronic exposure. Our data demonstrate that the impacts of fluoxetine on behavior and reproduction are dose and time dependent. In addition gene expression patterns differ significantly with dose and time and indicate that impacts occur at exposures that are lower than those seen using apical endpoints. Gene expression patterns also indicate the possible mechanisms for the increase in aggressive behavior in early exposure intervals versus longer-term exposures. Fluoxetine concentrations as low as 1  $\mu\text{g/L}$  were found to significantly impact certain behaviors in fathead minnow with the most dramatic changes occurring at 10  $\mu\text{g/L}$ . Gene expression patterns demonstrate a noticeable shift at 1  $\mu\text{g/L}$ . Previous studies have attributed impacts of these compounds to serotonin regulation and potential endocrine hormonal changes, however our research demonstrates that pathways involved with hematopoiesis, endocytosis, cell adhesion, neurogenesis, and plasticity are impacted without significant changes in hormone levels in either males or females at these low exposure levels. This is one of the first studies to examine global gene expression changes associated with chronic low-level exposures to fluoxetine and link these changes to adverse outcome endpoints.

**214 Environmentally-relevant mixture of fluoxetine and 17 $\alpha$ -ethynylestradiol reveals estrogen-like interactive effects in male goldfish** H. Silva de Assis, Federal University of Paraná; J.M. Zamora, University of Ottawa / Department of Biology; W.E. Lado, A.M. Al-Ansari, University of Ottawa; D.B. Simmons, J.P. Sherry, Environmental Canada; J.M. Blais, V.L. Trudeau, University of Ottawa. The antidepressant fluoxetine (FLX) and the major active metabolite norfluoxetine are

released to aquatic systems via sewage-treatment effluents with potential endocrine disrupting effects. The synthetic estrogen, 17 $\alpha$ -ethynylestradiol (EE2), is a biologically persistent analogue of estrogen that is widely used in oral contraceptives and hormone replacement therapy. The presence of EE2 in surface waters is attributed to municipal sewage discharges. To better understand possible interactions between these compounds, male goldfish were exposed to environmentally relevant aquatic concentrations of FLX (0.54  $\mu\text{g/L}$ , nominal) and EE2 (5 ng/L, nominal) alone and in combination for 14 days. Ethanol (1.4 mL/70 L tank) was the solvent carrier and also served as the control. Real-time reverse-transcription polymerase chain reaction was used to assess pharmaceutical effects on gene expression and liquid chromatography tandem mass spectrometry (LC-MS/MS) to analyse the plasma proteome. Peptide intensities were calculated from extracted ion chromatograms, or the sum of the precursor m/z abundance from the MS scans (~ chromatographic peak area). The results showed an increase in hepatic estrogen receptor  $\alpha$  (ER $\alpha$ ) and vitellogenin (VTG) gene expression by 1.9-2.4 fold in the FLX and EE2 groups, but this did not reach statistical significance ( $p > 0.05$ ). In marked contrast, co-exposure upregulated hepatic ER $\alpha$  ( $p < 0.05$ ) and VTG gene expression ( $p < 0.05$ ) by 5.5- and 5.3- fold, respectively. FLX and EE2 alone did not affect ER $\beta$ , but the co-exposure downregulated ER $\beta$  expression by 50% ( $p < 0.05$ ). In the plasma, a total of 750 proteins were matched and validated, and the average percent yield of matched and validated spectra was 7%. Of those valid proteins, 474 were identified as network-eligible molecules. There was a significant increase in the number of proteins expressed in goldfish that were related to endocrine system disorders in the FLX and EE2+FLX treatment ( $p < 0.0001$ , Chi-square). Our study demonstrated that an ecotoxicologically relevant simple mixture of FLX and EE2 produces strong estrogen-like effects in the male goldfish. Funded by NSERC, CWN, and CAPES.

**215 Bioavailability-based techniques: Where are we now?** M. Lydy, Southern Illinois University Carbondale / Fisheries and Illinois Aquaculture Center and Department of Zoology, Southern Illinois University-Carbondale / Fisheries and Illinois Aquaculture; A.D. Harwood, Southern Illinois University / Fisheries and Illinois Aquaculture Center and Department of Zoology. The advantages of bioavailability-based techniques over exhaustive sediment extractions are well understood. While exhaustive chemical extractions provide a conservative estimate of exposure to sediment-associated contaminants, bioavailability-based techniques better assess the true hazard in these systems. Bioavailability-based techniques are broadly separated into two main categories: equilibrium- and desorption-based approaches, which represent the bioavailable and bioaccessible fractions, respectively. Since these methods only measure the fraction of contaminant available to the organism, they are more proportional to bioaccumulation. Several of these techniques are in current use including SPME fibers, SPMDs, Tenax TA, as well as others, and these methods are effective at estimating bioaccumulation for a variety of compounds and species. However, it had been hypothesized that these methods could also be effective for estimating toxicity even for biotransformed compounds. Additional applications for these methods include assessing toxicity in field sediments, evaluating remediation success, and source tracking of compounds. Despite these advancements, there are still several data gaps that need to be addressed such as standardization of methodology, further application of toxicity estimates in risk assessments, and a better understanding of the limitations of specific methods. This presentation will review bioavailability-based techniques and provide an introduction for this session.

**216 Assessing bioavailability of DDT and metabolites in marine sediments using SPME with performance reference compounds** L. Bao, University of California Riverside / Chinese Academy of Sciences, University of California, Riverside / Department of Environmental Sciences; F. Jia, University of California, Riverside / Department of Environmental Science; E.Y. Zeng, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences / State Key Laboratory of Organic Geochemistry; J. Gan, University of California, Riverside / Department of Environmental Science. Solid phase microextraction (SPME) has often been used to estimate the freely dissolved concentrations ( $C_{\text{free}}$ ) of organic chemicals in sediments. A significant limitation in the use of SPME for  $C_{\text{free}}$  measurement is the requirement of equilibrium partitioning that is often difficult to meet for highly hydrophobic organic chemicals such as DDT. A method was developed using SPME with stable isotope-labeled analogues as performance reference compounds (PRCs) to measure  $C_{\text{free}}$  in marine sediments. Six PRCs,  $^{13}\text{C}$ - $\alpha$ , $p'$ -DDE,

$^{13}\text{C}$ -*o,p'*-DDD, *p,p'*-DDE- $\text{d}_8$ , *p,p'*-DDD- $\text{d}_8$ , *o,p'*-DDT- $\text{d}_8$ , and *p,p'*-DDT- $\text{d}_8$ , were impregnated into polydimethylsiloxane (PDMS) fiber before use. The isotropy between absorption and desorption between labeled and non-labeled (native) compounds was validated in a range of sediments. With the use of isotope-labeled analogues as PRCs, reproducible measurements of  $C_{\text{free}}$  were achieved using sampling time less than 1 week, as compared to many weeks often needed for the conventional SPME approach. The method showed significant differences in the availability of DDTs in sediments after amendment of activated carbon and sand. The  $C_{\text{free}}$  values derived with the stable isotope-calibrated SPME were statistically equivalent to those obtained using the conventional SPME protocol. Results from this study clearly demonstrated the feasibility of using PRCs in SPME measurements to greatly shorten sampling time, thus affording much improved flexibility in the use of SPME for bioavailability evaluation.

**217 Passive Equilibrium Sampling of Polychlorinated Biphenyls in Baltic Sea Sediment as a Tool to Study Bioaccumulation** A. Jahnke, Stockholm University / Department of applied environmental science, Stockholm University / Inst for tillampad miljoetenskap, ITM; P. Mayer, Aarhus University / National Environmental Research Institute, Aarhus University / Department of Environmental Science, National Environmental Research Inst. / Environmental Chemistry & Microbiology; M. McLachlan, Stockholm University / Department of Applied Environmental Science (ITM). A passive equilibrium sampling approach using glass jars with  $\mu\text{m}$  thin coatings of the silicone polydimethylsiloxane (PDMS) on the inner walls was validated and applied to sediment samples from a 52 km transect in the Stockholm Archipelago. The PDMS coating is brought into contact with the sediment and analysed after equilibrium between the two phases is established, in order to determine freely dissolved concentrations, chemical activities and fugacities. These chemically defined bioavailability parameters for environmental pollutants in sediment are important since sediment is the dominant exposure medium for bottom-dwelling organisms and therefore is particularly relevant in a bioaccumulation context. The coated glass jar method makes use of three different coating thicknesses (2  $\mu\text{m}$ , 4  $\mu\text{m}$  and 8  $\mu\text{m}$ ), which allows equilibrium between the sample and the PDMS to be confirmed for each sample and analyte (QA/QC), while at the same time verifying the absence of sampling artefacts. From the concentrations of polychlorinated biphenyls (PCBs) in the PDMS, we assessed: i) freely dissolved concentrations in the sediment interstitial porewater ( $C_{\text{Sediment, free}}$ ); ii) the equilibrium status between sediment and water; iii) the equilibrium status between sediment and biota; iv) site-specific sediment/water distribution ratios ( $K_D$ ). The results showed that: i) Stockholm remains to be a source of PCBs to the open Baltic Sea manifested in significantly lower  $C_{\text{Sediment, free}}$  at the outer stations; ii) in autumn/winter, the fugacity in sediment exceeds that in water from monitoring programs by an average factor of 4.0; iii) the fugacity in sediment exceeds that in herring from annual monitoring programs by an average factor of 5.2; iv)  $K_D$  values near Stockholm Harbor are by 0.3 up to 1.7 log units greater than in the outer Baltic Sea, possibly due to the strong anthropogenic impact. Altogether, the coated glass jar approach yields precise sediment data at trace levels ( $C_{\text{Sediment, free}}$  between 1.06 fg/L and 1140 pg/L) with built-in QA/QC that provide valuable insight into multimedia environmental processes: As an example, the equilibration of PDMS as the reference phase with sediment, water and biota can provide new, thermodynamically based understanding of bioaccumulation.

**218 Utilizing Passive Sampling for Rapid Response to Assess Atmospheric Exposure to PAHs Before, During and After the Deepwater Horizon Oil Spill** L.G. Tidwell, S. O'Connell, S. Allan, K. Hobbie, G. Wilson, K.A. Anderson, Oregon State University / Environmental & Molecular Toxicology. Polycyclic aromatic hydrocarbons (PAHs) are present in crude oil and may persist in the environment even after visible evidence is gone. Volatilization of crude oil can be one route of exposure for PAHs. Exposures of PAHs from crude oil spills typically occurs concurrent with the spill or prior to significant weathering of the oil. Acute chemical spills generally initiate a rapid clean up response; however, there is often a significant exposure period prior to elaborate air monitoring equipment setup. Because PSDs do not require elaborate equipment or electricity, we were able to initiate sampling within days of the Deepwater Horizon Oil Spill. We deployed passive sampling devices (PSDs) for air sampling prior to, during and after shoreline oiling. Study locations included sites in Louisiana, Mississippi, Alabama and Florida. PSDs mimic the chemical uptake of biomembranes

by exploiting the fugacities of vapor phase compounds in the atmosphere. Chemical data from PSD extracts can be employed to assess potential exposure, transport, fate and sourcing of emerging and legacy contaminants in the atmosphere. Forty two samples were collected over a 15 month period beginning in May 2010; passive sampling devices were used to monitor the bioavailable concentration of PAHs in air. Prior to shoreline oiling, baseline data was obtained at all the study sites, allowing for direct before and after comparisons of PAH air contamination due to oiling. Samples were analyzed using a method composed of 33 emerging and legacy PAHs. As many as 18 PAHs were quantified in some air PSD extracts. Fluoranthene, pyrene and phenanthrene were the largest contributors to the total vapor phase PAH concentration at our sampling sites. PSDs were also screened for an additional 1,200 contaminants of concern. Analysis of PSDs with this screening method resulted in positive identification of oxygen, sulfonate and nitrogen substituted PAHs, as well as pesticides, and compounds used in industry such as musks and flame retardants. Our study demonstrates the utility of air PSDs to respond to acute chemical spills and collect chemical data sets on a wide range of contaminants in a more rapid fashion than traditional air monitoring technologies. During this study OSU's Superfund Research Program Research Translation and Community Engagement Cores developed resources including workshops, brochures, and web-based information available to the communities impacted by the spill.

**219 In vivo passive sampling of nonpolar organic contaminants in brown trout, *Salmo trutta*** L.J. Allan, Norwegian Institute for Water Research, Norsk Institutt for Vannforskning; K. Hawley, T. Haugen, A. Lillicrap, K. Baek, Norwegian Institute for Water Research. Nonpolar organic contaminant concentrations in biota tissues and organs are often assumed to be in equilibrium. This, to an extent, is the reason why a surrogate measure of contaminant body burden can be obtained from measurements in liver or muscle, normalised to lipid content. Contaminant mass transfer within an organism such as fish is expected to be higher than in water. This is the reason why contaminant concentrations in passive sampling phases immersed for 2-4 days in intact fish muscle tissues are expected to reach equilibrium with that in tissue. Another challenge with measurements of contaminant levels in tissues is the normalisation to lipid content. Lipids may or may not be the only sorption phase and different quantification methods for lipids exist. A relatively novel approach to the measurement of non-polar organic contaminant body burden in brown trout (*Salmo trutta*) was applied here. Small tags made of medical-grade polydimethylsiloxane (PDMS) tubing were inserted in the cavity of brown trout. Fish were caged and re-located to a contaminated area of the River Alna in Oslo (Norway) for up to 1 month. Upon retrieval, chlorinated organics (PCBs) were analysed in the tags and in the various tissues (e.g. muscle, liver). Additional in-tissue sampling with a similar PDMS phase was undertaken for comparison with the tags and with lipid-normalised tissue concentrations. The degree of equilibrium reached was evaluated by comparing tissue-PDMS distribution for native PCBs and labelled-PCBs spiked into the tags prior to caged exposures. Fish exposures were supplemented with PDMS-based passive sampling in the water phase and suspended matter sampling. Data obtained was interpreted further using literature values of lipid-PDMS distribution coefficients.

**220 Application of the DGT-2DDFIS/BLM approach to assess site-specific toxicity risk for water and sediment at a river associated with mining activities** T.T. Huynh, University of Queensland / Centre for Mined Land Rehabilitation; B. Noller, The University of Queensland / Centre for Mined Land Rehabilitation. Determining the bioavailable fractions of contaminants in water and sediment is being recognised as a necessary step to predict the effects of metals on biota and for application in the decision tree for assessment of contaminated water and sediment. Bioavailability of a metal generally refers to the potential entry of metal into the ecological domains via the solution phase. The bioavailability of metals in an aquatic system is commonly assumed to mean the ability to be taken up by and across a biological membrane, or as the amount of accumulated metal or metalloid in water that correlates with the observed toxicity in aquatic biota. In a river system, sediment can act as a sink for contaminants in benthic organisms and can potentially be transferred into the aquatic food chain, thus significantly influencing surface water quality. Understanding the kinetics that control the equilibrium of metals in the sediment and water system is crucial, as it can control the metal resupply to biota. The Diffusive Gradients in Thin Film Technique (DGT) Induced Fluxes in Sediment (2D DIFS) is a dynamic numerical model developed to simulate the

transport and reactions occurring within the DGT device and its deployment medium by incorporating first order exchange of solute between solid and solution phases. The 2D DFIS allows accurate determinations of the distribution ratio ( $K_d$ ); equilibration response times ( $T_C$ ) from the DGT interfacial concentration ( $C_{DGT}$ ) measurements; the ratio ( $R_{diff}$ ) of the mean interfacial concentration due to resupply by diffusion concentration to the bulk concentration and then calculate an effective concentration ( $C_E$ ). This study presents a new approach to provide more realistic risk assessments by determining not only the bioavailability but also the kinetics that control the rate of equilibration between them using the DGT-2DDFIS/BLM approach. A total of 5 sampling sites were selected for water and sediment at a river associated with mining activities. Bulk samples were collected for water/sediment quality assessment concurrently with *in situ* deployment of DGTs. The effective concentration ( $C_E$ ) of copper in the sediment is used in the Biotic Ligand Model (BLM) for site-specific criteria derivation instead of the conventional 0.45  $\mu\text{m}$  filtered copper concentration in water. The results for water and sediment quality criteria predicted by BLM using these two different concentrations of copper will be presented and compared.

#### 221 Bioavailability-based chronic toxicity measurements of benzo(a)pyrene and permethrin to *Chironomus dilutus*

J. Du, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences / State Key Laboratory of Organic Geochemistry; J. You, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences / State Key Laboratory of Organic Geochemistry. Benzo(a)pyrene (BaP, a polycyclic aromatic hydrocarbon) and permethrin (a pyrethroid insecticide) are widespread in aquatic ecosystems and their acute toxicity to benthic organisms have been well documented. However, study on chronic toxicity of those contaminants is limited. In the current study, adverse effects of sediment-associated BaP and permethrin on the whole life cycle of *Chironomus dilutus* were determined. The tests were initiated using the newly hatched (< 24 h old) midge larvae and terminated until the hatch of the second generation. The chronic toxicity endpoints included survival, growth, emergence, and reproduction. The BaP concentration of  $340 \pm 2.53$  and  $109 \pm 2.04$   $\mu\text{g/g}$  organic carbon (OC) in sediment caused 50% mortality in *C. dilutus* (LC50) after 20-d exposure and at the end of test, respectively, whereas the LC50 values of permethrin were about 10 times lower than those of BaP and were  $33.1 \pm 1.52$   $\mu\text{g/g}$  OC and  $23.3 \pm 1.37$   $\mu\text{g/g}$  OC, respectively. Rather, BaP and permethrin affected the growth of *C. dilutus* at lower concentrations with the concentration causing 50% effect (EC50) being  $98.0 \pm 1.99$  and  $5.76 \pm 0.76$   $\mu\text{g/g}$  OC, respectively. The EC50 values for emergence of *C. dilutus* were also recorded ( $52.7 \pm 1.72$  and  $3.87 \pm 0.59$   $\mu\text{g/g}$  OC for BaP and permethrin, respectively). In addition, both contaminants affected the sex ratio of the midges as well as egg production rates and hatchability. Recent studies showed that Tenax extractable concentrations better evaluated bioaccumulation and sediment toxicity of hydrophobic organic contaminants than the whole sediment concentrations because it took bioavailability into account. In the current study, bioavailability of sediment-associated BaP and permethrin were measured using a single point 24-h Tenax extraction, and results indicated only about half of the contaminants in sediment were bioaccessible after aging for one month. At last, the response spectra of both contaminants were developed using both OC-normalized whole sediment concentrations and bioavailability-based Tenax extractable concentrations. The development of bioavailability-based chronic toxicity endpoints of sediment-associated BaP and permethrin provide valuable benchmarks for evaluating ecological risk of those contaminants.

#### 222 Applications and advantages of Tenax TA for assessing bioavailability of sediment-associated contaminants

A.D. Harwood, Southern Illinois University / Fisheries and Illinois Aquaculture Center and Department of Zoology; M. Lydy, Fisheries and Illinois Aquaculture Center and Department of Zoology. Tenax TA is a porous polymer resin that has been used to measure desorption rates and quantify the rapidly desorbing fraction of hydrophobic organics from sediments. Studies have shown that both the rapidly desorbing fraction and a single extraction time correlated to bioaccumulation for hydrophobic organics in several species. Unlike other passive samplers, Tenax measures the desorption rates from sediments and is, therefore, a depletive method. It is for this reason, the applicability of Tenax to estimate bioaccumulation and toxicity consistency has been questioned. However, theoretically the fraction measured by equilibrium-based methods, such as SPME fibers, should also be primarily driven by the desorption rates of contaminants from sediments. Therefore, Tenax extractable

concentrations should be proportional to equilibrium-based methods for estimating bioavailability and we have found a correlation between the two measurements. Tenax has been used to successfully estimate bioaccumulation for several species in both laboratory and field-collected sediments for compounds including PCBs, PAHs, and pesticides. Recently, Tenax has demonstrated the potential to estimate toxicity, provide insight to remediation success, and be used for source tracking. There are several advantages to desorption-based techniques, including the rate at which data can be collected and increased sensitivity. Therefore, it is important to recognize this technique and encourage additional research using Tenax.

#### 223 Application of molecular target homology-based approaches to predict species sensitivities to two pesticides, permethrin and propiconazole

C. LaLone, U.S. EPA; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; L. Burgoon, C. Russom, US EPA; J. Berninger, Baylor University / Department of Environmental Science; J.E. Tietge, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / Mid-Continent Ecology Division; H. Helgen, Computer Sciences Corporation; M. Severson, US EPA; J. Cavallin, U.S. EPA, ORISE / National Health and Environmental Effects Research Laboratory; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division. In the U.S., registration of pesticide active ingredients requires a battery of intensive and costly *in vivo* toxicity tests which utilize large numbers of test animals. These tests use a limited array of model species from various aquatic and terrestrial taxa to represent all plants and animals potentially at risk. Predictive methods that systematically and quantitatively assess molecular target homology across species, i.e., at the molecular initiating event level of an adverse outcome pathway, show promise for identifying and ranking species most likely to respond to chemical perturbations of these protein targets. The advent and refinement of these strategies could lead to more focused and integrated approaches to testing and assessment, utilizing the most relevant species with mode of action (MOA) specific toxicity tests, thereby reducing cost and animal use. To further understand and demonstrate the capabilities of protein homology-based species sensitivity predictions, we conducted case studies with two pesticides with known MOAs: permethrin a common insecticide that targets voltage gated para-like sodium channels, and propiconazole a fungicide that inhibits sterol 14  $\alpha$ -demethylase (CYP51). Primary amino acid sequence and conserved functional domain analyses were conducted and non-target species were ranked according to their predicted relative sensitivity to the pesticides. We then compared the results of the homology analyses with empirical toxicity data as a means to demonstrate the appropriate domain(s) of applicability for such predictive methods. This presentation will describe these analyses, and additional progress made in the development of an automated web-tool for such protein-based assessments. The contents of this abstract neither constitute nor reflect official US EPA policy.

#### 224 Multiple ligands derived from pulp and paper mill effluents and trees modulate key molecular receptors and enzymes to suppress reproduction in fish

V.L. Trudeau, University of Ottawa / Advanced Research in Environmental Genomics; A. Waye, Centre for Advanced Research in Environmental Genomics; A. Tang, University of Ottawa / Biology; J.T. Popescu, Centre for Advanced Research in Environmental Genomics / University of Ottawa; J. Arnason, University of Ottawa; M. Hewitt, Environment Canada / National Water Research Institute; C. Milestone, National Water Research Institute; D. MacLachy, Wilfrid Laurier University / Canadian Rivers Institute, Wilfrid Laurier University / Department of Biology; P. Martel, FPInnovations – Paprican Division / Environment; N. Basu, University of Michigan / Department of Environmental Health Sciences, University of Michigan / Department of Environmental Health. Key observations from the Canadian Environmental Effects Monitoring Program indicate that pulp and paper mill effluents (PPMEs) may reduce reproductive potential of fish populations. Initially, it was hypothesized that mill effluents contained substances that interacted with estrogen or androgen receptors. While this is certainly part of the mechanism, it has been difficult to link the cause with the effect. Recent findings demonstrate that some but not all PPMEs could rapidly but reversibly suppress egg production in the fathead minnow. This strongly suggested an alternative hypothesis: that PPME components were affecting the neural (i.e., hypothalamic) control mechanisms of spawning. Bioassay-guided fractionation of PPMEs

from Canada, Brazil and New Zealand, feedstock trees and screening of dozens of known phytochemicals indicate clearly that there are neuroactive substances present. We have found that there are effluent fractions and phytochemicals that can interact with dopamine receptors and also inhibit monoamine oxidase, the key degradation enzyme for dopamine. Other extracts and compounds inhibit the key GABA synthesis enzyme glutamic acid decarboxylase. We performed a large-scale meta-analysis of microarray-derived expression profiles of hypothalamic tissues of PPME-exposed female fathead minnow in comparison with expression profiles of hypothalamic tissues from female goldfish treated with dopaminergic drugs. Effluents that inhibit egg production also affect similar molecular pathways compared with the highly specific dopamine agonists. This is important because it is well-known that dopamine is the single most potent inhibitory regulator of reproduction in teleosts. Components in PPMEs and tree extracts, and pure phytochemicals may increase dopaminergic activity by a combined action on molecular receptors and by inhibition of dopamine degradation. Moreover, it is known that GABA is a potent stimulator of reproduction, so inhibition of GABA synthesis would also contribute to inhibition of reproduction. Collectively, these data support a neuroendocrine disruption hypothesis for the inhibition of reproduction by components in complex PPMEs. Disruption is rapidly initiated at the level of the central nervous system because multiple ligands modulate key molecular receptors and enzymes to suppress reproduction.

**225 Species Differences in Disruption of Androgen Receptor Function by Brominated Flame Retardants** J. Kharlyngdoh, S. Asnake, A. Pradhan, H. Mujahed, Orebro University / School of Science and Technology; P. Olsson, Orebro University / Orebro Life Science Center, Orebro University / School of Science and Technology. With the development of new biological and chemical analyses there is an increased possibility to identify adverse effects of complex and low-level exposures on the health and well being of both humans and wildlife. In contrast to the estrogen receptor that is activated by 17 $\beta$ -estradiol in most vertebrate species, the androgens that activate AR differ between species. While the mammalian AR is preferentially activated by 5 $\alpha$ -dihydrotestosterone, AR from birds and fish are more responsive to testosterone and 11keto-testosterone. This suggests that there may be large species differences in the response to endocrine disrupting compounds (EDCs) with the ability to bind to AR. Using a combination of molecular modeling, receptor activation reporter systems and gene activation assays we are screening for brominated flame-retardants (BFRs) that interact with androgen receptors (AR) from different species. We have earlier identified 1,2-dibromo-4-(ethyl)-cyclohexane (TBECH) as a group of potent agonists to the human AR (hAR). TBECH exist as 4 isomers with corresponding enantiomers. We now have data to show that TBECH also induce AR activation in chicken and zebrafish. However, the responses to TBECH differ substantially between species. In addition to the identification of TBECH we have now identified several additional brominated compounds as androgen antagonists in mammals, birds and fish. Using qPCR arrays we have also obtained results that indicate complex and species specific responses of these androgen antagonists, including regulation of AR transcripts. As some of these BFRs are present in large amounts in the environment, including wildlife, there is a need to further analyze their possible contribution to reproductive disturbances observed in wildlife.

**226 Binding of perfluorochemicals to PPAR $\alpha$ : toward establishing the linkage between the initiating event and its downstream signaling** H. Ishibashi, Shokei University Junior College / Department of Food and Nutrition; M. Hirano, Ehime University / Center for Marine Environmental Studies; E. Kim, Kyung Hee University / Department of Life and Nanopharmaceutical Science and Department of Biology; H. Iwata, Ehime University / Center for Marine Environmental Studies. The peroxisome proliferator-activated receptors  $\alpha$  (PPAR $\alpha$ ) is a member of the ligand-activated nuclear hormone receptor superfamily. It is well known that chronic peroxisome proliferation induced by chemical exposure is associated with the promotion of tumors in the liver of rats and mice. Our previous studies have indicated the induction of hepatic expression levels of PPAR $\alpha$  mRNA and cytochrome P450 4A protein in wild Baikal seals (*Pusa sibirica*) contaminated with perfluorochemicals (PFCs). The *in vitro* reporter gene assay that the Baikal seal PPAR $\alpha$  was transiently expressed in CV-1 cells showed the PPAR $\alpha$ -mediated transactivation by the treatment with PFCs. However, whether a molecular initiating event like the binding of PFCs to PPAR $\alpha$  spans its downstream signaling has not been fully understood. In

this study, we thus measured the binding abilities of PFCs to the Baikal seal PPAR $\alpha$  with the LanthaScreen<sup>TM</sup> TR-FRET PPAR $\alpha$  Competitive Binding Assay. We successfully synthesized the GST-tagged recombinant Baikal seal PPAR $\alpha$ -ligand-binding domain (LBD) using a wheat germ cell-free protein synthesis system. Among eleven PFCs tested, six perfluoroalkyl carboxylates (PFCAs) and two perfluoroalkyl sulfonates (PFSA) bound to the Baikal seal PPAR $\alpha$ -LBD in a dose-dependent manner. PFOA-relative binding affinities (RBAs) of the PFCs were as follows; PFOS > PFDA > PFNA > PFUnDA > PFOA > PFHxS > PFHpA > PFHxA >> PFBA, PFPeA and PFBuS. To our knowledge, this is the first direct evidence of the binding of PFCs to the PPAR $\alpha$ . The quantitative structure-activity relationship analysis showed that PFCAs with 9 or less perfluorinated carbons (PCs) had a positive correlation between the PC number and the RBA of PFCAs, indicating that the PC number is one of the factors determining the binding abilities to the Baikal seal PPAR $\alpha$ . RBAs of PFCs with 7 or less PCs had a positive correlation with the respective PFOA induction equivalency factors (IEFs) obtained by the *in vitro* reporter gene assay. For PFCs with more than 7 PCs, the IEFs were lower than that of PFOA, although the RBAs were higher. These results suggest that this binding assay system may be useful for an initial screening of potential ligands, but the PPAR $\alpha$  binding ability of PFCs may not necessarily be reflected in the transcriptional activity.

**227 In vitro transactivation of avian AHR1 and AHR2 by dioxins to assess the species-specific sensitivity and CYP1A induction in the population-level** H. Iwata, J. Lee, L. Thuruthipallil, Ehime University / Center for Marine Environmental Studies; E. Kim, Kyung Hee University / Department of Life and Nanopharmaceutical Science and Department of Biology. Our recent studies revealed that avian species have at least two isoforms of the aryl hydrocarbon receptor (AHR1 and AHR2). To measure the transactivation potency of cytochrome P450 1A5 (CYP1A5) by TCDD through avian AHR, the reporter construct containing the 5'-flanking region of common cormorant CYP1A5 (*cc*CYP1A5) or chicken CYP1A5 gene (*ck*CYP1A5) was transfected into COS-7 cells with AHR expression plasmid of cormorant (*cc*AHR) or chicken (*ck*AHR). TCDD-EC<sub>50</sub> for the transactivation of *cc*CYP1A5-driven reporter gene by *cc*AHR1 was 0.29 nM, while that of *ck*CYP1A5 by *ck*AHR1 was 0.030 nM. The *cc*AHR1-*cc*CYP1A5 pathway is thus about 10-fold less responsive to TCDD than that of *ck*AHR1-*ck*CYP1A5. In *cc*AHR2-transfected cells, *cc*CYP1A5-reporter gene was dose-dependently transactivated by TCDD. In case of *ck*AHR2, *ck*CYP1A5 construct was constitutively activated, but non-responsive to TCDD. These results suggest that AHR2 contribution to the transactivation may vary among species. Moreover, we examined whether the species difference in the regulatory region of CYP1A5 gene affects the response to TCDD. The measurement of transactivation in a heterologous pair of *cc*AHR1-*ck*CYP1A5 and *ck*AHR1-*cc*CYP1A5 showed that TCDD response was mostly dependent on the species of transfected AHR, not on CYP1A5 construct. To validate whether TCDD dose-response obtained in COS-7 cells corresponds to that in native cells, we treated chicken embryonic hepatocytes with TCDD in which *ck*CYP1A5-reporter construct was transfected. In the hepatocytes, TCDD-EC<sub>50</sub> for *ck*CYP1A5-reporter gene transactivation was 0.046 nM. The similarity of TCDD-EC<sub>50</sub> for *ck*AHR1 in COS-7 with that in chicken hepatocytes suggests that TCDD dose-response in chicken hepatocytes is reproducible in COS-7 cells. As for each AHR isoform from the cormorant and black-footed albatross, TCDD relative potencies (REPs) of dioxin-like congeners (DLCs) were estimated and TCDD induction equivalency factors (IEFs) were determined. Using AHR1- or AHR2-IEFs and hepatic concentrations of DLCs in the respective wild populations, TCDD induction equivalents (IEQs) were calculated. We further constructed non-linear regression models on the relationships between AHR1- or AHR2-IEF derived total IEQs and CYP1A levels in the liver of wild populations. The results suggested that the non-linear regression models were predictable from the *in vitro* assay incorporating AHR of the respective species.

**228 Species- and congener-specific transactivation potencies of red seabream AHR1 and AHR2 by dioxins** S. BAK, Kyung Hee University / Department of Life and Nanopharmaceutical Science and Department of Biology; M. Iida, H. Iwata, Ehime University / Center for Marine Environmental Studies; E. Kim, Kyung Hee University / Department of Life and Nanopharmaceutical Science and Department of Biology. To construct risk assessment system based on aryl hydrocarbon receptor (AHR)-mediated signaling pathway, cross-species comparison of the ligand profile for AHR is

necessary. However, the function of multiple AHRs (AHR1 and AHR2) and the underlying mechanisms of toxicities induced by dioxin like compounds (DLCs) are still poorly understood in fish other than limited model species like zebrafish. Thus we investigated the transactivation potencies of red seabream (*Pagrus major*) AHR1 and AHR2 isoforms (RS-AHR1 and RS-AHR2) by DLCs. To evaluate the transactivation potencies of each AHR by DLCs, we constructed an *in vitro* reporter gene assay system. Each RS-AHR expression plasmid and a reporter plasmid containing red seabream CYP1A (RS-CYP1A) promoter with xenobiotic response elements (XREs) were transfected in COS-7 cells, and the cells were treated with seven selected DLC congeners. Results showed that both RS-AHR1 and AHR2 were dose-dependently activated by all the tested chemicals in this assay. This suggests that AHR1 and AHR2 isoforms play critical roles in CYP1A induction and dioxin toxicities may be triggered by both AHRs in the red seabream. These results of the AHR-mediated transactivation potency are contrastive to those of zebrafish AHR studies; AHR1 produced minimal XRE-driven transactivation but AHR2 induced the transcription in TCDD-treated COS-7 cells. TCDD induction equivalency factors (IEFs) of the tested DLCs for each RS-AHR isoform were estimated from the dose-responses in the reporter gene assay. Comparison of IEFs between RS-AHR1 and RS-AHR2 revealed that PeCDD-IEF for RS-AHR1 is ~10-fold lower than that for RS-AHR2 IEF. This suggests that RS-AHR1 and AHR2 have distinct ligand profiles. When RS-AHR1/2 IEFs are compared with WHO fish toxic equivalent factors (TEFs), both RS-AHR1/2 IEFs are higher for TCDF and PeCDF, but lower for PeCDD. These results were different from those of rainbow trout AHR2 alpha-mediated transactivation assay; PeCDD had a higher IEF, and TCDF and PeCDF had similar IEFs. Taken together, the function of fish AHR is unexpectedly diversified across species and isoform.

**229 Understanding the mechanisms of arsenic adaptation in earthworms – plasticity, epigenetic and genetic adaptation** D. Spurgeon, NERC Centre for Ecology and Hydrology; C. Anderson, Centre for Ecology and Hydrology; P. Kille, J. Andre, J. Morgan, Cardiff University. Mineral extraction is associated with the production of metalliferous soils that can contain highly elevated concentrations of trace elements. Even though highly contaminated, some organisms are able to develop viable population on the contaminated soils. Earthworms are one such group. To understand how earthworm are able to adapt and tolerate highly arsenic (and copper) polluted soils we have utilised a systems biology approach to understand the gene networks that are differentially regulated under arsenic exposure and the association between these networks and endogenous metabolism and internal arsenic speciation. The fully sequenced earthworm *Lumbricus rubellus* was the focus for this work. RNAseq analysis conducted using Illumina technology identified a number of pathways that are affected by arsenic exposure. These related to iron homeostasis, an effect borne out by measured changes in tissue iron concentrations and also the metabolism of amino acids. Metabolomic analysis using <sup>1</sup>H-NMR identified a number of metabolites that changed significantly in response to As exposure. Again amino acids were among the most highly significant of these metabolites. Two amino acids in particular, glycine and cysteine, were identified from this analysis. A link between these metabolites and the production of the metal specific peptide phytochelatin was confirmed through additional LC-MS measurement. With phenotypic data in hand, we next sought to address the mechanisms that determine the survival of earthworms at contaminated sites. Initial AFLP profiling in the taxonomical complex *L. rubellus* species complex identified unique profiles associated with populations inhabiting the most arsenic contaminated soils. Epigenetic changes associated with these exposed population was also found using a methylation sensitive AFLP approach. Whether populations show genetic or epigenetic adaptation as the prevalent mechanism for adaptation depended on the earthworm clade considered. Higher throughput SNP mapping using a RADseq approach is current also being applied to these populations with the potential to link genotype with the changes in phenotype that are known to occur in arsenic exposed earthworms.

**230 Use of mutual information theory to decipher the impacts of multiple stressors from molecular through whole-organism level effects** K.A. Gust, ERDC-EL-EP-P / Environmental Laboratory, US Army, Engineer Research and Development Center, US Army Engineer Research & Development Center, US Army Engineer Research and Development Center, ERDC-EL-EP-P; V. Chaitankar, P. Ghosh, Virginia Commonwealth University; M. Wilbanks, US Army Engineer Research and Development

Center; X. Chen, University of Virginia; C. McFarland, U.S. Army Public Health Command (provisional) / and Preventive Medicine, U.S. Army Public Health Command / Health Effects Research Program, U.S. Army Public Health Command, U.S. Army Center for HPPM; L. Talent, Oklahoma State University; E.J. Perkins, US Army Engineering Research & Development / Environmental Laboratory, US Army ERDC / Environmental Processes & Effect Division, US Army Engineering Research & Development / Environmental Genomics and Genetics Team. The complex nature of multiple stressor effects in biological systems requires new approaches for integrating and drawing inferences from highly diversified data sets. In the present study, we leverage a multiple-stressors investigation in the Western fence lizard (WFL, *Sceloporus occidentalis*) where combinations of climate change and habitat degradation related stressors including malarial parasitism, decreased basic resource (food) availability and exposure to chemical contamination (trinitrotoluene, TNT) were investigated in laboratory bioassays. Resulting datasets from this work include 29 toxicological endpoints ranging from whole organism level effects to blood chemistry parameters for single-stressor and pairwise-stressor exposures. In concert, microarray-based transcript expression datasets were also generated based on these bioassays to provide effects assessment at the molecular and metabolic pathway-level of organization. The data sets were merged and standardized using z-scores and then the popular mutual information theory based algorithm “context likelihood of relatedness” and a new in-house algorithm “R\_REVEAL” were utilized to reverse engineer the network-based relationships among transcription factors, protein-coding genes, protein levels in blood serum and ultimately, whole organism-level effects. An illustrative example of analysis results was identification of high network interconnectivity between genes involved in heme metabolic pathways and blood-hemoglobin levels in TNT exposures. Specifically, expression of genes involved in hemoglobin genesis increased in TNT exposures due to TNT-induced red blood cell RBC lysis and subsequent anemia. Additional components of this network included genes involved in hematopoiesis where gene expression was again increased. The overall response indicates a compensatory response to RBC loss where the molecular machinery of the organism has been engaged to produce new RBCs to mitigate anemia. Additional stressors (food limitation and malarial infection) tended to reduce this overall response. This and several other network-based observations will be presented to illustrate the utility of mutual information theory for providing insights given complex multi-stressor, multi-dimensional datasets.

**231 Spatial distribution of alternative flame retardants in air under GAPS Network: calibration of PUF-disk samplers** S. Lee, E. Sverko, L. Ahrens, Environment Canada; T. Harner, Environment Canada / Atmospheric Science & Technology Directorate, Environment Canada / ASTD; M. Shoeib, L. Jantunen, Environment Canada. This study reports air concentration of alternative non-BDE flame retardants (FRs) at the global scale from samples collected during 2005-2006 at more than 40 sites under the Global Atmospheric Passive Sampling (GAPS) Network. Under the current study, samples collected at GAPS sites over four, three-month consecutive periods between 2005 and 2006, were analyzed for alternative FRs. Samples and field blanks were screened for 16 non-BDE FRs: 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE/TBE); allyl 2,4,6-tribromophenyl ether (ATE/TBPAE); 2-bromoallyl 2,4,6-tribromophenyl ether (BATE); 2,3,5,6-tetrabromo-p-xylene (pTBX); pentabromobenzene (PBBe); hexabromobenzene (HBB); tetrabromo-o-chlorotoluene (TBCT); pentabromotoluene (PBTol); pentabromobenzylacrylate (PBBA); 2,3-dibromopropyl-2,4,6-tribromophenyl ether (DPTE); 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB/ EHTEBB); bis(2-ethyl-1-hexyl) tetrabromophthalate (TBPH/BEHTBP); 2,2',4,5,5'-pentabromobiphenyl (BB101); hexabromocyclododecane (HBCD); pentabromoethylbenzene (PBEB); and octabromotrimethylphenylindane (OBIND). Based on concentration data for all sampling periods, BTBPE had the highest frequency of detection (85%) globally, followed by ATE (71%), PBBe (67%), HBB (66%), TBCT (63%), TBB (60%), HBCD (56%), PBEB (49%), TBPH (46%) and DPTE (42%). The remaining non-BDE FRs were detected in 35% or less of the samples. BTBPE concentrations in air ranged from BDL to 187 pg/m<sup>3</sup>. Concentrations (pg/m<sup>3</sup>) for other non-BDE FRs were: ATE, BDL–8.3; PBBe, BDL–2.0; HBB, BDL–5.6; TBCT, BDL–2.8; TBB, BDL–170; HBCD, BDL–220; PBEB, BDL–7.6; TBPH, BDL–66; and DPTE, BDL–12. A field calibration study was undertaken over almost 1 full year to assess the performance of PUF disk samplers for a range of compound classes including high K<sub>ow</sub> FRs that are associated mainly with

the particle-phase. Preliminary results indicate that PUF disk samplers capture both gas-phase and particle-phase FRs with approximately the same sampling rate of 3–5 m<sup>3</sup>/day. These findings show promise for the use of PUF disk samplers for measuring both gas- and particle-associated chemicals in air. The GAPS Network samples are also being analysed for organophosphorous FRs to assess the applicability of PUF disk passive air samplers to these priority chemicals.

**232 Atmospheric distribution of flame retardants in Chicago, Illinois** Y. Ma, Indiana University / School of Public and Environmental Affairs; M. Venier, Indiana University / School of Public and Environmental Affairs, Indiana University; Z. Rodenburg, University of Iowa; D. Hu, The University of Iowa / Department of Civil & Environmental Engineering, IIHR-Hydrosience and Engineering; K.C. Hornbuckle, University of Iowa / Department of Civil & Environmental Engineering, IIHR-Hydrosience and Engineering; R.A. Hites, Indiana University / School of Public & Environmental Affairs,. Flame retardants are added to electronics, textiles, plastics, and furniture foam and are released into the environment as these products are used or discarded. Urban areas have large stocks of products treated with flame retardants, and as a result, people can be exposed to these chemicals through air, water, or dust. Here, we focus on the air of the greater Chicago, Illinois, area. We report the atmospheric concentrations of organohalogen and organophosphorus flame retardants [including, the polybrominated diphenyl ethers, 2-ethylhexyl-2,3,4,5-tetrabromobenzoate, *bis*(2-ethylhexyl) tetrabromophthalate, triphenyl phosphate, and *tris*(1,3-dichloro-2-propyl) phosphate]. Samples were collected along an urban-rural transect through downtown Chicago and along an urban-lake transect extending out to two water intake cribs located about 5 km east of the Lake Michigan shoreline. Passive samplers equipped with polyurethane foam absorbents have been deployed at each site every six weeks since December 2010. This study is designed to analyze the spatial variance of the flame retardant concentrations among the sampling sites and to estimate the possible source contributions of the urban area of Chicago to Lake Michigan.

**233 Heterogeneous Reactions of O<sub>3</sub>, OH Radicals and N<sub>2</sub>O<sub>5</sub> with Particulate-associated PAHs and Toxicity** N. Jariyasopit, Oregon State University / Department of Environmental & Molecular Toxicology; K. Zimmermann, University of California, Riverside / Air Pollution Research Center; J. Schrlau, Oregon State University / Environmental and Molecular Toxicology; J. Arey, R. Atkinson, University of California, Riverside / Air Pollution Research Center; S. Simonich, Oregon State University / Depts. of Chemistry and Environmental & Molecular Toxicology. In the atmosphere, polycyclic aromatic hydrocarbons (PAHs) partition between the gas and particulate phases depending on their chemical and physical properties and ambient temperature. In general, PAHs with more than four aromatic rings are found primarily in the particulate phase, allowing them to undergo long range atmospheric transport. The reactivity of particulate-bound PAHs is considered to vary, to some extent, with the composition of the particles. Previous heterogeneous reaction studies on particulate matter (PM) have used graphite, diesel soot, wood smoke and in-house soot samples. However, in this study, PM from Beijing, China was exposed to O<sub>3</sub>, OH radicals, and N<sub>2</sub>O<sub>5</sub> to simulate heterogeneous reactions that may occur during trans-Pacific transport. The PM samples were collected over 24 h periods at an urban site in Beijing, China. The filters were cut into two portions. The first portion was quantitatively analyzed for PAHs, nitrated-PAHs (NPAHs) and oxygenated-PAHs (OPAHs) and represented the unreacted masses. The second portion was placed in a ~7000-L indoor all-Teflon chamber and exposed to either O<sub>3</sub>, OH radicals, or N<sub>2</sub>O<sub>5</sub>. The concentrations of O<sub>3</sub>, OH radicals, and N<sub>2</sub>O<sub>5</sub> used in chamber experiments, combined with the duration of the exposures, simulated trans-Pacific atmospheric transport of the PM. The quantitative analysis of both the unreacted and reacted portions of the filter was done using gas chromatography coupled with mass spectrometry, with electron ionization for PAHs and negative chemical ionization mode for NPAHs and OPAHs. Analogous to the chemical studies, toxicological studies were carried out on the unreacted and reacted filters. Direct- and indirect-acting mutagenicities of the extracts were determined by Ames assays. In addition, PM samples were characterized by black carbon (BC) and organic carbon (OC) analyses. Our initial results show evidence of the occurrence of heterogeneous reactions of PAHs with the oxidants. N<sub>2</sub>O<sub>5</sub> was the most effective oxidant in transforming the particulate-bound PAHs. The concentrations of 1-nitropyrene, 1-nitrotriphenylene, 6-nitrochrysene, 2-nitrotriphenylene and 6-nitrobenzo[a]

pyrene increased significantly, while the concentration of 9-nitroanthracene decreased significantly. For the OH-radical exposure, only 1-nitropyrene and 6-nitrobenzo[a]pyrene concentrations were found to increase significantly. As expected, no significant NPAH products were formed in the O<sub>3</sub> reaction.

**234 Influence of future emissions and climate on atmospheric PAH transport** C. Friedman, MIT / Center for Global Change Science, University of Rhode Island; N.E. Selin, Massachusetts Institute of Technology / Engineering Systems Division. We use the 3D atmospheric chemical transport model GEOS-Chem to investigate the impacts of global changes, including emissions and climate, on long-range polycyclic aromatic hydrocarbon (PAH) transport. Unlike most persistent organic pollutants (POPs), PAHs are emitted unintentionally as byproducts of combustion, and their release to the atmosphere is ongoing. In the Arctic, PAHs have been termed “emerging contaminants” because marine animal tissue concentrations are increasing while other POP concentrations are declining. We assess the influence of global anthropogenic emissions changes and climate change on the transport of phenanthrene (PHE), pyrene (PYR), and benzo[a]pyrene (BaP) to the Arctic, focusing on categorizing the relative importance of these global changes. We conduct simulations with GEOS-Chem varying emissions and climate respectively. We estimate future PAH emissions for global regions based on expected changes in gross domestic product and average income, and also assess potential Arctic emission increases due to greater oil/gas exploration and shipping activity. Climate variables assessed include higher global mean temperatures, shifts in atmospheric circulation patterns, and changes in natural PAH emissions, such as from wildfires. We find that climate changes will reduce transport of primary emitted BaP via increases in wet deposition of the particle phase, but will have less impact on PHE and PYR. Emission reductions in developed regions will likely have a greater impact in the Arctic compared to increases in developing regions because of their spatial proximity.

**235 Atmospheric deposition of PCBs to the Delaware River** L.A. Rodenburg, Rutgers, the State University of New Jersey / Department of Environmental Sciences, RUTGERS UNIVERSITY / Department of Environmental Sciences; J. Guo, Rutgers, the State University of New Jersey / Department of Environmental Science, Rutgers Univ. / Environmental Science; S. Du, RUTGERS UNIVERSITY / Department of Environmental Science; T. Fikslin, G.J. Cavallo, Delaware River Basin Commission. In 2003, the Delaware River Basin Commission (DRBC) promulgated a Total Maximum Daily Load (TMDL) for Polychlorinated Biphenyls (PCBs) in zones 2 through 5 of the Delaware River. This was one of the first TMDLs for a persistent organic pollutant in a major US waterway. In support of the TMDL promulgation and implementation, the DRBC funded the Delaware Atmospheric Deposition Network (DADN), which grew out of the New Jersey Atmospheric Deposition Network. These two networks operated from 1996 to 2011 and comprised a total of 13 sites, although not all sites operated in all years. PCBs were measured in the gas, aerosol, and precipitation phases, and the resulting concentrations were used to calculate the deposition of PCBs to the Delaware River. In addition to the fixed monitoring sites, the DADN project also included two passive sampling campaigns designed to assess the spatial heterogeneity in gas-phase PCB concentrations. The data gathered by the DADN project has been used to investigate urban PCB sources, to examine the extent to which watersheds sequester their atmospheric PCB loads, and to better integrate water quality models with atmospheric data.

**236 Modeling urban areas as a source of PCBs and PBDEs to surrounding regions using a coupled multimedia and atmospheric transport model** S.A. Csizsar, University of Toronto / Dept. of Chemical Engineering and Applied Chemistry, , University of Toronto; L. Melymuk, University of Toronto / Dept. of Chemical Engineering and Applied Chemistry; S.M. Daggupati, Environment Canada; P.A. Helm, Ontario Ministry of the Environment / Environmental Monitoring and Reporting Branch; M.L. Diamond, University of Toronto / Department of Geography and program in planning, University of Toronto / Department of Geography. Urban areas, with their elevated persistent organic pollutant (POP) air concentrations as well as high geographic concentration of chemical inventories, are sources of polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) to surrounding regions. We estimated spatially resolved (on a 25km<sup>2</sup> scale) Σ<sub>88</sub>PCB and Σ<sub>26</sub>PBDE emissions to be ~140 and ~30 kg/y, respectively, based on chemical mass inventories and measured air data

from Toronto, Canada which borders Lake Ontario. Using these emission estimates and the coupled Multimedia Urban Model and the Boundary Layer Forecast Model (BLFM), called SO-MUM, we estimated the urban fate pathways and the importance of primary versus secondary emissions of PCBs and PBDEs by modeling reduced emission scenarios. SO-MUM estimated that ~95% and ~70% of air emissions were advected out of the city for PCBs and PBDEs, respectively. Urban surface films increased the air transport potential of PCBs whereas they acted as a transient sink from air for PBDEs allowing for further mobilization to storm water. The urban air plume traveled 60 and 50 km for PCBs and PBDEs, respectively, where concentrations dropped to background levels. We call this distance the Urban Travel Distance. However, the distances to reach 1/e or 63% were 25 and 30 km for PCBs and PBDEs, respectively. We suggest that the greater extent of the PBDE plume using 1/e estimate than 1/10 is due to the broader geographic distribution of the PBDE versus PCB inventory since PBDEs travel distances from source to sink are shorter than PCBs based on physical-chemical properties. For a spring 2008 simulation, the model predicted that Lake Ontario was a source to air for PCBs and a sink from air for PBDEs. The main urban loading pathway to Lake Ontario was wash-off from soils (~90%) for PCBs, and for PBDEs approximately equally air deposition (~56%) and wash-off from surface films (~39%) to storm waters. When the PCB inventory and emissions are reduced to less than 10 times, Lake Ontario becomes the main source of PCBs to air (secondary emissions), however at levels ~3 times lower than current estimated primary emissions. Secondary emissions of PBDEs to air from Lake Ontario or soils are expected to be negligible even at reductions of the inventory and primary emissions by 1000 times.

**237 Metals, PCBs, PAHs, Dioxins and Furans in ambient dust and rainfall along an urban-rural watershed gradient** R. Jack, King County / Department of Natural Resources; J.A. Colton, King County Department of Natural Resources / Water and Land Resources Division, King Cty. Dept. of Nat. Resources / Water and Land Resources Division. This talk presents project information along with sampling and analytical methodologies for a year-long study of atmospheric deposition in the Green/Duwamish River Basin in western Washington State, USA. The objective of this study is to compare the measurements of bulk deposition (combined dry particulate and rainfall) at a small number of stations in areas of different land use within the Green/Duwamish River Basin. These measurements provide the first atmospheric deposition data for many of these chemicals covering a western Washington basin. The goal of this study is to understand atmospheric sources to the Lower Duwamish Waterway (LDW) a 5-mile long, working harbor and Superfund site. Samples were analyzed for select metals, mercury, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), seven polychlorinated dibenzo-dioxins (PCDDs), and ten polychlorinated dibenzo-furans (PCDFs). These chemicals have been identified as contaminants of concern (COCs) for the LDW Superfund site. The sampling method was consistent with that used in previous King County and Puget Sound Partnership air deposition studies. Data collected from this study enhance the understanding of how atmospheric deposition may contribute COCs to the combined sewer system leading to the LDW in Seattle, Washington. The data also allow estimation of bulk deposition from upper watershed areas within the Duwamish/Green River Basin which contributes COCs to the Green River, and subsequently the LDW.

**238 Sources of Aroclor and Non-Aroclor PCB congeners in urban, industrial, rural and indoor environments** K.C. Hornbuckle, University of Iowa / Department of Civil & Environmental Engineering, IIHR-Hydroscience and Engineering. Polychlorinated biphenyls (PCBs) are found in ambient air throughout the world and are an important source of PCBs in fish and other wildlife. PCBs have both historical (Aroclors and other commercial mixtures) and current (manufacturing byproducts) origins. PCB congeners of all molecular weights are found in the gas phase but the sources of gas-phase PCBs are not well understood, even in highly contaminated cities and industrial regions. The major categories of gas-phase PCB sources include: 1) Volatilization from soils historically contaminated from use and disposal of commercial mixtures; 2) Volatilization from contaminated waters and underlying sediments; 3) Volatilization from PCB-containing building materials; 4) Emission of non-Aroclor congeners as by-products of manufacturing and; 5) Emission to ambient air from contaminated indoor air. We have conducted field studies of airborne PCB congeners in urban and rural environments and have found evidence for localized sources of each of these

categories. Here we summarize our findings about residential soils in a small midwestern city; emissions from contaminated sediments of an industrial harbor; the presence of PCBs in current commercial house paint; and emission of PCBs from contaminated indoor air ventilation. The nature of these sources is identified primarily through direct measurements of a large suite of congeners (up to 170 congener groups and all 209 congeners) using tandem mass spectrometry. These analytical techniques make analysis of congener patterns a useful component of mechanistic models that describe PCB emissions from distinct source categories.

**239 A Different Type of Urban Runoff Management Practice – Pollution Prevention** K.D. Moran, TDC Environmental, LLC. Research on urban runoff treatment systems has shown that some common toxic pollutants—like copper and pesticides—cannot be effectively removed by compact treatment systems (like storm drain inserts) that are readily installed in urban areas. It is unlikely that existing cities will ever be fully retrofitted to treat all of the nation's urban runoff with the types of land-intensive treatment systems capable of achieving water quality standards, due to land cost and unavailability, the costs for drainage infrastructure reconstruction, and the associated societal disruption. Land-intensive treatment is not the only option. Another management practice can control hard-to-treat pollutants—Pollution Prevention. Pollution Prevention involves two general strategies: (1) modifying how pollutant-containing products are used and (2) product reformulation. Examples of Pollution Prevention include the elimination of lead from vehicle fuels, phase out of most diazinon and chlorpyrifos use in urban areas, local ordinances prohibiting use of coal tar pavement sealcoat, California regulations limiting how pyrethroid insecticides are applied by professional structural pest control applicators, and vehicle brake pad reformulation to remove lead and copper. Unlike treatment systems, effective pollution prevention control strategies that do not have undesirable side effects are not generic. They must be custom designed for each pollutant based on research, starting with a pollutant source identification study that identifies the true (product) source(s) of the pollutant. Follow-up research depends on the pollutant's sources, but often includes development of robust data linking pollutant-containing products to pollutant loads in urban runoff, product usage characterization, and examination of the feasibility and potential environmental consequences of potential control strategies. The presentation will review specific examples of the research behind the design and implementation of Pollution Prevention control strategies for pesticides and metals in urban runoff, discuss the strengths and shortcomings of the measures that were implemented, and summarize available data characterizing effectiveness in reducing pollutant loads.

**240 Evaluating the effects on lake biota of chronic exposure to two P-inactivation agents and providing lake managers with a context for the results** S.J. Clearwater, National Institute of Water & Atmospheric Research / NIWA; C.W. Hickey, K.A. Thompson, National Institute of Water and Atmospheric Research. Application of phosphorus (P) inactivation agents is a eutrophic lake management technique to reduce the internal release of P from lake sediments. Effective mitigation of nutrient release from lake sediments may require the repeated application of large quantities (i.e., tonnes) of P-inactivation agents, therefore rigorous evaluation of non-target effects as well as efficacy is essential. Both acute and chronic effects must be evaluated, using both field and laboratory exposures. A laboratory mesocosm approach was used to evaluate the effects of chronic exposure (two months) to alum (aluminium sulphate solution buffered with sodium carbonate; 3 application rates 37, 73, or 220 g alum m<sup>-2</sup>; n = 3) or 200 g m<sup>-2</sup> Aqual-P<sup>TM</sup> (a proprietary product based on aluminium-amended zeolite) on freshwater crayfish *Paraneoprops planifrons*, fingernail clams *Sphaerium novaezelandiae*, mussels *Echyridella menziesii* and fish *Gobiomorphus cotidianus*. Combining the species in a flow-through mesocosm incorporates the effects of bioturbation, especially by the crayfish, on the inactivation agents. Site-specific information was provided by using sediments from the application site (Lake Rotorua, central North Island, New Zealand). In comparison to the control treatment, growth and survival of the fish, mussels and crayfish was not significantly affected by two months exposure to the P-inactivation agents, but clam survival, and reburial rates decreased significantly after exposure to the highest alum dose ( $P < 0.001$ ). Oxygen consumption rates were slightly lower in mussels exposed to Aqual-P ( $P < 0.04$ ), otherwise oxygen consumption rates and ammonia excretion by the mussels and crayfish were unaffected by the treatments. Crayfish accumulated aluminium in the hepatopancreas in a dose-dependent response to alum exposure ( $P < 0.001$ ),

but not after the exposure to Aqual-P. These results establish a threshold alum dose of  $73 \text{ g m}^{-2}$ , or  $200 \text{ g m}^{-2}$  Aqual-P for effects on these non-target species. These application rates will be put into context with factors such as the proposed application to the deep, anoxic zone of the lake where few benthic macroorganisms are present, and product characteristics such as different P-binding rates, metal- or ammonia-binding, or metal loss rates, and effects on the sediment microbial community resulting in ammonia release.

**241 Evaluation of a Vegetated Treatment System and Landguard A900 Enzyme: Reduction of Water Toxicity Caused by Organophosphate and Pyrethroid Pesticides** B.M. Phillips, University of California – Davis / Environmental Toxicology, University of California-Davis / Granite Canyon; B. Anderson, UC Davis / Environmental Toxicology; K. Siegler, J. Voorhees, University of California Davis / Environmental Toxicology; R. Tjeerdema, UC Davis / Environmental Toxicology; R. Shihadeh, P. Robins, Monterey County Resource Conservation District; R. Budd, California Department of Pesticide Regulation. Runoff from irrigated agriculture in Monterey County contributes a significant amount of water to local stream flow, and several studies have measured toxic pesticide concentrations and biological impacts in receiving systems. On-farm practices such as vegetated treatment systems (VTS) and enzyme application can reduce concentrations of pesticides in runoff. A redesigned integrated VTS was evaluated with a series of field experiments. The VTS was constructed in a ditch that included a 40m section for sedimentation, a 170m section of vegetation, and included a flashboard riser to control the volume of water in the vegetated section. Laboratory experiments were conducted to determine the optimal dose and mixing time of Landguard A900 enzyme to reduce concentrations of organophosphate pesticides. A series of trials were conducted on a larger, unvegetated drainage ditch to determine the efficacy of the enzyme in a setting with up to twenty times the discharge volume. Field trials included measurements of water toxicity and chemistry at the input and output of each system. These trials were conducted during actual irrigation events that varied in runoff magnitude. The VTS reduced concentrations of pyrethroids, organochlorines and total suspended solids by 97-100%. Landguard application in the larger drainage completely removed chlorpyrifos and diazinon.

**242 Overview of Urban and Agricultural Stormwater Treatment Projects** N. David, D. Yee, San Francisco Estuary Institute; L.J. McKee, San Francisco Estuary Institute / Watershed Program. Detrimental impacts of stormwater runoff from transportation infrastructure and intensive agricultural land use have been well documented. The performance of a variety of Best Management Practices (BMPs) and Low Impact Development practices (LID) for reducing pollutant loads from stormwater is being monitored in northern California. In urban settings, reductions can be achieved through the construction of rain gardens, vegetated swales, infiltration and flow-through planters, curbside extensions, or a combination of these techniques, and structural BMPs in drainages (e.g., filters), coupled with monitoring to evaluate their effectiveness. Additionally, walnut and stone fruit orchard runoff was monitored in the Central Valley of California to examine growing practices such as integrated pest management, and certified organic practices. The agricultural BMPs implemented included the use of organic pesticides and pheromone disruption, cover crops, filter strips, beneficial insects, and monitoring of insects and insect fertility. The results from these studies suggest that rain gardens and swales are effective in reducing pollutant loads from urban stormwater runoff. They also suggest that pesticide and nutrient loads can be reduced in agricultural runoff during irrigation and storms. Pollutants that bind strongly to sediment particles (e.g., most metals, PCBs, PAH, pyrethroids) are especially amenable to removal relative to dissolved phase pollutants when flow is reduced and stormwater is filtered. Despite these differences in treatment efficiency, depending on the physical characteristics of the pollutant and the treatment method, the data indicate reductions in pollutant concentrations and loads between 40 and 90% even in larger storm events.

**243 Phytoremediation of atrazine-contaminated water by expression of anti-atrazine antibody fragment (scFv) in duckweed (*Lemna minor*)** S. Leelachao, University of Guelph / School of Environmental Sciences; A. Ziauddin, K.R. Solomon, University of Guelph; J.M. Hall, Arkansas State University / Department of Mathematics and Statistics. Atrazine is widely used as the main active ingredient for broadleaf weed control in corn, sugarcane and sorghum crops. Atrazine is an environmental concern since water resources may be contaminated with atrazine from runoff emanating from

corn and sorghum fields. An anti-atrazine single chain variable fragment (scFv) gene was randomly inserted into the genome of common duckweed (*L. minor*), an aquatic macrophyte, to sequester atrazine in the transformed plant. Transgenic *L. minor* was produced via *Agrobacterium*-mediated transformation. The molecular weight and expression of the poly-histidine tagged scFv with was confirmed by Western blot. It was determined using dose-response analysis ( $EC_{50}$ ) that the wild-type versus transgenic *L. minor* was more sensitive to atrazine 7 days after exposure.  $EC_{50}$  values for wild-type and transgenic *L. minor* were significantly different. The results of this proof of concept study suggest that antibody expression in plants can potentially be used for phytoremediation of waters contaminated with atrazine.

**244 Potential remediation of nitrate-contaminated water in space-limited areas using microbial-based bioreactors** P. Wilson, University of Florida / IFAS / IRREC- Soil & Water Science; J. Albano, USDA/ARS-Horticulture Research Laboratory. Nitrate is one of the most common contaminants in surface water throughout the world. Losses in surface runoff and drainage water from nursery and agricultural production areas, as well as from the managed landscapes can be significant. This study evaluated the potential use of microbial-based (denitrification), flow-through bioreactors for their nitrate-remediation ability. Duplicate bioreactor systems were constructed at a local foliage plant nursery. Each bioreactor system consisted of four 242 L tanks with connections alternating between bottom and top. Each tank was filled with approximately 113 L of Kaldness media to provide surface area for attachment of native microflora. Molasses was supplied as a carbon source for denitrification and water flow rates through the systems ranged from 5 to  $18 \text{ L} \cdot \text{min}^{-1}$  during tests. Automatic water samplers were used to collect composite samples every 15 minutes from both the inflow and the exit flow water. Results indicate consistent removal of 80-100% of the nitrate flowing into the systems. Accumulation of ammoniacal and nitrite nitrogen did not occur, indicating that the nitrate-nitrogen was removed from the water, and not simply transformed into another water-soluble species. Occasions where removal rates were less than 80% were usually traced to faulty delivery of the carbon source. Results indicate that modular microbial-based bioremediation systems may be a useful tool for helping water managers meet stringent nitrogen water quality regulations, especially in areas with limited space for construction or expansion of water retention facilities.

**245 The potential of using rice (*Oryza sativa*) to mitigate agricultural runoff** M.T. Moore, USDA-ARS, National Sedimentation Laboratory, USDA-ARS National Sedimentation Laboratory / National Sedimentation Laboratory; M.A. Locke, USDA-ARS National Sedimentation Laboratory / National Sedimentation Laboratory. Agriculture is faced with providing food and fiber for a growing global population. With little new land availability, farmers must maximize production on limited acreage. Often these challenges are intersected by precipitation events which lead to non-point source runoff discharges. Innovative, cost-effective conservation practices are needed to address issues of agricultural runoff mitigation. A current approach being examined is the management of existing rice (*Oryza sativa*) fields for phytoremediation and mitigation of pesticides and nutrients. Scaled experiments studied the efficiency of rice at mitigating concentrations and loads of various pesticides. Initial results are promising, with rice mitigating 71-92% of applied pesticide mass, while non-vegetated systems removed only 42-51% of pesticide mass. Additional studies are examining possible pesticide transfer from plant to seed to determine if rice can also serve as a food source for developing countries' efforts at water quality improvement.

**246 Using Groundwater Protectiveness Demonstration Tools to incorporate more UICs into Stormwater Management Plans** H.H. Blischke, M. Kohlbecker, GSI Water Solutions, Inc.; B. Adkins, City of Portland / Bureau of Environmental Services. Stormwater is widely viewed as a source of contamination to surface water. Concentrations of copper, biological oxygen demand (BOD), and temperature that are highly detrimental to ecological receptors in surface water are readily attenuated in the natural treatment capabilities of the subsurface environment. Underground Injection Control Devices (UICs) are included in the City of Portland's comprehensive watershed plan to use stormwater as a resource by infiltrating it back into the ground. UICs preclude the need to install or increase the capacity of piped stormwater infrastructure that eventually discharges into local surface water bodies. In 2005, the City of Portland was issued the first

Water Pollution Control Facility (WPCF) permit for UICs in the nation for management of stormwater from public rights-of-way. Permit conditions would have required hundreds of the City's UICs to be decommissioned. Stormwater sampling data from 7 years of monitoring for a wide range of constituents including total and dissolved metals, volatile and semi-volatile organic compounds, and selected herbicides and pesticides collected from over 75 unique UICs showed that pentachlorophenol (PCP) was regularly measured at concentrations above the permit discharge limit of 1 µg/L. Because of its low sorptive properties, PCP was the primary driver posing risk to groundwater. Fate and transport modeling demonstrated that PCP discharged directly into groundwater attenuates to protective concentrations within less than 275 feet of a typical UIC. Vadose zone modeling showed that the chemicals found in municipal stormwater attenuate within 5 feet of the bottom of the UICs. Oregon Department of Environmental Quality (DEQ) concurred with the modeling results allowing the City to retain over 300 UICs that were considered noncompliant under the permit. Groundwater protectiveness demonstrations were successfully conducted for other Oregon municipalities. As a result, DEQ revised the WPCF permit template encouraging the use of UICs to manage stormwater where they can be shown to be protective of groundwater receptors. Use of groundwater protectiveness tools allow for the use of UICs in municipal watershed management plans as a cost-effective method to recharge groundwater, cool water, and attenuate pollutants prior to reaching surface water bodies.

**247 Chemical speciation of dissolved trace metals in estuarine, coastal and open ocean waters: modelling based on humic type ligands** A. Stockdale, Centre for Ecology and Hydrology / Lancaster Environment Centre, University of Manchester / School of Chemistry; E. Tipping, Centre for Ecology & Hydrology; S. Lofts, NERC Centre for Ecology & Hydrology / Shore Section; J. Hamilton-Taylor, Lancaster University. If water quality standards for estuaries and coastal areas are to be formulated on a site specific basis and based on chemical speciation concepts then there is a pressing need to validate chemical speciation models, which are widely used for terrestrial systems, for saltwater environments. We apply the chemical speciation model WHAM/Model VI to investigate the distribution of metal species (of Fe(III) and the divalent cations of Ni, Cu, Zn, Cd, Hg and Pb) in the water column of estuaries and coastal areas as well as open oceans. In doing this we compare, for the same sites, modelled results with experimentally measured values. The advantage to using a single model for a wide range of data sets, is that it can help to identify whether there are consistent trends in activities obtained using different analytical methods, i.e. relative to a consistent set of predictions. We show that in some cases, speciation of trace metals in brackish and seawater environments may be reasonably predicted using this model with its default parameter set, without any model fitting. Comparisons for several metals and different salinity environments will be presented.

**248 Cu and Pb speciation and toxicity to sea urchin larvae (*Paracentrotus lividus*) in marine samples enriched with dissolved organic matter** P. Sanchez Marin, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement, INRS-ETE / INRS-ETE; J. Lorenzo, R. Beiras, University of Vigo. Dissolved organic matter (DOM) may greatly influence metal speciation in seawater environments, due to its complexation capacity, but the effects of DOM on metal bioavailability in seawater are not yet well known. Previous results using artificial seawater enriched with commercial DOM (as humic and fulvic acids) have shown that DOM decreased Cu toxicity to the larvae of the sea urchin, *Paracentrotus lividus*, in agreement with the decrease in labile Cu concentrations as measured by anodic stripping voltammetry (ASV). However, Pb toxicity to *P. lividus* larvae increased in the presence of humic substances, despite their Pb complexation ability. In order to test if these patterns were also observed in natural samples, Cu and Pb toxicity to *P. lividus* was evaluated in different environmental samples: estuarine seawater, two sediment elutriates and sewage-influenced seawater. Cu and Pb complexation properties were measured by anodic stripping voltammetry (ASV), and the carbon content (DOC) and the optical properties (absorbance and fluorescence) of the coloured DOM fraction were determined. The same series of analysis were performed on the samples subjected to a UV-irradiation treatment in order to oxidize the organic matter present. The results confirmed that Cu toxicity can be predicted according to ASV measurements of labile Cu and that DOC content and fluorescence of the DOM are good predictors of the complexation (and protective) capacity of the water towards Cu. Lead complexation was lower than that of Cu

and not enough to significantly affect Pb toxicity, except for an unexpected enhancement of Pb toxicity observed in some UV-irradiated samples. These results contribute towards our understanding of the effects of DOM on Cu and Pb bioavailability in seawater, but they are limited by the relatively high concentrations of Cu and Pb needed to cause toxicity in short-term studies. Similar studies at lower – more environmentally relevant – metal concentrations are clearly needed.

**249 Influence of salinity and DOC on acute Cu toxicity to the rotifer *Brachionus plicatilis*** C.A. Cooper, T. Tait, J.C. McGeer, Wilfrid Laurier University; R. Santore, HDR/HydroQual; S.D. Smith, Wilfrid Laurier University. Static acute copper (Cu) toxicity tests (48-h LC50) using the euryhaline rotifer *Brachionus plicatilis* were performed to assess the effects of salinity and dissolved organic carbon (DOC). Rotifers were acclimated to 3 different salinities (3, 16 and 30 ppt), exposed to 4 different concentrations of DOC (ranging from zero added DOC to 13.7 mg C L<sup>-1</sup>) and total Cu concentrations ranging from 0 to 390 µg L<sup>-1</sup>. Total Cu was measured using anodic stripping voltammetry (ASV) and free Cu concentrations using an ion selective electrode (ISE). There was a protective effect of salinity when no DOC was added; with the LC50 values being significantly higher at 30 ppt (34.4 µg L<sup>-1</sup>; 95% CI = 28.5–43.1 µg L<sup>-1</sup>), when compared to 3 ppt (13.5 µg L<sup>-1</sup>; 95% CI = 11.7–15.6 µg L<sup>-1</sup>) and 16 ppt (14.6 µg L<sup>-1</sup>; 95% CI = 12.9–16.6 µg L<sup>-1</sup>). DOC complexation significantly reduced Cu toxicity. For all salinities, the protective effect of DOC against Cu toxicity was linear up to concentrations of 5 mg C L<sup>-1</sup>. However, at high concentrations of DOC (13.7 mg C L<sup>-1</sup>) the LC50 values were lower than expected; the degree of protectivity per mg of C decreased as DOC increased. This relationship was more pronounced at higher salinities, indicating the possibility of salt induced colloid formation decreasing the number of available reactive sites within DOC to complex Cu. Taking into account LC50 values, DOC concentrations and salinity, modeling of free Cu concentrations appeared to support salt induced colloid formation at high DOC concentrations, as well as the protective effect of increasing cation concentrations on Cu toxicity. ISE measurements of free Cu were comparable to the modeled data at high DOC concentrations, but not so when both salinity and DOC concentrations were low. The most likely cause of this discrepancy was the weak buffering capacity and resultant poor ISE reliability at low total Cu concentrations. Data from this research will be used in the development of a marine and estuarine biotic ligand model, and ultimately criteria for the protection of organisms in these environments.

**250 The influence of salinity on the acute toxicity of Cd to estuarine killifish: A comparison of Cd, Cu, Zn, and Ni toxicity** G.K. Bielmyer, Valdosta State University / Biology, Valdosta State University / Department of Biology; M. Grosell, University of Miami. The euryhaline killifishes, *Fundulus heteroclitus* and *Kryptolebias marmoratus* inhabit estuaries that rapidly change salinity on both daily and seasonal basis. It is well known that metal toxicity in freshwaters can vary with water chemistry and that metal bioavailability is controlled by ligand interactions and competing ions. However, the characterization of metal toxicity in estuarine and marine systems has been given far less attention. Additionally, current environmental regulations do not account for organism physiology in different salinity waters even though metal sensitivity is likely to change in such environments. More data is needed to better understand mechanisms of metal toxicity so that toxicity can be predicted in estuarine waters and criteria can be derived to protect the organisms inhabiting these environments. In this study, we investigated the effects of changing salinity on acute toxicity of Cd to larval (7–9 d old) *F. heteroclitus* and *K. marmoratus*. The 96-h median lethal concentrations (LC50) for Cd were determined for both fish species at six different salinities. Further, previous studies with Cu, Zn, and Ni are reviewed for comparison. In general, as salinity increased, metal toxicity decreased in both fish species. However, clear differences were apparent on the extent of salinity protection among metals and between fish species, particularly at intermediate salinities. These results could be useful for development of marine/estuarine biotic ligand models and for the determination of site-specific water quality criteria.

**251 Toxic physiological effects of Pb, Zn, Cu and Ni on early life stages of the sea urchin (*Strongylocentrotus purpuratus*)** M.S. Tellis, McMaster University / Biology; M.M. Lauer, Federal University of Rio Grande; S.R. Nadella, McMaster University / Biology; A. Bianchini, Federal University of Rio Grande; C.M. Wood, McMaster University / Department of Biology.

The early life stages of echinoderms are among the most sensitive organisms to many contaminants in the marine environment. In order to elucidate mechanisms of metal toxicity, we examined the physiological responses of larvae of *S. purpuratus* in 100% sea water to continuous sublethal exposure to Zn, Pb, Cu, or Ni (at 30-70% of EC 50 levels) from shortly after fertilization to 72-96 h of development. Under control conditions, whole body Ca concentrations increased approximately 20-fold over this period, accompanied by large changes in unidirectional Ca uptake rates from the water, as measured by  $^{45}\text{Ca}$  influx, and large variations in  $\text{Ca}^{2+}$ -ATPase activity. Whole body Mg concentration also increased, whereas Na and K concentrations exhibited a biphasic pattern. Chronic exposure to each of the 4 metals caused pronounced decreases of Ca uptake rate at the blastula, gastrula, and pluteus stages, with the largest inhibitions occurring at the time of gastrulation.  $\text{Ca}^{2+}$ -ATPase activity and whole body Ca concentrations were also greatly reduced. Mg accumulation was moderately disturbed, whereas effects on whole body Na and K were negligible. However acute challenges with much higher levels of each metal had no effect on Ca uptake rates at any time, indicating that the inhibitions of Ca accumulation during chronic exposure did not occur via direct metal competition for uptake sites. These similar effects of the 4 metals on Ca metabolism occurred despite diverse patterns of metal bioaccumulation, ranging from negligible (Zn, Ni) to modest (Cu) to pronounced (Pb). We conclude that non-competitive interference with calcification may be a unifying feature of metal toxicity to developing echinoderm larvae. (ICA, CDA, ILZRO, IZA, NiPERA, Teck Resources, Vale Canada, Xstrata Zinc, NSERC CRD Program, IDRC-IRC program, CNPQ).

**252 Comparative biogeochemical controls on seawater:sediment nickel bioavailability and lifecycle toxicity to sediment-dwelling amphipods and copepods** G. Chandler, University of South Carolina / Department of Environmental Health Sciences, University of South Carolina / Arnold School of Public Health; J. Ferry, University of South Carolina / Dept. of Chemistry and Biochemistry; K. Washburn, University of South Carolina / Dept. of Environmental Health Sciences; L. He, University of South Carolina; E. Stewart, University of South Carolina / Arnold School of Public Health; C.E. Schlegel, NiPERA; E.C. Rogevich-Garman, NiPERA / Ecotoxicologist. Nickel:sediment biogeochemical controls on bioavailability and comparative toxicity to two key estuarine crustaceans were evaluated using partial to full lifecycle bioassays in fine organic-rich estuarine sediments, and, for comparison, in seawater alone. *Leptocheirus plumulosus* is a marine gammarid amphipod that broods 12-25 young to hatching and then releases them at a size equivalent to most adult meiobenthic copepods (~0.7 to 1 mm). These juveniles spend 2-3 weeks in the meiobenthos as free burrowing sediment ingesters before becoming semi-sessile suspension-feeding tube dwellers in the oxic layer of fine muddy sediments in east coast USA estuaries. *Amphiascus tenuiremis* is a lifetime free-burrowing errant meiobenthic copepod that also dwells in the 0-2 cm oxic layer of estuarine sediments as a sediment ingester and diatom/bacterial grazer. It spans a lifecycle size spectrum from 0.05 to 0.7 mm and is representative of sediment copepods that coexist with *L. plumulosus* and other small macrobenthos. Both species experience similar but importantly different routes of sediment and porewater metal exposure influenced by their feeding and lifestyle ecologies. Divalent metal bioavailabilities in marine sediments are strongly influenced by multiple interactive biogeochemical controls of sulfide, manganese:iron (oxyhydroxides, etc.), quantity/qualities of organic carbon (particulate and dissolved), water ionic strength, temperature, redox, sediment porosity, and intensity of sediment bioturbation and ingestion/processing. Toxicity is driven by metal type and bioavailable concentration, exposure duration, faunal feeding modes, and, for crustaceans, the frequency of molting and amount of body surface area exposed to metal uptake. This study used redox-controlled flow-through sediment microcosms to measure nickel bioavailability and toxicity to *L. plumulosus* and *A. tenuiremis* in the context of each's life history/stage and sediment use. In sediment-free partial lifecycle exposures, juvenile *A. tenuiremis* are 2-3 times more sensitive to nickel than juvenile *L. plumulosus* even though similar in body size. As body size increases with *L. plumulosus* growth, the disparity in X-species nickel sensitivity increases in seawater alone, but for sediment exposures, nickel differential toxicity was attenuated by multiple interactions of biogeochemistry that were measured, predictive, acting at the population level, and interesting.

**253 Is energy metabolism impairment the unifying response to copper exposure in marine invertebrates?** M.M. Lauer, V.C. Azevedo, A. Bianchini, Universidade Federal do Rio Grande – FURG / Instituto de Ciências Biológicas. In freshwater invertebrates and fish, acute copper (Cu) toxicity is associated with ionoregulatory disturbances. We have demonstrated that Cu is also an ionoregulatory toxicant in some euryhaline invertebrates acclimated to low water salinities. However, we have failed to demonstrate any ionoregulatory impairment in euryhaline invertebrates (molluscs and crustaceans) exposed to Cu in sea water. In contrast, several biochemical and physiological effects (changes in oxygen consumption, oxidative stress, and energy metabolism), have been reported in marine invertebrates after acute exposure to Cu. However, most of these effects have been demonstrated using high Cu concentrations. At environmentally relevant Cu concentrations, a unifying mechanism explaining the mode of the metal toxic action in marine invertebrates is still under debate. After observing that the Cu-induced ionoregulatory disturbance observed in copepods acclimated to dilute sea water was ameliorated by feeding, experiments to evaluate the effect of environmentally relevant Cu concentrations on energy metabolism were performed in different groups of marine invertebrates (sea urchins, sea anemones, sea cucumbers, and crabs). Endpoints analyzed included those associated with the activity of key metabolic enzymes (those involved in glycolysis, Krebs' cycle, and the mitochondrial electron transport chain) and oxidative-stress related parameters in respiratory "organs". Changes in membrane potential of mitochondria isolated from crab gills were also considered. Results showed that Cu exposure inhibited the activity of several key metabolic enzymes in all marine invertebrates studied, and disrupted the membrane potential of mitochondria isolated from crab gills. In addition, reduced antioxidant capacity and increased oxidative damage (lipid and protein oxidation) were observed in the respiratory "organs" of the marine invertebrates. These findings clearly indicate that Cu is impairing energy production, with consequent oxidative damage to the respiratory "organs" of marine invertebrates. In light of the above, we suggest that the observed Cu-induced impairment in energy metabolism at the respiratory "organ" could be considered as a unifying mode of toxic action for Cu in marine invertebrates. Implications of the findings reported here for the development of a marine version of the Biotic Ligand Model will be also discussed. [Support: IDRC (Canada), ICA (USA), CNPq and CAPES (Brazil)].

**254 Copper effects on physiology of estuarine guppy *Poecilia vivipara*: understanding mechanisms and potential biomarkers** A.A. De souza machado, Federal University of Rio Grande-FURG / Institute of Oceanography; M. Muller Hoff, Federal University of Rio Grande-FURG / Institute of Biology; R.D. Klein, J. Goulart Cardozo, Federal University of Rio Grande-FURG; M. Mussoi Giacomini, Universidade Federal do Rio Grande – FURG / Instituto de Ciências Biológicas; G.L. Pinho, Federal University of Rio Grande-FURG; A. Bianchini, Universidade Federal do Rio Grande – FURG / Instituto de Ciências Biológicas. In freshwater fish, the mechanism of acute waterborne copper toxicity is reported to be related to ionic and osmotic imbalances, following the inhibition of gill  $\text{Na}^+/\text{K}^+$ -ATPase activity. However, the same mode of toxic action is not always evident in estuarine and marine fish. In the euryhaline guppy *Poecilia vivipara*, gill estuary activity was shown to be not affected by copper exposure. Therefore, we have evaluated the response of a large suite of genetic, physiological and biochemical biomarkers to environmentally relevant copper concentrations. Endpoints were analyzed in tissues and whole-body of guppies exposed (96 h) to waterborne copper (5, 9 and 20  $\mu\text{g Cu/L}$ ) in salt water (salinity 24 ppt). Comet assay score and frequencies of nuclear abnormalities, as well as micronucleated cells were analyzed in peripheral erythrocytes, while copper and ions (Na, K, Ca, Mg and Cl) concentrations were determined in fish whole-body. Antioxidant enzymes [superoxide dismutase (SOD), catalase (CAT), glutathione reductase (GST), and glutathione S-transferase (GST)] activity, metallothionein-like proteins (MTLP) concentration, reactive oxygen species (ROS) production, total antioxidant capacity against peroxyl radicals (ACAP), and lipid peroxidation (LPO) were evaluated in liver, gills and muscle. Results show that guppies were able to regulate the whole-body copper concentration at low copper concentrations, but metal was shown to be accumulated after exposure to 20  $\mu\text{g Cu.L}^{-1}$ . Whole-body Na, K, and Mg disturbances were observed after exposure to copper, suggesting that ionoregulatory mechanisms taking place at gills and likely also kidney were impacted by copper exposure. Also, disturbances of ionic regulation were significantly correlated with the level of oxidative damage in gills ( $r^2=0.97$ ), suggesting an indirect (oxidative) effect of copper on the ion-transporting

mechanisms. Copper exposure also induced oxidative damages to DNA (strand breaks, micronuclei formation and other nuclear abnormalities). CAT activity in liver, ROS, ACAP and LPO in muscle, gills and liver, micronuclei frequency in erythrocytes, as well as whole-body ion (Na, K, and Mg) composition showed to be the most promising biomarkers to assess the exposure of *P. vivipara* to environmentally relevant copper concentrations, since they showed a concentration-dependent response to copper exposure and biological relevance.

**255 Design and Calibration of an AQUATOX Ecosystem Model for Assessing Effects of the Herbicide Prosulfocarb on Aquatic Food Webs** D.A. Rudnick, Integral Consulting, Inc; R.A. Pastorok, Integral Consulting; D.V. Preziosi, Integral Consulting Inc; Y. Bramley, Syngenta; E. Farrelly, Syngenta / Ecological Sciences; D. Huggett, Syngenta; P. Thorbek, Syngenta Ltd / Environmental Safety, Syngenta / Environmental Safety. The use of toxicity experiments in laboratory, mesocosm, and field applications plays an important role in pesticide risk assessment but cannot address all issues related to indirect effects mediated through species interactions within food webs. For example, as part of the European Union registration process for the herbicide prosulfocarb, available laboratory toxicity data and aquatic mesocosm results indicated the potential for short-term effects on phytoplankton and periphyton species, but the nature and time-frame of potential indirect effects on aquatic animals, including fish, were unknown. Aquatic ecosystem modeling can be used to evaluate not only direct toxic effects of pesticides but also indirect effects mediated through trophic interactions of species (e.g. competition and predation). We have developed an aquatic ecosystem model using AQUATOX (updated v. 3.0) to evaluate the potential direct and indirect ecological effects of prosulfocarb on freshwater systems. We report here on the design and calibration of AQUATOX to represent mesocosms originally intended for assessing community-level effects of prosulfocarb. Physical characteristics, nutrient loading, and major biotic groups in the AQUATOX mesocosm-mimic model corresponded to those of the prosulfocarb-study mesocosms. Biological communities included phytoplankton, periphyton, zooplankton, benthic and epiphytic macroinvertebrates, and macrophytes, but not fish as the latter were absent from the mesocosms. To match characteristics of the mesocosms, our mesocosm-mimic model assumes spatial homogeneity in the water column and lacks immigration and emigration. The model was parameterized using data from the prosulfocarb-study mesocosms, from the AQUATOX internal library, and from the open literature. Information on toxicity and environmental fate of prosulfocarb was obtained mainly from the Draft Assessment Report developed by the responsible Rapporteur Member State. Overall, the model is well calibrated (generally within a factor of 2-3) to the mesocosm data, particularly for prosulfocarb concentration and biological variables. We conclude that aquatic ecosystem modeling complements empirical approaches to pesticide risk assessment by allowing efficient evaluation of indirect effects, testing of multiple exposure scenarios, and assessment of potential long-term effects and recovery times.

**256 Accounting for Intended Use Application in Characterizing Contributions of D5 to Aquatic Loadings Following Marketed Personal Care Product Use** B. Montemayor, Canadian Cosmetic, Toiletry and Fragrance Association, Canadian Cosmetic, Toiletry and Fragrance Association / Toiletry and Fragrance Association; B. Price, Procter & Gamble; R. van Egmond, Unilever Research Laboratory Colworth / SEAC. Decamethylcyclopentasiloxane, commonly known as D5 (cyclopentasiloxane) has a wide application of use across a multitude of personal care product categories. The relative volatility of D5 is one of the key properties attributed to this substance that provide for the derived performance benefits attributed to the use of this raw material in personal care formulations. On this basis, rapid evaporative loss following use of many products comprising D5 is expected following typical use application and corresponding wear time. Studies were conducted on three key product categories containing D5 (antiperspirants, skin care products and hair care products) to investigate the amount of D5 that may be destined to go down the drain following simulated typical personal care use scenarios. Marketed antiperspirants and skin care products were applied to human subjects and hair care products were applied to human hair tresses and subsequently rinsed off at designated time points. Wash water was collected at 0, 8 and 24 hours (antiperspirant and hair care analysis) and additionally at 4 hours (skin care analysis) post product application and samples analyzed by isotope dilution headspace gas chromatography/mass spectrometry (GC/MS) to quantify the concentration of D5

destined to be available to go down the drain in captured wash water. It is demonstrated that only a very small fraction of the D5 in products (less than 1%, 0.3 % and 0.02% for antiperspirants, skin care and hair care products, respectively) is available to go down the drain from 'leave-on' type personal care products following typical conditions of use.

**257 The Role of Hazard Property and Exposure Based Approaches in the Assessment of Industrial Substances** M.A. Bonnell, Environment Canada / New Substances Division, Environment Canada / Science and Risk Assessment Directorate. The domestic inventories of industrial chemicals in many countries number in the tens of thousands. Given the global demand to ensure public and environmental safety from commercial chemical use, regulatory agencies have shifted their approaches from lengthy single-chemical assessments, that require substantial resources and time to complete, to rapid evaluation approaches that prioritize the most potentially harmful chemicals for further assessment. Because there are different approaches that can be used to prioritize chemicals, we will examine hazard property driven approaches (e.g., vPvB, PBT) and exposure driven approaches (e.g., risk quotients) and ask the question of when these approaches are most effective when making regulatory decisions in light of the protective goals of the assessments. The decision-making process is very much connected to science/policy driven metrics such as weight of evidence and precaution as well as uncertainty. We will therefore examine the interrelationship of these factors as well. Canada's experience and insights over the last ten years from Categorization, the new chemicals program and other activities under the Chemicals Management Plan will serve as a template for discussion.

**258 Use of Fugacity Ratio Methodology for Assessment of Bioaccumulation Potential: Concepts, Applications, and Caveats** K.B. Woodburn, Dow Corning Corporation / Health & Environmental Sciences; D.E. Powell, Dow Corning Corporation / Health & Environmental Sciences, Dow Corning Corporation / Health & Environmental Sciences (C03101). A historic but infrequently used approach for comparing bioaccumulation (B) data is to express the B assessment metrics in terms of the thermodynamic status of the chemical with respect to a reference phase using fugacity ratios. Participants in a 2009 SETAC Pellston Conference concluded that the fugacity ratio approach is a practical framework for decision making in chemical management and regulation, particularly with regard to assessing bioaccumulation potential. Fugacity is an equilibrium criterion and can be used to assess the relative chemical activities or chemical potentials of a chemical in a specific system. At thermodynamic equilibrium, the chemical fugacities in the different phases are equal. A fugacity ratio between an organism and a reference phase (e.g., water, sediment, or diet) greater than 1 indicates that the chemical in the organism is at a higher fugacity (or chemical activity) than the reference phase. The application of the fugacity ratio methodology has a number of advantages. First, the technique can make use of all laboratory data for which bioaccumulation metrics exist. Secondly, the fugacity ratios are able to express the alphabet soup of bioaccumulation measures (i.e., BCF, BMF, BSAF, TMF) on a similar basis, i.e., as a dimensionless ratio. Third, the fugacity ratios can be visualized in a weight-of-evidence approach, which allows all available data to be viewed together and which also increases confidence in the outcome of the assessment. Most importantly, the fugacity ratio approach provides a formal method for testing the hypothesis whether biomagnification may occur by testing whether fugacity ratios are generally greater than unity (1.0). This presentation will review the fugacity ratio concept, its practical application with a variety of chemical families, how use of fugacity ratios may inform ecological risk assessments, and a discussion of appropriate caveats when applying this technique.

**259 Advances in mechanistic effect modeling can contribute to value-relevant ecological risk assessments** V.E. Forbes, University of Nebraska Lincoln / School of Biological Sciences; P. Calow, University of Nebraska Lincoln / Office of Research and Economic Development. Current methods for ecological risk assessment are often protective, but they are not consistently so. The most common outputs of the risk assessments (i.e., hazard- or risk quotients) are far removed from environmental protection goals and therefore are not as helpful for informing management decisions as they could be. Recent advances in mechanistic effect modeling (which include toxicokinetic/toxicodynamic models, dynamic energy budget models, as well as various types of population models) have demonstrated that spatial and temporal variability in exposure, avoidance and dispersal behavior of

exposed organisms, and differences in life history among species can measurably influence impacts of chemicals on populations and should be more systematically explored in a risk assessment context. An important advantage of such models is that their outputs are more directly related to protection goals, i.e., the outputs are value relevant. In addition, coupling information on the impacts of chemicals on populations or groups of populations to the delivery of ecosystem services, through the development of robust ecological production functions, can provide a scientific basis for more transparent risk management decisions. A key question is whether future risk assessments should add non-traditional information on top of traditional approaches or whether the time is right for a paradigm shift in our overall approach to ecological risk assessment.

**260 The Effect of Pre-exposure on *in Vitro* Biotransformation Rates of Hydrophobic Chemicals in Rainbow Trout (*Oncorhynchus Mykiss*)** L.J. Saunders, Simon Fraser University / Department of Biological Sciences; S.V. Otton, Simon Fraser University / School of Resource and Environmental Management; F.A. Gobas, Simon Fraser University / School of Resource and Environmental Management (Faculty of Environment), Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment, Simon Fraser University. Knowledge of chemical biotransformation rates in fish and other organisms has been identified as a key requirement for assessing the bioaccumulative potential of highly hydrophobic chemicals. There is much effort to develop *in vitro* to *in vivo* extrapolation methods to obtain metabolic transformation rates but a criticism of these methods is that the laboratory animals used as the source of liver metabolizing enzymes for *in vitro* testing may not represent organisms in real environments. The activity of biotransformation enzymes in organisms exposed to multiple pollutants can be inhibited or induced. The present study examined the effect of pre-exposure of rainbow trout (*Oncorhynchus mykiss*) to secondary treated municipal wastewater effluent on the *in vitro* biotransformation rates of polycyclic aromatic hydrocarbons (PAHs). Fish were exposed under static conditions for 7 days to environmentally relevant dilutions of effluent at 0, 0.1, 1 and 10%. PAH biotransformation rates in liver S9 fractions were measured in each exposure group via the conventional substrate depletion method. Pyrene and benzo[a]pyrene depletion rate constants were significantly higher in liver fractions from fish exposed to 10% diluted effluent compared to controls, suggesting that pre-exposure induced the activity of PAH-metabolizing enzymes. The results indicate that *in vitro* tests using laboratory animals may underestimate biotransformation rates occurring in organisms in the field. Using organisms that represent *in situ* situations may provide more accurate laboratory assessment when measuring biotransformation rates in animals for bioaccumulation assessment.

**261 The Chemical Footprint as a Ruler for Impactful Risk Management of Toxic Pollution** M.C. Zijp, National Institute for Public Health and the Environment; D. van de Meent, Radboud University Nijmegen / Institute of Wetland and Water Research; L. Posthuma, RIVM / Lab. for Ecological Risk Assessment, RIVM / LER; A. Hollander, Radboud University Nijmegen / Institute of Wetland and Water Research. The term 'chemical footprint' was coined to express whether gross chemical emissions (separate compounds or mixtures) are larger than the capacity of the environment to accommodate emissions. The concept encompasses a strong communicative element, allowing for evaluating effects of chemical risk management. However, a generally accepted method for deriving a chemical footprint does not seem to exist yet. We have tested the utility of- and expanded the calculation procedures published earlier by Harbers et al (2006) and Eurostat (2009) for this purpose. Earlier calculations have suffered from limited data availability. This technical problem has been solved by REACH, the European Community Regulation on chemicals, implying that substances can be marketed only when safe use has been proven. Substance information is becoming available now from REACH registration dossiers, which have currently been submitted for over 6000 different chemical substances. This information gave us the opportunity to derive the Risk Characterization Ratios (RCReco) for 350 substances representing 60% of the used tonnages in EU. The summed RCReco remained below unity, indicating that all chemicals together exerted a toxic pressure that, produced from one chemical only, would have been considered acceptably low. In addition to this, we have reworked the calculation result into a chemical footprint of EU-wide use of these substances, applying the principles of Species Sensitivity Distributions. Applying the generally accepted criterion that no more than 5% of the species should be exposed to concentrations greater than their NOEC, We

calculated the chemical footprint of the EU to be approximately 50% of the total fresh water capacity in Europe. In other words: half of the existing fresh water ecosystem is occupied to its set maximum capacity. To summarize we used the following steps to derive the chemical footprint for Europe: 1) hazard definition: scale and endpoint (e.g. biodiversity in fresh waters); 2) sub-selection of chemicals; 3) exposure and fate modeling; 4) dose effect modeling; 5) derive the multi substance Potentially Affected Fraction of species; 6) conversion of this to the footprint unit. During the presentation, the relative and absolute meaning of the outcomes of the classical RCR and the footprint method are discussed and usages of chemical footprints on product-, organization- and regional level will be evaluated.

**262 Standard and non-standard ecotoxicity data in risk assessment of chemicals** M. Agerstrand, Royal Institute of Technology (KTH) / Div. of Philosophy; M. Breitholtz, ITM, Stockholm University; C. Ruden, Royal Institute of Technology (KTH). Guidance documents for pharmaceuticals, plant protection products, biocides and industrial chemicals recommend the use of standard ecotoxicity tests in regulatory risk assessments. These recommendations have decreased the use of non-standard test data. On the positive side, this has increased the reliability of the data since the strict reporting requirement for standard tests enhance reliability, and thereby the reproducibility of the data. On the negative side, it could have implications for the relevance of the risk assessment. Standard tests may not always be sensitive enough to measure the specific effects expected for instance from endocrine disrupting chemicals, nanoparticles and pharmaceuticals. Bisphenol A is an illustrative example since three standard tests are preferred by several risk assessors over 200 non-standard studies with lower effect values. Previous studies indicate that ecotoxicity studies published in the open scientific literature are surprisingly often insufficiently reported. This may be a major reason why they are often seen as less reliable in a risk assessment context. Choice of reliability evaluation method could also affect the outcome of the evaluation. Several guidance documents recommend that the method described by Klimisch et al. (1997) should be used for evaluating the reliability of ecotoxicity and toxicity data but the Klimisch criteria give a strong preference for standard tests. We present a novel and more comprehensive method for evaluating and reporting non-standard ecotoxicity data. Its aim is to enable an increased use of non-standard data in risk assessments. As part of this work we clarify the definitions of "reliability" and "relevance" in order to promote the consistent use and application of these concepts in risk assessment procedures.

**263 Purpose of the Special Symposium "21st Century Environmental Risk Assessment"** J. Toll, Windward Environmental LLC; M.S. Johnson, US Army, Public Health Command / Health Effects Research Program, US Army Institute of Public Health / Health Effects Research Program, Army Institute of Public Health / Health Effects Research Program, US Army Ctr for Health Promotion & Preventive Med. / Health Effects Research Program. The special symposium "21st Century Environmental Risk Assessment" is meant to help kick off a new Ecological Risk Assessment Advisory Group (ERA EG) work group on solution-focused risk assessment. The idea of forming the work group was inspired by the U.S. National Research Council's Silver Book (*Science and Decisions: Advancing Risk Assessment*, National Academies Press 2009), particularly Chapter 8, "Improving the Utility of Risk Assessment." A brief article about this appeared in the February 2012 *Globe* ([www.setac.org/globe/2012/february/era.html](http://www.setac.org/globe/2012/february/era.html)). SETAC's ERA AG should play a role in vetting ideas about improving the utility of environmental risk assessment, identifying good ideas that we think should be implemented, and promoting those ideas. That includes ideas about how to improve the environmental risk assessment framework and ideas about better risk assessment tools. That's what this special symposium and the work group on solution-focused risk assessment are about.

**264 Solution-Focused Risk Assessment and Its Challenges** B.K. Hope, CH2M Hill. Solution-focused risk assessment (SFRA) is an attractive idea, and one that may play a role in environmental risk assessment, provided it can overcome certain challenges. My insights into these challenges stem from being a member of the National Research Council committee that considered SFRA and from having reviewed and critiqued the first extended explication of it. SFRA's fundamental premise is that, after sensing a problem (i.e., a "signal of harm"), you first consider possible solutions, then examine risks and benefits associated with each potential solution. This is in opposition to the current paradigm that senses a signal then uses risk

assessment to analyze and characterize it (and perhaps turn a non-problem into an illusory big one). SFRA's first challenge lies with how that "signal of harm" is sensed, by whom, and whether there's agreement as to its magnitude or very existence. A second challenge, should that signal's existence and magnitude be agreed, is discerning its source. This may be a simple task or a legally complex matter of attribution and responsibility, but is an essential one if resources are to be found to consider and implement solutions. A third challenge, which applies to both problem- and solution-focused approaches, is the assessment itself. If it embodies overly conservative assumptions, it may turn a small signal into a large one and thus distort the risk/benefit ratio for different solutions. And, if it is a dichotomous hazard, rather than a true, risk assessment, it will not address the continuous relationships between exposure and consequence envisioned by SFRA. These challenges notwithstanding, a realistic path to SLRA may be possible if we used the extant first (albeit often *pro forma*) step in risk assessment – problem formulation – to meet SLRA's requirement that risk managers and assessors take time to consider solutions before analysis and opportunities before problems.

**265 Integrating adaptive management into the risk assessment process** L. Barnthouse, LWB Environmental Services, Inc.. The National Academy of Sciences' 2009 report *Science and Decisions* made an important contribution to risk assessment by providing a framework for ensuring that risk assessments support management decision-making. The 2009 report expands on recommendations made in a 2005 Academy report on risk assessment and risk management at large Superfund sites. This earlier report similarly stressed the need for risk assessment to support management decision-making. A key recommendation of the 2005 report was that EPA adopt adaptive management as a strategy for restoring sites that cannot be managed using the conventional RI/FS process because the size and complexity of the sites makes it impossible to design a "final remedy" prior to the initiation of remedial actions. At such sites, a phased approach to remediation, often accompanied by research on site characteristics or treatment technologies, is necessary to achieve success. The concept of adaptive management, originally developed more than 40 years ago and now widely utilized by resource management agencies, provides a systematic means of designing and implementing environmental management programs for these types of sites. The term "adaptive management" generally describes an approach to environmental resource management in which information obtained during the implementation of a management action is used to refine the action and ensure that it meets management objectives. Key technical elements of adaptive management include conceptual or quantitative models that are used to predict the outcomes of actions, performance metrics and targets for evaluating the success or failure of actions, and contingency plans for responding to unexpected outcomes. Key institutional elements of adaptive management include institutional commitment and active involvement of stakeholders. To be effective, however, adaptive management must be applied throughout all phases of the risk assessment and risk management processes, from problem formulation through risk characterization and beyond. Using examples from actual sites, this paper identifies requirements for successfully applying adaptive management principles to complex risk assessment and risk management activities.

**266 Science and Decisions in the EPA's Risk Assessment Forum** G.W. Suter, U.S. Environmental Protection Agency / National Center for Environmental Assessment, U.S. EPA / National Center for Environmental A; L. Martin, U.S. EPA / Risk Assessment Forum. The National Research Council's (NRC) report *Science and Decisions: Advancing Risk Assessment* was commissioned by the U.S. Environmental Protection Agency as an update to the 1983 red book. Since its publication, the Agency's Risk Assessment Forum (RAF) and National Center for Environmental Assessment have taken the lead in implementing its recommendations. Most notably, the NRC replaced the old framework for human health risk assessment with a more complex one that is concerned with decision support and adopts the concept of problem formulation from the ecological risk assessment (ERA) framework. The RAF is developing a human health risk assessment framework that is responsive to the NRC. On the ecological side, the RAF organized a colloquium on ecological risk assessment that developed recommendations for advancing ERA and subsequently condensed that into an Ecological Assessment Action Plan. The plan includes major, policy-relevant projects on using ecosystem services as assessment endpoints, communicating ecological risks, inference by weight of evidence, integration of ecological

assessments, applying adaptive management to environmental protection, and strengthening ecological goals. Proposed projects related to technical practices include improved training and access to information, quality assurance, multiple stressors, and uncertainty characterization and communication. There are also collaborations between human health and ecological assessors on cumulative risk, uncertainty, and terminology. SETAC members are providing input to these projects and they should find the results to be useful in various contexts. *The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency.*

**267 Building Opportunities for Habitat Restoration or Control of Invasive Species into Environmental Risk Assessments** K.G. Keil, US Army Corps of Engineers / Buffalo District, US Army Corps of Engineers; L.C. Carroll, US Army Corps of Engineers. The U.S. Army Corps of Engineers performs environmental risk assessments for at least two types of projects: hazardous, toxic, or radioactive waste (HTRW) sites, as well as non-HTRW sites (dredged material disposal). The HTRW sites may be part of a Base Realignment and Closure site, a Defense Environmental Restoration Program site, or a Formerly Utilized Sites Remedial Action Program site (sites with residual radioactivity from the Manhattan Project). The non-HTRW project sites result from maintenance dredging of U.S. waterways, and may involve engineered confined disposal or unconfined upland placement. In following our mission to ensure that our project sites are fully protective of human health and the environment, the EPA's Environmental Risk Assessment (ERA) framework is used to determine whether or not contamination at a site may pose an unacceptable risk to ecological receptors. However, many of these sites are undergoing redevelopment as land uses change, and the traditional EPA ERA framework often does not serve overall project objectives to strive for green remediation, sustainable development, or ecosystem restoration. Sites with little to no habitat are allowed to "by-pass" the ERA process altogether (reasoning that there are not any complete ecological exposures pathways), even though these sites could provide opportunities for habitat creation. Furthermore, sites with disturbed but recovering habitat may "fail" the ERA (due to presence of low level contamination) but can provide great opportunities for ecosystem restoration or enhancement through invasive species control projects. Thus the ERA is often performed but then set aside as decisions are made for the project to either remediate the site to protect human health (in the case of many HTRW brownfield sites) or continue with ecosystem improvements (only using the ERA indirectly). The USACE's Environmental Operating Principles challenge us to "strive to achieve environmental sustainability" and to "seek balance and synergy among human development activities and natural systems". Those guidelines should be reflected somehow in the ERA process. Several case studies of HTRW and non-HTRW sites will be presented and the associated ERA process will be evaluated to determine what adjustments in the ERA would be useful in providing information that would assist in actually improving environmental conditions at the project site.

**268 Looking Back to See Ahead: The Current and Future Role of Ecological Risk Assessment in Sediment Remedial Decisions** K.B. Bradley, GEI Consultants, Inc. / Ecologist, GEI Consultants / Project Scientist/ Ecologist; B.W. Gensemer, GEI Consultants / Ecological Division; B. Hermanson, GEI Consultants, Inc.; S.A. Roark, GEI Consultants. Incorporation of developing risk assessment methodologies and models into solution-based ecological risk assessments (ERAs) can only be successful if these approaches are integrated into the remedial investigation/feasibility study (RI/FS) process. Sediment remediation projects often include ERA approaches based upon recent scientific advances, only to have remedial decisions, even preliminary remediation goals (PRGs), selected for practical feasibility, cost, or risk-based conservatism, rather than relying on information from the ERA. This is primarily due to the use of the pre-1988 paradigm for the RI/FS process, where the RI and FS work in series. The RI/ERA step focuses on characterizing the site and quantifying risk, with little regard for potential remedies. The focus on characterization and risk identification relies primarily on a goal of scientific integrity in the analysis, and production of a high degree of certainty about the characteristics of the site. The FS step then introduces practical issues, defining risk management options based on the problems defined in the previous step with concerns about feasibility and cost efficiency. In this presentation several high profile the sediment remediation projects will be reviewed to highlight the use of the old RI/FS paradigm, and identify the points of disconnect between the

science-based conclusions resulting from the ERA and the ultimate remedial decisions made from the RI/FS process. The presentation will then point to the “new” parallel process paradigm of the RIFS process established in 1988, and show how solution-based ERA guidelines that focus on an integrated risk-based decision making process will provide better information throughout the RI/FS process.

**269 Some Practical Ideas for Accelerating Progress at Contaminated Sediment Sites** J. Toll, Windward Environmental LLC. The “top five actions” presented by Todd Bridges, Steve Nadeau and Megan McCulloch in “Accelerating Progress at Contaminated Sediment Sites: Moving from Guidance to Practice” (IEAM 8(2):331-338) represent an important set of normative guidelines that could accelerate progress at contaminated sediment sites. An important next step is to use those guidelines to develop recommendations about good practices. This presentation will offer some recommendations of that sort, paired with the guidelines from Bridges et al. that inspired them. The objective is to draw more attention to solving the important problem of how to accelerate progress toward cost-effective cleanup, closure and beneficial future use of contaminated sediment sites.

**271 Computational Toxicology: A More Efficient and Effective Testing and Assessment Paradigm for Chemical Risk Management** S.P. Bradbury, U.S. Environmental Protection Agency / Office of Pesticide Programs Office of Chemical Safety and Pollution Prevention. A major challenge confronting chemical risk management is to address the potential ecological and human health risks for large numbers of chemicals with greater speed and accuracy using fewer resources. From a strategic and tactical viewpoint, an integrated approach that relies on existing knowledge (including mechanistic information of both chemistry and biology from novel computational toxicology) is needed to advance progressive and focused assessment strategies, as well as to advance the utility of risk assessment by providing more relevant information. This presentation will describe the use of “Integrative Approaches to Testing and Assessment” is a means to efficiently use existing exposure and toxicity information combined with (Q)SAR predictions and in vitro data in a systematic and coordinated manner for a chemical or a group of similar compounds.

**272 Using Transcriptomic Data in the Risk Assessment Paradigm** R.S. Thomas, The Hamner Institutes for Health Sciences / Institute for Chemical Safety Sciences, Center for Genomic Biology and Bioinformatics. The integration of transcriptomic data into the risk assessment paradigm is a challenge currently facing risk assessment. To assess the value of applying transcriptomics in risk assessment, a series of rodent studies were performed across five chemicals that were positive for lung or liver tumors in a standard cancer bioassay, with transcriptional changes in the lung or the liver evaluated using microarrays. The dose-response changes in gene expression were analyzed using standard benchmark dose methods that have been commonly employed in risk assessment. A comparison of the transcriptional benchmark dose values with those for the traditional noncancer and cancer apical endpoints was conducted showed a high degree of correlation for specific signaling pathways. Many of the correlated pathways have been implicated in noncancer and cancer disease pathogenesis. The results demonstrate that transcriptomic changes in signaling pathways can be used to estimate noncancer and cancer points-of-departure for use in quantitative risk assessments.

**273 Adverse outcome pathway Adverse Outcome Pathways as a Unifying Concept in Environmental Toxicology** K.M. Crofton, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL. An adverse outcome pathway (AOP) is a subset of a source to outcome pathway that delineates documented and testable linkages between a molecular initiating event and an adverse outcome at the individual or population levels. AOPs, by definition, span multiple levels of biological organization. The amount of detail and linearity characterizing the AOP between a molecular initiating event and an adverse outcome within an AOP can vary substantially, both as a function of existing knowledge and risk assessment needs. Development of AOPs can provide insight into the uncertainties in linking chemical use, exposure and outcome, thereby focusing research on critical data needs. Well defined AOPs provide utilitarian framework to build quantitative and qualitative models useful in: understanding the degree of perturbation associated with adverse outcomes, target for the development and use of efficient chemical testing methods, and extrapolation between species and lifestages.

The development and use of AOPs can provide a framework in which high-throughput and high-content information informs more efficient and predictive risk decisions.

**274 Will Global Climate Change Influence the Conduct of Human and Ecological Risk Assessments for Contaminated Sites?** R.G. Stahl, DuPont Company / Corporate Remediation Group; T. Bingman, A. Guiseppe-Elie, DuPont Company / Corporate Remediation Group. The potential for global climate change (GCC) to impact humans and ecosystems has been discussed in multiple scientific and policy forums in past years, and in numerous published articles in the scientific and lay press. In 2011 SETAC sponsored an international, Pellston workshop on the potential for GCC to influence the scientific underpinnings of environmental toxicology and chemistry, and results from that effort have been presented in 2011 at SETAC North America (Boston), and in 2012 at SETAC World Congress (Berlin). Results from these efforts indicate that GCC is likely to manifest as a series or suite of stressors that may require changes in human and ecological exposure scenarios, or in estimating the magnitude of chemical impacts on humans and ecosystems. With this in mind, we have considered the question of whether or not GCC will influence the conduct of human and ecological risk assessments for contaminated sites. In this presentation we will discuss the potential for GCC to require changes in human and ecological exposure scenarios for contaminated site assessment, as well as the potential to influence risk management decisions to protect humans and ecological receptors.

**275 Integrating Emerging Technologies into Chemical Safety Assessment** L. Ritter, University of Guelph / Canadian Network of Toxicology Centres. In response to a request from the Pest Management Regulatory Agency of Health Canada, the Council of Canadian Academies convened an expert panel to examine the use of integrated approaches to testing and assessment (IATA) for the regulatory risk assessment of pesticides. The Panel concluded that, although there is no set of alternative tests that can completely replace the existing battery for data-rich chemicals today, the state of the science is evolving rapidly. IATA offers a transparent and scientifically robust framework to integrate new scientific knowledge into regulatory toxicity testing in a way that significantly augments the protection of human health and the environment. This, in turn, will help address the risk communications challenge, which will be instrumental in establishing public confidence and trust. The Panel concluded that transparency, coupled with sincere and early engagement of all stakeholder groups, will be instrumental in establishing public confidence and trust. The Panel also concluded that advances in computational sciences have established a foundation that may permit the use of epidemiological data in pre-market assessment of structurally related chemicals. This, coupled with advances in biomarker development, represents an exciting opportunity to address a major criticism in the existing approach. The report offers a near-term perspective, focusing on strategies that could be adopted over the next decade. Ongoing implementation would help move toxicology away from asking *what* and towards explaining *how*. The state of science is evolving rapidly and opportunities exist to address some of the limitations that were not, until now, addressable. Furthermore, continued advances will likely identify new limitations that were previously unidentified. These 21st century problems will need 21st century solutions. Although IATA may not be able to address all of these issues, it represents a transparent and pragmatic blueprint by which change may be effected.

**276 MABEL: use of preclinical data to set acceptable standards for exposure** G. Bruce, Intertox. The growing availability of sensitive pharmacological data and preclinical data characterizing the agents' mechanisms of action presents a unique opportunity to explore their use in developing screening levels for these compounds. This presentation will demonstrate use of the Minimum Anticipated Biological Effect Level (MABEL)—the lowest dose with any measurable effect on biological systems—an alternative to deriving a point of departure for ADIs for emerging compounds, particularly PPCPs, in drinking water.

**277 Management of risks from cumulative exposures to chemicals: Moving beyond TEQs and Hazard Indices** P.S. Price, The Dow Chemical Company / Toxicology & Environmental Research & Consulting. The human health and ecological risks posed by cumulative exposures to chemicals, including exposure to mixtures, have traditionally been investigated using

additive models. These models include screening models such as the Hazard Indices, systems of TEQs that are based on a common mechanism of action, and Toxicity Units that are based on empirical measurements of acute toxicity endpoints. More recently the IPCS/WHO has proposed a tiered framework of modeling approaches for the evaluation of mixtures. This framework proposes the use of both screening assessments and higher tiered approaches that consider detailed mechanisms of joint action and or use of probabilistic models of toxicity and exposure. The European chemical industry (Cefic) has developed a Decision Tree approach that extends the IPCS/WHO framework to include a determination of the value in performing cumulative assessments. These new tools provide increased flexibility in the evaluation of risks from mixtures. They allow the use of screening evaluations that can be performed with minimal data and describe how additional data can be used to refine the screening assessments. Finally, the new tools allow the identification of specific groups of chemicals and specific populations where cumulative risk assessments are most needed.

#### **278 The Case for Activity and Fugacity Based Environmental Risk Assessment: The Example of the Plasticizer DEHP** *EA Gobas*, Simon Fraser University / School of Resource and Environmental Management (Faculty of Environment), Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment, Simon Fraser University; V. Otton, Simon Fraser University; K. Clark, BEC Technologies Inc.; M. Ikononou, Institute for Ocean Sciences. A novel application of thermodynamic activity and fugacity in risk assessment is presented to assess the environmental risks of the common plasticizer di-ethylhexyl-phthalate ester (DEHP) and its main metabolite mono-ethylhexyl-phthalate ester (MEHP). The theoretical basis of activity based risk assessment is the expression of exposure and toxicity concentrations in similar units of activity and/or fugacity. This approach enhances the data base used in environmental risk assessments by including concentration data from different environmental media and toxicity data from in-vitro and in-vivo studies in one single risk analysis. The approach also identifies erroneous concentrations measurements that cannot exist in the environment. The application of this risk assessment methodology is illustrated for the common plasticizer DEHP and its metabolite MEHP. The risk assessment is based on the compilation of hundreds ( $n=1129$ ) of measured exposure concentrations in air, water, sediment soil, fish and wildlife species and the review of large numbers of toxicity studies by the EU, the US Consumer Product Safety Commission and Staples et al. (2011) in a variety of biological species and in a range of in-vitro systems. The risk analysis is based on the analysis of all available exposure and toxicity data in a single graphical presentation and probabilistic analysis. The risk analysis shows that environmental risks of DEHP and MEHP are very low.

**279 Impacts of Sediment Resuspension on Metal Bioavailability and Toxicity Assessments** *K.J. Farley*, Manhattan College / Civil and Environmental Engineering, Manhattan College / Civil & Environmental Engineering; R. Bubnyte, M.P. Villarosa, Manhattan College / Civil & Environmental Engineering; R.F. Carbonaro, Manhattan College / Civil and Environmental Engineering, Manhattan College / Department of Civil and Environmental Engineering, Mutch Associates, LLC; K.J. Rader, Mutch Associates, LLC, Manhattan College / Civil and Environmental Engineering. The presence of sulfides in sediments has been shown to play an important role in sequestering toxic metals (e.g., Cd, Cu, Ni, Pb, Zn) and in limiting metal bioavailability. This effect has been considered in regulatory decision-making through static or "snap-shot" measures of simultaneously extractable metals (SEM) and acid volatile sulfide (AVS) ratios. A potential weakness in this approach is the oxidation of metal sulfides and associated changes in metal bioavailability that are likely to occur during sediment resuspension events (e.g., due to episodic storms, propeller-induced disturbances and dredging activities). Our colleagues have therefore been examining metal release during resuspension in laboratory chamber studies with sediments from the Anacostia River (Maryland), Lake DePue (Illinois) and San Diego Bay (California). In companion studies, we have used the laboratory results in constructing a one-dimensional model of resuspension events using the Tableau Input Coupled Kinetic Equilibrium Transport (TICKET) model. A large part of this work has been the comparison of laboratory chamber and TICKET modeling results to assess our ability to model metal behavior during resuspension events and to evaluate the relative importance of various physical and chemical processes in controlling metal release. Overall results show that coupled kinetic, equilibrium, transport models such as TICKET

provide an appropriate framework for evaluating the complexities of metal behavior during resuspension events. Results also show that metal release and bioavailability during resuspension is intricately linked to the mass of resuspended sediment, metal sulfide oxidation rates, carbonate buffering, and metal binding to natural organic matter and oxide surfaces. Based on these findings, SEM/AVS, BLM and other regulatory assessment tools will need to be considered in a more dynamic framework to properly address the potential impacts of metals during sediment resuspension events.

**280 Lead bioavailability to soil invertebrates as affected by soil physico-chemical characteristics** *R. Lanno*, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; K. Albanese, The Ohio State University / Environmental Science Graduate Program; J. Chowdhury, International Lead Zinc Research Organization (ILZRO); K. Oorts, ARCHE (Assessing Risks of CHEmicals). The bioavailability and toxicity of lead (Pb) to terrestrial invertebrates may be markedly modified by variations in the physicochemical properties of soil. Other factors that modify the toxicity of Pb include aging and leaching, yet most toxicity data are obtained from toxicity tests conducted with soils freshly amended with metal salts and the relevance of data from such tests to contaminated field soils is unclear. This study compares the chronic toxicity of Pb to *Eisenia fetida* and *Folsomia candida* in six European soils varying widely in physicochemical properties (i.e., pH, organic matter content, texture, eCEC). Toxicity across all six soils was compared using soils that were leached and pH corrected after freshly spiking with lead chloride. This was done to exclude the confounding factors of increased ionic strength and decreased pH due to spiking. Two of these soils (Barcelona, Woburn) were also amended with lead nitrate in 2004 and aged under field conditions for five years prior to conducting laboratory toxicity tests and additionally tested directly after freshly spiking (without leaching or pH correction). These treatments allow for the estimation of leaching/aging factors to extrapolate toxicity from laboratory to field conditions. Significant positive correlations were observed between  $\log(\text{EC}_{50})$  for earthworm reproduction and  $\log(\text{eCEC})$ , total C, exchangeable Ca and Mg, clay) of the soils, but toxicity of Pb to *F. candida* was low and not affected by soil properties. Ageing processes generally decreased the toxicity of Pb to soil invertebrates, but the effects of leaching compared to the toxicity of freshly spiked soils were less distinct. The toxicity data, together with leaching and aging correction factors, provide important information on the bioavailability of lead to invertebrates in soil under realistic conditions.

**281 Modeling the Transport, Effects and Fate of Metal Concentrates in a Lake Using the TICKET Unit World Model** *R.F. Carbonaro*, Manhattan College / Civil and Environmental Engineering, Manhattan College / Department of Civil and Environmental Engineering, Mutch Associates, LLC; K. Delbeke, European Copper Institute; K.J. Rader, Mutch Associates, LLC, Manhattan College / Civil and Environmental Engineering. When evaluating the transport, effects and fate of metals in the aquatic environment, the form of the metal released plays a critical role. Toxicity assessments typically focus on dissolved metal while intermedia transport and ultimate loss of metal from the aquatic system via burial is principally a function of particulate metal. Therefore, one would expect different impacts from metals released as soluble salts (e.g.,  $\text{CuSO}_4$ ), which dissolve instantaneously and particulate metal concentrates/powders/massives, which release metals to the dissolved phase at characteristic kinetic rates. Numerical models can provide insight into the transport, effects and fate of both types of metals and assist in regulatory decision-making. They are particularly useful in grappling with the added complexity associated with kinetic dissolution of concentrates/powders/massives. A unit world model for metals in lakes, TICKET-UWM, has been developed that considers key processes affecting metal transport, fate, and toxicity including complexation by aqueous inorganic and organic ligands (e.g., DOC), adsorption to particulate organic carbon (POC), binding to biological receptors (biotic ligands), and transport of dissolved metals and solids between the water column and sediment. TICKET-UWM was used to model the dynamics of two metal concentrates released in the water column of a generalized lake. Transformation/dissolution data for these two concentrates were used to parameterize kinetic rate expressions for dissolution in the model. Settling rates for the concentrates were estimated using particle size and density data. Simulations were made to examine metal removal from the water column, metal speciation changes upon entering the sediment and the remobilization potential of metals in sediment. Model results indicate that settling of concentrates limits the direct impact dissolution had on water column metal concentrations.

Continued dissolution of concentrates in the sediment did affect the water column indirectly as some of the additional metal released was recycled to the water column through transport processes. Results generally indicate that metal removal from the water column was rapid.

### 282 Predicting Ni toxicity to plants: Comparison of three approaches

Y. Gopalapillai, Vale Canada Limited / School of Environmental Sciences, Natural Resources Canada / CANMET Mining and Mineral Sciences Laboratories, Natural Resources Canada / Metal and Mineral Sciences Laboratories; B. Vigneault, Natural Resources Canada / CANMET, Natural Resources Canada; B. Hale, University of Guelph / School of Environmental Sciences. Models that predict toxicity based on some estimate of the true exposure to a contaminant in media can be cost-effective tools for reliable and rapid risk assessment of metals in soils, water, air and foods. The challenge lies in defining how 'true exposure' is measured or estimated, as for both organic and inorganic contaminants, the characteristics of the exposure medium and the physiology of the organism can profoundly alter what would otherwise likely be a simple relationship between external dose and response. Currently, most Ni risk assessment is based on  $[Ni_{tot}]$ , but, as for many trace elements, it is not considered a good predictor of toxicity since the metal's speciation in the exposure media has the potential to greatly affect its bioavailability to the organism. Three currently available modeling approaches (Biotic Ligand Model (BLM) framework, Predicted No Effect Concentration (PNEC) and Tissue Residue Approach (TRA)) were compared for their ability to predict Ni toxicity to plants, either in aquatic culture (*Lemna minor*) or terrestrial species in soil culture (*Avena sativa*). All three of these approaches are underpinned by the same fundamental mechanism, i.e. that toxicity is related to the 'true exposure'; they differ in their approach to estimating 'true exposure'. Generally, the results indicate that the major assumptions behind the three main modeling approaches do not fully apply to Ni toxicity in the tested plant species (*L. minor* or *A. sativa*). The BLM's assumption of competitive cation interaction does not apply to *L. minor*; PNEC's assumption of the normalizing effect of CEC on toxicity based on total [Ni] does not apply to all soil types; and finally, TRA's assumption that [Ni] in plant tissue is the best predictor of toxicity is not valid for Ni accumulation in *L. minor*, as the more practical total [Ni] in solution better related to observed plant response. Although some water chemistry effects on Ni toxicity to *L. minor* were observed, these effects did not cause large enough changes in the relationship between total [Ni] in solution and Ni toxicity over the wide range of water chemistry tested. Thus, we conclude that total [Ni] is sufficient for rapid and practical assessment of the risks posed by Ni contamination to aquatic and terrestrial plants (sandy and till clay soils).

**283 Update of Water Quality Criteria for Molybdenum** H. Latimer, J. Diamond, Tetra Tech, Inc.; J. Flippin, Tetra Tech, Inc. / Center for Ecological Sciences. This research team developed acute and chronic water quality criteria for the protection of aquatic life for molybdenum for the State of Nevada in 2008, which were subsequently adopted as state standards. More recently, the State of Pennsylvania has proposed adoption of a slightly modified version of these criteria as state standards. In the intervening years two studies have been published in the peer-reviewed literature that provide toxicity data both for species considered in the 2008 criteria and for species for which no data were available in 2008. Using current US Environmental Protection Agency (EPA) criteria development methodology and updating the 2008 criteria to include these new data resulted in a slight increase in the final calculated acute criterion and a significant increase in the chronic criterion. The nature of the resulting changes to these updated criteria are attributable to the generally low toxicity of molybdenum (e.g., the four lowest mean chronic values in the updated database range from 36 to 86 mg/L), the relatively small database (acute data for 14 genera and chronic data for 10 genera), and the limited variability among final toxicity values. This work highlights three elements that should be considered by researchers and regulators when considering new or updated water quality criteria: 1) all water quality criteria considered for adoption as standards should be supported by a recent review of the scientific literature, 2) generation of data for even a few additional genera can have a large impact on the final criteria value for compounds with a fairly limited toxicity database, and 3) the variation among the toxicity values as well as the values themselves play a substantial role in calculating final criteria values using US EPA methodology.

### 284 Development of BLM-based Ambient Water Quality Criteria for Lead following USEPA Guidelines

D.K. DeForest, Windward Environmental LLC; K.A. De Schampelaere, Ghent University; K.V. Brix, McMaster University; B. Church, Windward Environmental LLC; R. Blust, University of Antwerp; M. Chowdhury, International Lead Zinc Research Organization; R.C. Santore, HDR|HydroQual, Inc.. The United States Environmental Protection Agency's (USEPA's) current ambient water quality criteria for lead in fresh water are adjusted for hardness and were last updated in 1985. Since then, there have been two primary advancements in the assessment of lead toxicity to aquatic organisms. First, the acute and chronic toxicity databases for freshwater organisms have expanded substantially, thereby allowing us to explore the chronic toxicity data for lead relative to the USEPA's minimum phylogenetic diversity requirements for deriving criteria. Second, the influence of water chemistry on lead bioavailability has been evaluated in several studies with multiple species, which coincides with the development and validation of acute and chronic biotic ligand models (BLMs) for lead. Using the lead BLMs, acute and chronic species sensitivity distributions (SSDs) based on the geometric mean critical accumulation concentrations for each species and exposure type were constructed and the 5<sup>th</sup> percentiles of these SSDs were derived following the statistical approach described in the USEPA guidelines. Application of these 5<sup>th</sup> percentile acute and chronic critical accumulation concentrations allow for the estimation of the 5<sup>th</sup> percentile dissolved lead concentrations for a broad range of water chemistries (analogous to the USEPA's final acute and chronic values). Unlike other metals for which BLM-based criteria have been developed (e.g., copper, zinc), there are marked differences between organisms in response to water quality parameters. For example, the influence of hardness on lead toxicity is not consistent between species, but dissolved organic carbon (DOC) plays a primary role in protecting aquatic organisms against lead toxicity. A comparative analysis of BLM-based and hardness-based criteria for lead will be provided.

### 285 A Biotic Ligand Model based revision to the U.S. water quality criteria for copper in saltwater for marine and estuarine organisms

R.C. Santore, HDR | HydroQual, Inc.; A.C. Ryan, HDR | HydroQual; R. Arnold, Stephen F. Austin State University; A. Bianchini, Universidade Federal do Rio Grande – FURG / Instituto de Ciências Biológicas; G. Rosen, SPAWAR Systems Center Pacific / Environmental, SPAWAR Systems Center Pacific / Scientist, SPAWAR Systems Center / Scientist; S. Smith, Wilfrid Laurier University / Department of Chemistry, Wilfrid Laurier University / Chemistry; C. Delos, US Environmental Protection Agency, U.S. EPA / Mail Code 4304, US Environmental Protection Agency. A recent update to the water quality criteria for copper in saltwater has been completed. As part of this effort, a literature review was conducted to update the toxicity database used to develop the species sensitivity distribution. Over 700 toxicity endpoints were obtained from this review suitable for inclusion in the marine document. These data represent toxicity information for 80 species in 67 genera, compared to 33 species in 26 genera that were used in the previous document. In the updated database, the most sensitive organisms to copper toxicity were embryo-larval forms of marine invertebrates including *Mytilus edulis*, *Mytilus galloprovincialis*, *Strongylocentrotus purpuratus*, *Dendroaster excentricus*, *Crassostrea gigas*, and *Crassostrea virginica*. There was also considerable evidence in recent literature showing the importance of bioavailability in determining copper toxicity to these sensitive marine invertebrates. Measurements of copper toxicity and copper accumulation in sensitive embryo-larval forms of these marine invertebrates are reduced in the presence of NOM, suggesting that NOM-bound copper is not bioavailable. A marine Biotic Ligand Model (BLM) for copper was calibrated to predict the speciation of copper in marine waters, and accumulation of copper in sensitive invertebrates. The marine BLM for copper was used in this update to incorporate bioavailability effects in the marine criteria, using a methodology that was similar to the most recent update to the freshwater ambient criteria for copper. For the marine invertebrates used to develop and test the marine BLM, little is known about bioavailability effects in estuaries where variation in salinity and pH are common. In this presentation, the marine BLM for copper will be applied to several estuarine species across salinity gradients to evaluate whether the marine BLM is predictive and protective for sensitive estuarine organisms.

**286 Toxicogenomic Screening of Environmental Pollutants on Toxicity** X. Zhang, Toxicology centre, University of Saskatchewan / State Key Laboratory of Pollution Control and Resource Reuse & School of the

Environment, Nanjing University / School of the Environment, State Key Laboratory of Pollution Control and Resource Reuse & School of the Environment, Nanjing University / School of Environment, Nanjing University / School of Environment; G. Su, State Key Laboratory of Pollution Control and Resource Reuse & School of the Environment, Nanjing University; J.P. Giesy, University of Saskatchewan / Biomedical Veterinary Sciences & Toxicology Centre, Michigan State University / Department of Animal Science, University of Saskatchewan / Toxicology Centre; H. Yu, State Key Laboratory of Pollution Control and Resource Reuse & School of the Environment, Nanjing University. The number of new chemicals or materials developed in industry keeps growing rapidly every year and their chemical structures are heterogeneous. There is urgent need for development of high throughput methods that allow evaluation of large numbers chemicals that can enter the environment for their potential toxicity and to prioritize these chemicals for further toxicity testing. However, the conventional toxicological testing methods cannot meet this need because they are costly, especially time consuming and less efficient. Here a few examples will be presented on our applications of high throughput and genomic technologies in screening and mechanistic assessment of environmental pollutants.

**287 Determining the molecular toxicological effects of organic flame retardants using an avian *in vitro* screening method** D.E. Crump, Environment Canada / National Wildlife Research Centre, Environment Canada / Canadian Wildlife Service; E. Porter, Environment Canada; S. Chiu, Environment Canada; S.W. Kennedy, Environment Canada, University of Ottawa / Department of Biology, Environment Canada / National Wildlife Research Centre. Risk assessors are challenged with the task of providing data for an increasing number of chemicals. High throughput toxicity screening methods, which permit rapid determination of toxic, molecular and/or biochemical effects of a wide range of chemicals, are essential to help meet this demand. The chicken embryonic hepatocyte (CEH) *in vitro* screening method has been utilized by our laboratory to assess the effects of a wide range of environmental contaminants on (i) cytotoxicity and (ii) mRNA expression of genes associated with xenobiotic metabolism, the thyroid hormone pathway, lipid metabolism and growth. Sixteen structurally variable organic flame retardants (FRs) including, tris(2-butoxyethyl) phosphate, tricresyl phosphate, tetrabromomethylcyclohexane (TBECH) and tris(1-chloropropyl) phosphate (TCPP), were screened using the CEH method in this study. Cytotoxicity data were obtained immediately following the exposure experiment while transcriptional effects, determined via quantitative PCR (QPCR), for 10 target genes were generated in approximately two weeks (from RNA isolation to QPCR data interpretation). Therefore, the screening method is rapid and has the potential to help prioritize chemicals for further assessment. For example, FRs that elicit significant effects on cytotoxicity and/or mRNA expression are prime candidates for egg injection studies that determine adverse effects on the whole animal but are more costly from a time, money and embryo utilization standpoint. The *in vitro* method is also amenable for use with wild avian species (e.g. herring gulls) enabling the determination of (i) effects in species naturally exposed to environmental contaminants and (ii) species differences in sensitivity. This multi-tiered approach – *in vitro* to *in ovo* – to toxicity testing for avian species has been successfully employed for a number of priority environmental contaminants and the screening method offers great promise for FRs and other diverse groups of chemical stressors.

**288 Development of neuromuscular toxic equivalency factors for non-coplanar structures in the rainbow trout (*Oncorhynchus mykiss*)** E.B. Holland Fritsch, I.N. Pessah, University of California- Davis / Molecular Biosciences. Throughout the early part of the 20<sup>th</sup> century polychlorinated biphenyls (PCBs) were used for a number of industrial purposes including a role as plasticizers, adhesives, hydraulic fluid, and flame retardants. Even though they were banned in the 1970's, PCB still remain widely dispersed in the environment and are among the most commonly detected contaminants in fish tissue. Research in fish has focused on toxic effects of coplanar or dioxin-like congeners and their well documented impact on aryl-hydrocarbon receptor (AhR). Therefore, PCBs that effect the AhR are assigned a toxic equivalency factor (TEF) representing their potency as compared to the strongest known AhR activator, 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD). To date little work has focused on the effects of non-coplanar PCBs (ncPCB), or non-dioxin like congeners, which have very little impact on the AhR. Interestingly, studies assessing specific congeners show that ncPCB's are detected in more than 95% of fish tissue from US

lakes accounting for at least 50% of the known PCB load. In mammals, ncPCBs, and other non-coplanar compounds, activate the ryanodine receptor a calcium release channel necessary for excitation-contraction in skeletal and cardiac muscle. Here, ncPCBs cause the receptor to remain in the open state leading to excess calcium release and loss of muscle function. We have utilized similar high-throughput *in vitro* assays to address this impact on rainbow trout skeletal muscle looking at single ncPCBs or environmentally relevant congener mixtures. We have found that PCB95, the most potent ncPCB congener, leads to a 300 fold increase in receptor activity in fish skeletal muscle. The activity of ncPCBs, in relation to PCB95, will be discussed in aim of developing a neuromuscular toxic equivalency for regulatory purposes. Once established these tools can be utilized to address impacts of other non-coplanar structures and combined with TEF matrixes to provide a more complete picture of contaminant effects in the environment.

**289 Multi-tiered Approach to Development of Increased Throughput Assay Models to Assess Endocrine-Disrupting Activity of Chemicals** K.B. Paul, The Hamner Institutes for Health Sciences / Institute for Chemical Safety Sciences, Integrated Systems Toxicology Division / NHEERL, ORD, US EPA, ORISE Postdoctoral Fellow, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL; J.M. Hedge, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL; P.C. Hartig, L.E. Gray, ORD, US EPA / Toxicity Assessment Division, NHEERL; K.M. Crofton, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL; V.S. Wilson, US EPA, ORD, NHEERL, TAD / Reproductive Toxicology Branch, U.S. EPA / Office of Research and Development, ORD, US EPA / Toxicity Assessment Division, NHEERL, U.S. EPA, ORD, NHEERL / Toxicity Assessment Division; S.O. Simmons, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL. Screening for endocrine-disrupting chemicals (EDCs) requires sensitive, scalable assays. Current high-throughput screening (HTPS) approaches for estrogenic and androgenic activity yield rapid results, but many are not sensitive to physiological hormone concentrations, suggesting that less potent EDCs may not be identified. And although thyroid hormone (TH) receptor assays are available, environmental thyroid-disrupting chemicals act primarily via other mechanisms, including inhibition of thyroid hormone synthesis; yet, no HTPS assays exist for TH synthesis targets. We used the following multi-tiered approach to improve assays available for EDC screening: (1) re-optimization of sensitive estrogen and androgen transcriptional activation assays (ER-TA, AR-TA) for HTPS; (2) re-development of an *ex vivo* rat thyroperoxidase (TPO) inhibition assay; and (3) *de novo* development of an *in vitro* model system for human TPO inhibition. We tested the hypothesis that T47D-kbluc ER-TA and MDA-kb2 AR-TA assays could be miniaturized to a 384-well plate, and used controls, dynamic range, variability, and Z' to evaluate this effort. Results demonstrated that the AR-TA assay can be miniaturized without loss of dynamic range (10-fold), increased variability (< 10%), or loss of sensitivity, but that the ER-TA assay could only be automated in 96-well plates due to loss of sensitivity in the 384-well format. Cross-validation of these assays with other ER and AR assays is ongoing with a 90-chemical reference set. Further, we hypothesized that use of a peroxidase substrate (Amplex UltraRed, AUR, LifeTech) and automated reagent delivery could increase the throughput of an *ex vivo* rat TPO assay. The potency of methimazole (MMI)-induced TPO inhibition was similar with AUR compared to the existing guaiacol assay (IC<sub>50</sub> reduced from 5  $\mu$ M to ~1  $\mu$ M), and the AUR signal was stable > 30 min after reaction initiation. Finally, preliminary work demonstrated that lentiviral-transduction of a human cell line (HEK293T) with recombinant TPO could be used to test for human TPO inhibition. Cell fractions showed responsiveness to MMI using AUR as a substrate (IC<sub>100</sub> = 100  $\mu$ M). The results of this step-wise approach to improving and developing assays for EDC screening indicate that systematic evaluation of assay sensitivity and specificity is critical for adaptation of assays to HTPS for EDCs. *This abstract does not necessarily reflect the policy of the US EPA.*

**290 Mechanistic Toxicity Assessment by cellular stress response pathway system ensemble-based Whole-Cell-Array** J. Lan, Northeastern University / Civil & Environmental Engineering; N. GOU, Northeastern University / Civil & Environmental Engineering, Northeastern University / Civil and Environmental Engineering; C. Gao, Northeastern University / Civil and Environmental Engineering; A. GU, Northeastern University / Department of Civil & Env Engineering, Biotechnology Initiative Program, Department of Civil & Env Engineering / Biotechnology Initiative Program.

Toxicological assessment approach for the future (Tox21) demands a paradigm shift from *in vivo* whole animal-based test to *in vitro* mechanistic qualitative biochemical or cell-based assays for rapid, cost-effective toxicological evaluation and characterization of toxic compounds. However, many challenges remain in realizing this transition such as the uncertainty in biomarkers and pathways selection. In recognition of the complexity of the cellular toxic response network, focus on toxicity pathways that result in adverse health outcomes was proposed as Adverse Outcome Pathways (AOP). In this study, we explored and demonstrated the application of cellular stress response pathway ensemble-based toxicogenomics approach for toxicity evaluation of a variety of toxicants. GFP-infused whole-cell array of both *E. coli* and *S. cerevisiae* were employed that allow for real time measurements of the transcriptional and protein expression level activities in exposure to chemicals. Genes/proteins that have been reported to be specific for stress responses in both species were selected and clustered into five stress groups indicative of different types of damage. The 3-D (time, gene, magnitude of change) differential molecular change profiles have sufficient resolution power to discern different chemicals as well as same chemicals at different doses with mechanistic information indicative of their mode of action (MOA). The revealed toxicity mechanisms for the chemicals tested were consistent with their previously known toxic effects. We proposed a new molecular effect level index (TELI for transcriptional level in *E. coli* and PELI for protein expression level in yeast) to quantify the altered gene/protein expression changes, which was shown to exhibit dose-response patterns. Furthermore, the molecular disturbance level-based toxicity endpoints derived from the MELI-based dose response curves were found to correlate with phenotypic endpoints. The demonstration of phenotypic anchoring suggest that, using the stress response pathway ensemble for toxicity assessment is valid and it captures the essential toxic responses that ultimately lead to adverse health outcome, therefore can be applied as a potential method for toxicity assessment.

#### 291 Impacts of Engineered Nanomaterials on Marine Phytoplankton

B. Cole, University of California, Davis / Bodega Marine Laboratory; R. Miller, T. Martin, R. Nesbit, H. Lenihan, University of California, Santa Barbara; G. Cherr, University of California, Davis. Potential impacts of engineered nanomaterials on the marine environment are largely unknown. Determining what these impacts may be is a complicated endeavor that is made more difficult by the nearly limitless diversity in size, shape, and composition of nanomaterials. To determine these impacts we have examined the effects of long-term low-dose exposures of metal and metal oxide nanomaterials on marine phytoplankton. Phytoplankton are fundamental to assessing ocean health as they are the basis of most marine foodwebs, so even subtle changes in growth rates can have large outcomes when scaled up to population or ecosystem levels. Endpoints examined in this study were chosen with the aim of linking cellular targets of toxicity with population and ecosystem level effects so as to provide a broad scale perspective on this issue. We have adapted a suite of fluorescence based assays for cellular targets of cytotoxicity in two species of phytoplankton. These assays can be performed in high-content screens using a fluorescence plate reader, thus facilitating rapid and inexpensive examination of a large number of nanomaterials. Specific cytotoxicity targets include reactive oxygen species production, mitochondrial membrane potential and cell death. Additionally we have determined the population growth rates and decreases in photosystem efficiency in phytoplankton exposed to nanomaterials. These data can be modeled using dynamic energy budgets to predict ecosystem-wide impacts. In combination these assays provide a framework for testing the environmental impacts of nanomaterials on marine phytoplankton across a broad yet interdependent range of scales.

#### 292 High Throughput Bioassays of Urban Stormwater in Combination with AIQS Database GC-MS Screening

M. Allinson, J. Myers, University of Melbourne / CAPIM; V.J. Pettigrove, The University of Melbourne / CAPIM; G. Allinson, Department of Primary Industries, Victoria / Future Farming Systems Research Division; K. Kadokami, University of Kitakyushu. Urban stormwater may contain a large number of organic chemicals, some of which may prove directly toxic to aquatic organisms, while others may elicit more subtle effects, including endocrine disrupting effects. Consequently, stormwater can be a continuing source of water pollution and cause adverse effects to aquatic organisms, directly or indirectly, through immediate exposure, food chain transfer, or through changed prey behaviour or diversity. This pilot study utilised high throughput cytotoxicity test and

hybrid receptor yeast bioassays to assess stormwater quality in five different types of catchments, including industrial and residential areas. The spring and summer in Australia is the most critical time to assess stormwater quality because this is the time of highest demand for recycled water resources, and lowest flow in receiving waters. Grab water samples were collected four times from October 2011 to January 2012 monthly and extracted onto C18 Empore disks after filtration with glass fibre filters. The eluents were split into two and sample non-specific baseline toxicity tested via growth inhibition of *Vibrio fischeri*; the second aliquot was separated into non polar to polar fractions using a Florisil cartridge, and the fractions screened using for a range of yeast-based recombinant receptor-reporter gene bioassays. To investigate the widest possible range of micropollutants, sample extracts were also tested using a gas chromatographic Automated Identification and Quantification System database screening system (GC-MS-AIQS-DB) that can screen samples for more than 900 semi-volatile compounds, including numerous halogenated and non-halogenated hydrocarbons, polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyl compounds (PCBs), and range of pharmaceutical and personal care products (PPCPs), and pesticides. The GC-MS-AIQS-DB detected a wide range of chemicals, including herbicides such as simazine, atrazine, and metolachlor, PPCPs such as caffeine and DEET, and the phosphorus based flame retardants, tributyl phosphate and tris(1,3-dichloro-2-propyl) phosphate. The combination of AIQS database screening and bioanalytical tools proved a very useful method to assess stormwater quality, and appeared to contain the inherent periodic chemical variability of this water resource.

#### 293 Combining *in vitro* toxicity data with QSARs and mass balance exposure models for high throughput risk assessment

J.A. Arnot, ARC Arnot Research & Consulting Inc., University of Toronto Scarborough / Department of Physical and Environmental Sciences; T.N. Brown, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Environmental Chemistry, Helmholtz Centre for Environmental Research / Department of Analytical Environmental Chemistry, Helmholtz centre for environmental research – UFZ / Department of Analytical Environmental Chemistry; K. Breivik, Norwegian Inst. for Air Research; R.S. Thomas, The Hamner Institutes for Health Sciences / Institute for Chemical Safety Sciences, Center for Genomic Biology and Bioinformatics; B.A. Wetmore, The Hamner Institutes for Health Sciences. Few measured exposure and toxicity data are available for the majority of the thousands of chemicals produced and used in society. Evaluating the potential human health and environmental risks for all chemicals using traditional monitoring and animal testing data is not feasible. *In vitro* and *in silico* methods provide plausible alternatives for screening level, high throughput risk assessment (HTRA) (i) to prioritize existing chemicals for more comprehensive evaluation, and (ii) to provide guidance for the design of new and replacement chemicals. Due to data gaps in chemical information, particularly for chemical usage and release rates, estimated values and Quantitative Structure-Activity Relationships (QSARs) are required resulting in considerable assessment uncertainty. Here, we combine recently developed strategies in *in vitro*, *in silico*, emission rate estimation, and screening level uncertainty methods for HTRA. The Risk Assessment, IDentification And Ranking (RAIDAR) mass balance model combines information on chemical emissions, partitioning, degradation rate, environmental fate, food web bioaccumulation, far-field human exposure, and toxicity in an evaluative framework. The model quantitatively links chemical emissions and internal doses and intake rates corresponding to effects. In this study, *in vitro* high-throughput screening data and pharmacokinetic (PK) models are used to estimate intake rates and internal concentrations (*i.e.* estimated *in vivo* doses) associated with the biological pathway altering dose (BPAD) in humans and to parameterize RAIDAR to back-calculate the “critical” emission rate corresponding to the BPAD. The calculated critical emission rates include the propagation of uncertainty in BPAD estimates and in chemical partitioning properties and degradation rates that are also used to parameterize the model. Calculated distributions for the critical emission rates are then compared with estimates of actual emission rates (also including uncertainty estimates) to provide an indication of the likelihood for potential risk. The *in vitro-in silico* HTRA framework thus links chemical emissions with *in vitro* biological activity including the propagation of uncertainty in key information used in chemical assessments in the model calculations. The method is applied as a case study to chemicals that are part of the U.S. Environmental Protection Agency's ToxCast program™. Future improvements to the methods are discussed.

#### 294 Using isotopically modified silver nanoparticles to assess their bioavailability and toxicity at environmentally realistic exposures M. Croteau, U.S. Geological Survey; A. Dybowska, Natural History Museum London / Mineralogy; S.N. Luoma, University of California Davis / John Muir Institute of the Environment, U.S. Geological Survey, University of California, Davis; E. Valsami-Jones, University of Birmingham. One challenge in understanding the environmental implications of nanotechnology lies in tracing nanoparticles in organisms during controlled experimental studies as well as in the environment. Tracers are usually required because the natural background metal concentrations limit the ability to detect bioaccumulation at environmentally relevant exposures. Stable isotope methodologies offer great potential to address these challenges as metallo-nanoparticles can be synthesized from a metal enriched with a rare stable isotope. For example, we demonstrate that newly accumulated Ag concentrations as low as 0.05 nmol g<sup>-1</sup> can be detected in freshwater snails exposed to waterborne Ag concentration as low as 0.1 nM, if isotopically enriched is used (e.g., <sup>109</sup>Ag enriched at 99.7%). Exposures more than 20-times higher would otherwise be required to detect Ag uptake if no tracer were used. Without a tracer, Ag uptake rates can only be determined at concentrations typical of extreme contamination. Here we use a stable isotope methodology to quantify the bioavailability of silver nanoparticles (AgNPs) from food and water under conditions that might be typical of nature, and develop links to toxicity. Citrate-capped Ag NPs were synthesized using enriched <sup>109</sup>Ag isotope. The tracing technique allows determining uptake rate constant for freshwater snails exposed to AgNPs either dispersed in water at concentrations ranging from 0.1 to 30 nM, or mixed with food at dietborne concentrations ranging from 1 to 200 nmoles per gram. The isotope tracer methodology was also used to quantitatively evaluate physiological processes like feeding rates and assimilation efficiency that might be adversely affected by exposure to AgNPs in diet. Along with distribution coefficients, the rate constants developed in these experiments were used to model Ag bioaccumulation from both routes under environmentally realistic conditions.

#### 295 Impact of Nano-Ceria Fuel Additive on Physicochemical and Toxicological Properties of Diesel Exhaust Particles J. Zhang, Div of Env Health, Keck School of Medicine, University of Southern California; L. Zhang, Env and Occup Health Sciences Institute; G. Mainelis, Y. Nazarenko, L. Calderon, Dept Env Sciences, Rutgers University; P.J. Liroy, Env and Occup Health Sciences Institute; S. Sarkar, S. Schwander, UMDNJ-School of Public Health, Dept of ENOH; W. Baker, J. Seiffert, A.J. Thorley, T.D. Tetley, K. Chung, National Heart and Lung Institute, Imperial College London; P. Subramaniam, K. Lee, E. Garfunkel, Dept of Chemistry and Chemical Biology, Rutgers University; S. Chen, M. Ryan, A. Porter, Dept Materials and London Centre for Nanotechnology, Imperial College London; H. Kipen, UMDNJ-Robert Wood Johnson Medical School; H. Solomon, Div of Env Health, Keck School of Medicine, University of Southern California. As a catalyst to promote combustion efficiency, ceria (CeO<sub>2</sub>) nanoparticles, have been increasingly used in Europe and elsewhere as diesel fuel additive. Although the use of ceria additive leads to increased fuel combustion efficiency and reduced particle mass emissions, it remains unknown if the additive would affect physicochemical and toxicological properties of the exhaust. We conducted a series of experiments to evaluate the impact of a commercially available ceria-based diesel additive, Envirox™ (Energenics Ltd., UK) at various ceria concentrations in a regular ultra-low sulfur diesel fuel, ranging from 0 to 10 times the manufacturer's recommendation. Using a one-cylinder electrical generator (Yanmar) under 100% load, we directed a portion of the exhaust into a stainless steel testing chamber where gaseous constituents (CO, CO<sub>2</sub>, NO<sub>x</sub>, and aldehydes) and particulate components (particle size, mass concentration, and number concentration) were characterized. Exhaust particles were also collected onto filters to analyze their chemical composition (e.g. elemental carbon, organic carbon, elements, and PAHs), charge (zeta potential) and toxicity. We observed that with increasing CeO<sub>2</sub> concentrations in the fuel: (1) the total energy output per liter of fuel (kW/liter) increased as expected for a combustion catalyst; (2) the total exhaust particle number concentration increased per particles mass basis, (3) the median particle diameter decreased, (4) the ratio of particle mass concentration to CO<sub>2</sub> concentration decreased, (5) total PAH mass content in exhaust particles decreased, (6) elemental carbon and total carbon mass content in exhaust particles decreased, respectively, (8) NO<sub>x</sub> concentration increased per particle mass basis, and (7) the zeta potential of exhaust particles decreased. Preliminary data also suggests a change in the toxicological response of the particles. Using *in vitro* cell culture studies,

we observed that with increasing CeO<sub>2</sub> concentrations in the fuel, exhaust particles exhibited *decreased* induction of inflammatory cytokine mRNA and *decreased* production of TNF-α, IL-1β proteins in THP-1 cells. To further examine toxicological impacts of the CeO<sub>2</sub> additive, we are currently conducting additional *in vitro* tests using other cell types and endpoints. These changes in toxicity will be discussed in the context of the variation in the physicochemical properties of exhaust particles.

#### 296 Diesel Exhaust Particle and DEPenvirox Effects on Protein and mRNA Expression in Stimulated THP-1 and Primary Human Peripheral Blood Mononuclear Cells S. Schwander, S. Sarkar, UMDNJ-School of Public Health, Dept of ENOH; J. Zhang, Div of Env Health, Keck School of Medicine, University of Southern California; L. Zhang, Env and Occup Health Sciences Institute; W. Baker, J. Seiffert, National Heart and Lung Institute, Imperial College London; M. Ryan, A. Porter, Dept Materials and London Centre for Nanotechnology, Imperial College London; K. Lee, Dept of Chemistry and Chemical Biology, Rutgers University; A.J. Thorley, T.D. Tetley, K. Chung, National Heart and Lung Institute, Imperial College London. Correlations between physicochemical characteristics of freshly collected DEP from conventional diesel fuel sources and diesel fuel supplemented with cerium oxide-containing Envirox additive (DEP<sub>envirox</sub>) (see abstract from J. Zhang) and biological responses in *M. tuberculosis*-stimulated human immune cells have not been studied in detail. As part of our *in vitro* studies of cellular, molecular and immune reactivity, we set out to assess the effects of DEP and DEP<sub>envirox</sub> in the human monocytic leukemia cell line THP-1, in human peripheral blood mononuclear cells (PBMC) and human alveolar lung cells from healthy adult donors. Cells were exposed to DEP and DEP<sub>envirox</sub> or left untreated (control) for 4 and 24 hrs followed by extraction of total RNA. THP-1 cells were also stimulated with LPS (100ng/mL) as a positive control for gene expression. cDNA was then generated and mRNA expression assessed using gene specific primers by Real-time PCR with Power SYBR green PCR master mix in a ABI 7900HT. Data were analyzed by the relative quantitation method (DDCt method). Abundance of specific mRNAs in MNP exposed THP-1 cells was determined relative to untreated control THP-1 cells. Exposure of THP-1 cells and PBMC to DEP led to a dose-dependent increase of expression of mRNAs encoding *TNFA*, *IL1b*, *IL6*, and *IL12p40*. Interestingly, this DEP-mediated increase of inflammatory cytokine mRNA expression was not observed in cells exposed to DEP<sub>envirox</sub>. Similarly, the production of TNF-α and IL-1β proteins was increased in a dose-dependent fashion in presence of DEP but not in presence of DEP<sub>envirox</sub> in THP1 cells. Thus, the exposure of THP-1 cells to DEP and DEP<sub>envirox</sub> led to clearly distinguishable activation and gene expression patterns. DEP<sub>envirox</sub> obtained from the combustion of diesel fuel containing increasing proportions of Envirox™ additive (0.1x, 1.0x, 10x) was correlated with further reduced induction of inflammatory cytokine mRNA and protein production in THP-1 cells. We currently examine the effects of DEP and DEP<sub>envirox</sub> from another collection in our CEF in additional experiments to confirm our observations. These studies are also being extended to examine the bioreactivity of DEP and DEP<sub>envirox</sub> using *in vitro* models of human alveolar epithelial cells. Nevertheless, our data suggest that diesel additive Envirox™ may alter the physicochemical properties typical for DEP with a resulting decreased immunotoxicity.

we observed that with increasing CeO<sub>2</sub> concentrations in the fuel, exhaust particles exhibited *decreased* induction of inflammatory cytokine mRNA and *decreased* production of TNF-α, IL-1β proteins in THP-1 cells. To further examine toxicological impacts of the CeO<sub>2</sub> additive, we are currently conducting additional *in vitro* tests using other cell types and endpoints. These changes in toxicity will be discussed in the context of the variation in the physicochemical properties of exhaust particles.

#### 297 Potential Consumer Exposure to Airborne Ag and Zn Nanoparticles due to the use of Nanotechnology-enabled Consumer Sprays G. Mainelis, L. Calderon, Y. Nazarenko, Dept Env Sciences, Rutgers University; K. Lee, E. Garfunkel, Dept of Chemistry and Chemical Biology, Rutgers University; S. Schwander, UMDNJ-School of Public Health, Dept of ENOH; T.D. Tetley, National Heart and Lung Institute, Imperial College London; P.J. Liroy, Env and Occup Health Sciences Institute; K. Chung, National Heart and Lung Institute, Imperial College London; J. Zhang, Div of Env Health, Keck School of Medicine, University of Southern California. Engineered nanomaterials are increasingly applied in consumer products; however, potential exposures to nanoparticles and the resulting adverse health effects have been only minimally explored. We investigated potential consumer exposures to the use of sprays designed for cleaning, odor control, and sun protection containing either silver or zinc nanoparticles. We chose to study silver or zinc nanoparticles because they were shown to induce toxic changes in respiratory epithelial cells and immune cells. The potential size range of particles released during spray use was investigated by aerosolizing each product in a testing chamber using Collison nebulizer (BGI, Inc.) and C-flow (Saville, Inc.) atomizer, and a sprayer supplied with each product.

we observed that with increasing CeO<sub>2</sub> concentrations in the fuel, exhaust particles exhibited *decreased* induction of inflammatory cytokine mRNA and *decreased* production of TNF-α, IL-1β proteins in THP-1 cells. To further examine toxicological impacts of the CeO<sub>2</sub> additive, we are currently conducting additional *in vitro* tests using other cell types and endpoints. These changes in toxicity will be discussed in the context of the variation in the physicochemical properties of exhaust particles.

Size distribution and concentration of the released particles were measured using a Scanning Mobility Particle Sizer and an Aerodynamic Particle Sizer (models 3080 and 3321, TSI, Inc., Shoreview, MN). The cleaning and odor control products were then realistically used in a simulated home environment while measuring the user's personal exposure. The use of sun protection products was simulated using a human mannequin while sampling through its nose. Air samples were taken to investigate sizes, shapes and agglomeration of the released particles using Transmission Electron Microscopy and other techniques. When tested in the chamber, the products released particles not only in the nanosize range ( $< 100$  nm) but, interestingly enough, in coarse (2.5-10  $\mu\text{m}$ ) and for some products in super-coarse ( $>10\mu\text{m}$ ) particle size ranges. The particle number concentration depended on the product and ranged from  $10^4$  to  $10^6$  particles/ $\text{cm}^3$  with the mass of particulate matter being in tens of  $\mu\text{g}/\text{m}^3$ . When used in the simulated home environment, potential exposures to nanosized, micron-sized, and super-micron sized particles were observed as well. The TEM analysis confirmed that for most of the products, the released particles included nanoparticles, their agglomerates as well as nanosized particles attached to larger particles. The release and inhalation of nanoparticles and their agglomerates in such a wide size range would result in particle deposition in all regions of the respiratory system and thus, health studies should focus not only on single nanoparticles, but also on deposition and health effects of larger agglomerates. The next steps of the study include *in vitro* and *in vivo* investigation.

### 298 Bioreactivity of Zinc Oxide and Silver Nanoparticles with the Human Lung Respiratory Unit and Human Monocytic Cells T.D. Tetley,

W. Baker, A.J. Thorley, J. Seiffert, K. Chung, National Heart and Lung Institute, Imperial College London; J. Zhang, Div of Env Health, Keck School of Medicine, University of Southern California; A. Porter, M. Ryan, Dept Materials and London Centre for Nanotechnology, Imperial College London; S. Sarkar, S. Schwander, UMDNJ-School of Public Health, Dept of ENOH. These studies aim to determine the effect of nanoparticles (NP) on the alveolar unit. Alveolar type I (AT1) epithelium accounts for 95% of the alveolar surface and are important target cells. We have shown that nanoparticles can translocate across the alveolar epithelium, to access the interstitial compartment (where fibroblasts reside, being important in maintaining structure and in repair) and may then access the vasculature. Immortalized human ATI cells and primary human lung fibroblasts were exposed to ZnO and silver (Ag; 1-50mg/ml) for 4 and 24h and assessed for cytotoxicity and bioreactivity. At 4h polydisperse ZnO induced dose-related cell death, viability falling to 60%, then 50%, of control at 10 and 50mg/ml. By 24h, viability fell to only 10% of control at  $>25\text{mg}/\text{ml}$  ZnO. LDH release increased with increased cell death. Oxidative cell stress increased with ZnO dose at 4h, but by 24h could not be detected. ZnO caused a similar loss of cell viability in fibroblasts at 4h, with no further change at 24h. However, at the high doses of ZnO, there was marked fibroblast LDH release at both time intervals, suggesting that, whilst AT1 cells do not recover from ZnO-induced cell death, fibroblasts proliferate to replace damaged cells. These responses will be compared to ZnO nanowires, which have now been synthesized for these studies. AT1 cells were exposed to 10 and 50nm Ag spheres, and Ag nanowires. There was a small but consistent fall in AT1 cell viability at 24h, to between 80-90% of control, following exposure to  $>10\text{mg}/\text{ml}$  of all types of Ag. Bioreactivity was measured as CXCL8 (IL-8; attracts neutrophils) and CCL-2 (MCP-1; attracts monocytes) release. Although 5mg/ml of 10nm Ag had no effect on CXCL8, 25mg/ml caused a 12-fold increase. 50nm Ag caused a 3-fold and 5-fold increase in CXCL8 at 5 and 25mg/ml. In contrast, Ag nanowires did not affect CXCL8 release. Ag either had no effect (50nm), or inhibited CCL2. Thus, 25mg/ml 10nm spheres inhibited CCL2 to 40%, while 5 and 25mg/ml of silver nanowires inhibited CCL2 release to 50% and 25%, respectively, of control levels. Thus, Ag spheres stimulated CXCL8, while 10nm spheres inhibited CCL2; nanowires did not affect CXCL8, and inhibited CCL2. Therefore, responses to ZnO and Ag nanoparticles depend on structure, chemistry and target cell. These studies are being extended to other human alveolar cells and human monocytic cells, THP1 and monocyte-derived macrophages, before and after infection with M tb.

### 299 The Biostability and Immunogenic Effects of Silver Nanostructures in Simulated Body Fluids (SBFs) and Human Epithelial and Blood Cells M. Ryan, A. Porter, S. Chen, I. Theodorou, A. Goode, B.F. Leo, E. McGuire, Dept Materials and London Centre for Nanotechnology, Imperial College London; M. Shaffer, Dept. Chemistry and London Centre for

Nanotechnology, Imperial College London; A.J. Thorley, T.D. Tetley, K. Chung, National Heart and Lung Institute, Imperial College London; S. Sarkar, S. Schwander, UMDNJ-School of Public Health, Dept of ENOH; J. Zhang, Div of Env Health, Keck School of Medicine, University of Southern California. Ag nanoparticles are in wide-spread use in consumer products such as wound-dressings, anti-bacterial sprays, odor-control fabrics and in a whole range of electrical systems which release Ag nanoparticles to impart some 'hygienic' function (for example in washing machines and hair-dryers). The market for nano-Ag products is already significant and growing rapidly; the potential for individual exposure of airborne Ag-nanoparticles by inhalation is therefore high. The toxicity of metallic and metal oxide nanomaterials has been linked to their dissolution behaviour. The aim of this project is to assess whether, and by which mechanism, the physiological properties (*i.e.* aggregation state, morphology and chemistry) of the Ag nanostructures (both wires and particles) change in biofluids and human cells (lung epithelial, THP-1 and PBMC cells). Using a combination of *in-situ* scattering and spectroscopic methods, we have demonstrated that the dissolution rate of the silver nanoparticles increases with decreasing pH and is size-dependent. The Ag nanoparticles dissolved more rapidly in a simulated body fluid of lysosomal pH, whereas they were comparatively stable at extracellular pH. The silver particles dissolved *inside* epithelial cells and their destination inside the cell became modified when they were incubated in lung surfactant prior to cell exposure. We will discuss visualization of the degrading nanowires inside the cells using energy filtered transmission electron microscopy (EFTEM) in combination with electron energy loss spectroscopy (EELS) to assess the morphological changes observed during intracellular dissolution. The implications of silver dissolution on cell metabolism and lung function will be discussed.

### 300 Characterisation of exposure and effects of silver nanoparticles to the earthworm *Lumbricus rubellus* N. Van den Brink, Alterra / Dept. of

Ecology & Environment; M. van der Ploeg, Alterra, Wageningen UR; H. van den Berg, Wageningen University / Division of Toxicology; R. Handy, University of Plymouth / School of Biomedical and Biological Sciences; R. Peters, RIKILT, Wageningen University / Residues & Contaminants, RIKILT / Contaminants; P. Waalewijn-Kool, VU University / Department of Ecological Science; G. Koopmans, B. Molleman, Wageningen University / Sub-department of Soil Quality; I. Rietjens, Wageningen University / Division of Toxicology. Risks of engineered nanoparticles are under debate, and further scientific underpinning of the assessment of these risks is still needed. Silver nanoparticles (Ag-NPs) are used widely, and relatively many studies have investigated hazards that these particles may pose to organisms. However, up till now relatively little attention has been paid to soil organisms. Literature shows that effects of Ag-NPs on earthworms depend on, among others, soil type, particle size and the surface coating of the NPs (Shoults-Wilson et al 2011a,b). In order to elucidate the hazards of non-coated Ag-NPs to earthworms, we exposed earthworms (*Lumbricus rubellus*) to non-coated Ag-NPs (NM-300K in Tween20,  $< 20$  nm, Fraunhofer). Adult earthworms were exposed for four weeks, after which growth and reproduction was assessed (cf. OECD 222). Animals were exposed to Ag-NPs at 0, 1.54, 15.4 and 154 mg/kg soil and to  $\text{AgNO}_3$  as a ionic control (15.4 mg/kg). F1 animals were further exposed to the same levels to which their parents were exposed and effects on stage dependent growth and mortality were quantified. The Ag-NPs in spiking extract and the exposure during the experiments were characterised by using AF4 in combination with UV and ICP-MS, single-particle ICP-MS, Atomic Absorption Spectrometry (AAS) and SEM-EDX. Extensive exposure characterisation showed the occurrence of primary particles in soil extracts, which were approximately 16 nm in size, but also the presence of larger agglomerates was detected. Furthermore, in contrast to Ag-NPs in the spiking solution, Ag-NPs in soils showed traces of Cl, indicating possible deposition of AgCl on the surface of the Ag-NPs. Ag-NPs in the soil with the highest levels showed release of Ag ions in the soil pore water, even after 6 months of incubation. The lower Ag-NP and  $\text{AgNO}_3$  treatments of the soil showed only low ionic concentrations in the pore water after 6 months. Effects of Ag-NP treatment were evident at different levels of biological integration. Juvenile mortality was 100% at the highest Ag-NP dose, adult growth and cocoon production were also affected at this concentration. Effects of  $\text{AgNO}_3$  were visible at 15.4 mg/kg. In the presentation, more details will be given on the effects of Ag-NPs on histological endpoints and on the population growth rate. These effects will be discussed in relation to the exposure characterisation to elucidate whether

Ag-NP toxicity may just be caused by ionic exposure or also through NP-properties.

**301 Interactions of Humic and Fulvic Acids with Silver Nanoparticles and the Resultant Toxicity to *Chlamydomonas Reinhardtii*** R.M. Sofield, Western Washington University / Huxley College of Environment; B. Wagner, Eawag; L. Sigg, Eawag, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; R. Behra, Eawag / Environmental Toxicology. It is generally accepted that the free ion form of most metals is the toxic form, but this concept was not developed with consideration of the unique characteristics of nanoparticles. For example, with silver nanoparticles (AgNPs) in solution the Ag can exist as both elemental silver and Ag<sup>+</sup>. When natural organic matter (NOM) is present, it may complex the Ag<sup>+</sup> or interact with the AgNP, potentially affecting the rate of Ag oxidation; this suggests that the kinetics of ion release are essential to consider with metals based nanoparticles. Finally, many AgNPs have capping agents, which may themselves alter the chemical fate, transport, and toxicity. The goals of this study were to evaluate the chemical complexation and toxicity to *Chlamydomonas reinhardtii* of Citrate, CO<sub>3</sub>, and PVP capped AgNPs and AgNO<sub>3</sub> in MOPS buffer only and in MOPS with 8 mg/L Suwannee River humic or fulvic acids (representative of NOM). The Ag was pre-equilibrated in the appropriate solution at room temperature in the dark for 24 hours. Polymer based Ion Selective Electrodes were then used to determine the concentration of dissolved Ag<sup>+</sup> for each AgNP or AgNO<sub>3</sub> solution. The photosynthetic effects (IC50s) to *C. reinhardtii* were also determined in the MOPS solutions. The toxicity ranking of the capped AgNPs in MOPS only was PVP > Citrate > CO<sub>3</sub>. In the presence of both humic and fulvic acids, the toxicity of all AgNPs and AgNO<sub>3</sub> as total Ag decreased. Further work is being conducted to confirm the concentrations of dissolved Ag<sup>+</sup> for each of the AgNPs and AgNO<sub>3</sub> solutions. This will be compared to the toxicity results based on total Ag.

**302 Identification of novel polyfluorinated compounds in natural waters using accurate mass TOFMS** M.J. Strynar, US Environmental Protection Agency / National Exposure Research Laboratory, U.S. EPA / HEASD, U.S. EPA / NERL/HEASD; S. Dagnino, IRCM Institut de Recherche en Cancérologie de Montpellier, INSERM U896; A.B. Lindstrom, U.S. Environmental Protection Agency / National Exposure Research Laboratory, U.S. EPA; E.M. Andersen, U.S. Environmental Protection Agency / US EPA; L. McMillan, National Caucus & Center on Black Aged, Inc.; M. Thurman, University of Colorado in Boulder / Center for Environmental Mass Spectrometry; I. Ferrer, Center for Environmental Mass Spectrometry, University of CO – Boulder / Civil, Environmental and Architectural Engineering; C. Ball, Agilent Technologies, Inc.. Perfluorinated compounds (PFCs) have been detected in a multitude of environmental and biological matrices across the globe for a number of years. This scientific scrutiny and concerns over exposure, toxicity and risk has led to international regulatory efforts that have resulted in the reduction or elimination of certain perfluorinated compounds in various products and waste streams in recent years. In addition, a few manufacturers have been moving toward the production of shorter chain per- and polyfluorinated compounds in order to reduce the potential for bioaccumulation in humans and wildlife. Some manufacturers are producing polyfluorinated compounds that contain central ether oxygens in order to avoid traditional perfluorinated structures. At present, there has been very limited information published on these "replacement chemistries" in the peer reviewed literature. Using an Agilent 6200 series accurate mass LC/MSD TOF we were able to identify novel polyfluorinated compounds in natural water samples taken from locations with historical perfluorinated compound contamination. Identification of these novel compounds includes accurate mass fragments from in-source collision-induced dissociation (CID), evaluation of adducts formed during analysis, and confirmation with authentic standards when possible. An additional line of evidence that is often seen is a homologous series of similar compounds that differ by multiples of CF<sub>2</sub> ( $m/z = 50$ ). These related compounds have logical chromatographic separation from the major target compound and they also have comparable fragments and adducts produced during analysis. A key element to this type of evaluation is the manipulation of the fragmenter voltage used in the TOF system in order to form both ionized parent molecules and a logical series of diagnostic fragment ions that help elucidate structures. This presentation will focus on TOF-based analytical approaches that can be used to quantify traditional PFCs from areas with known historical

contamination and to identify new per- and polyfluorinated materials that have not yet been described in the literature.

**303 Are all N-alkyl substituted perfluorooctane sulfonamides PFOS-precursors? The case of SAmPAP diester biodegradation in marine sediments** J.P. Benskin, AXYS Analytical Services Ltd; M.G. Ikonomou, Institute of Ocean Sciences / Department of Fisheries and Ocean; F.A. Gobas, Simon Fraser University / School of Resource and Environmental Management (Faculty of Environment), Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment, Simon Fraser University; M.B. Woudneh, AXYS Analytical Services Ltd / R&D Chemist; T. Begley, Food and Drug Administration / Center for Food Safety and Applied Nutrition; J.R. Cosgrove, AXYS Analytical Services Ltd. N-ethyl perfluorooctane sulfonamidoethanol-based phosphate (SAmPAP) diester is a commercial surfactant which was widely used in the food paper and packaging industry from the 1970s to 2002 and continues to be manufactured in Asia. SAmPAP diester was recently measured for the first time in urban marine sediments, but little is known about its stability in this environment. In the present work, the biodegradation of SAmPAP diester and N-ethyl perfluorooctane sulfonamidoethanol (EtFOSE) by bacteria in marine sediments was examined over 120 days at 4°C and 25°C. At both temperatures, EtFOSE was transformed to a suite of products, including N-ethyl perfluorooctane sulfonamidoacetate, perfluorooctane sulfonamidoacetate, N-ethyl perfluorooctane sulfonamide, perfluorooctane sulfonamide and perfluorooctane sulfonate. Transformation was significantly more rapid at 25°C compared to 4°C. In contrast to EtFOSE, SAmPAP diester was highly recalcitrant to microbial degradation, with negligible loss and/or product formation observed after 120 days at both temperatures. We hypothesize that the hydrophobicity of SAmPAP diester reduces its bioavailability, thus hindering microbial biotransformation in sediments. The resistance of SAmPAP diester to biodegradation may explain why this substance is still observable in marine sediments over a decade after its phase-out in North America.

**304 Analysis of Chlorinated and Fluorinated Contaminants Formed in Thermal Degradation of Halogenated Polymers** A.L. Myers, University of Toronto / Chemistry; S.A. Mabury, University of Toronto / Department of Chemistry; K.J. Jobst, E.J. Reiner, Ontario Ministry of the Environment. Chlorine and fluorine are incorporated into commercial thermoplastics, such as poly(vinyl chloride) (PVC), poly(vinylidene fluoride) (PVDF), poly(chlorotrifluoroethylene) (PCTFE) and poly(tetrafluoroethylene) (PTFE) to increase the thermal stability of the polymer. Nevertheless, these polymers have been shown to thermally degrade to form persistent and toxic halogenated environmental contaminants. This is a result of the eventual fate of these compounds, which includes thermal degradation through waste incineration, recycling, accidental fire, or backyard barrel burning. In this study, we have investigated the formation of chlorinated and fluorinated contaminants through thermal degradation of PVC, PVDF, PCTFE, and PTFE in a quartz tube furnace. The identification of the resulting degradation products was achieved by Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS), as well as by gas chromatography mass spectrometry (GC-MS), and liquid chromatography tandem mass spectrometry (LC-MS/MS). Our preliminary results indicate that a wide range of halogenated compounds, including perhalogenated-carboxylic acids, are generated in the thermolysis experiments. This study also shows that the degree and type of polymer halogenation determines the structural nature of the thermal degradation products.

**305 Identification of Novel Fluorochemicals in Aqueous Film-Forming Foams (AFFF) Used by the US Military** B. Place, Oregon State University / Department of Chemistry; J. Field, Oregon State University / Department of Environmental and Molecular Toxicology. Aqueous Film-Forming Foams (AFFF) are chemical mixtures that are used by military and non-military organizations to extinguish hydrocarbon-based fires (such as aircraft crashes and petroleum fires). Historical releases of AFFF (both controlled and uncontrolled) have been reported and previous studies identified high concentrations of commonly studied fluorochemical surfactants (such as PFOA and PFOS) in environmental compartments adjacent to these AFFF spills. The difficulty in fully understanding the environmental impact of the release of AFFF is that most AFFF products are mixtures of proprietary fluorochemicals. An analytical method was developed to identify the elemental composition of multiple fluorochemicals in AFFF. The method utilized two

mass spectrometric tools for this purpose: fast atom bombardment mass spectrometry and high resolution mass spectrometry (via quadrupole-time-of-flight mass spectrometer analysis). In addition, patent-based structural information was combined with mass spectrometry to elucidate the chemical structure of the fluorochemicals. US military-approved AFFF products were sampled from twenty different military bases across the US, representing all military AFFF manufacturers and covering a wide range of AFFF manufacturing dates. Eleven different fluorochemical classes were identified as primary components in AFFF from seven different formulators. The fluorochemical classes determined include surfactants with anionic, cationic and zwitterionic functionalities and with fluorinated chains lengths from 4 to 10. Of these identified components, ten of the classes have minimal peer-reviewed studies related to the environmental presence and/or toxicity.

**306 Identification of biomarkers of exposure to PAPs and FTOHs in urine and serum with LC-time-of-flight-MS** S. Dagnino, IRCM Institut de Recherche en Cancérologie de Montpellier, INSERM U896; A.B. Lindstrom, U.S. Environmental Protection Agency / National Exposure Research Laboratory; L. Mc Millan, E.M. Andersen, U.S. Environmental Protection Agency; C. Ball, Agilent Technologies, Inc.; C. Lau, US EPA / Toxicity Assessment Division; M.J. Strynar, US Environmental Protection Agency / National Exposure Research Laboratory, U.S. EPA / HEASD, U.S. EPA / NERL/HEASD. Perfluorinated compounds (PFCs), such as perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), have become the subject of intense investigation and growing regulatory control in the USA and the EU. In contrast, little is known about many of the more complex or newly formulated PFCs, despite the fact that they are used in a wide range of consumer products and human exposure routes remain poorly described. Some of the less well-studied compounds include the fluorotelomer alcohols (FTOHs) and polyfluoroalkyl phosphate esters (PAPs) both of which are used in numerous applications such as oil and water repellent treatments for carpets and coatings for food packaging. Although their toxicity has yet to be clearly determined, FTOHs and PAPs are known to degrade to terminal perfluorinated carboxylic acids (PFCAs) through metabolic pathways that produce a number of toxic reactive intermediates. Therefore, it is important to characterize exposures for FTOHs and PAPs, and to elucidate their complex metabolism *in vivo*. The first aim of this study was to identify FTOH and PAP metabolites in a rodent model, and then to determine if these compounds can be used as biomarkers for human exposure research. A sensitive liquid chromatography-electrospray ionization time-of-flight mass spectrometry method was established for the identification of urinary and serum metabolites of 8:2 FTOH and the 8:2, 8:2 diPAP in adult Sprague-Dawley male rats dosed at 5 mg/kg and 50 mg/kg. Resulting PFOA levels were as high as 1500 ng/mL in serum and 600 ng/mL in urine of FTOH and PAP dosed rats. Unique and specific biomarkers were also detected in these test animals and correlations between urine and serum concentrations have been established. With the application of these methods to anonymous adult human serum and urine samples (n = 100), previously reported and new per- and poly-fluorinated metabolites were identified. This work has led to the tentative identification of biomarkers of exposure for FTOHs and PAPs in humans while also demonstrating the potential utility of urine-based biomarkers as a non-invasive approach for human studies.

**307 Time-resolved global emission inventories for C4-C14 perfluoroalkyl carboxylic acid homologues from 1951 to 2050** Z. Wang, Swiss Federal Institute of Technology (ETH Zurich) / Institute for Chemical and Bioengineering; I.T. Cousins, Stockholm University; M. Scheringer, Swiss Federal Institute of Technology (ETH Zurich) / Institute for Chemical and Bioengineering; R.C. Buck, E. I. duPont de Nemours & Co., Inc. / DuPont Chemicals & Fluoroproducts, DuPont / Chemicals & Fluoroproducts, E. I. duPont de Nemours & Co., Inc. / Chemicals & Fluoroproducts; K. Hungerbuehler, Swiss Federal Institute of Technology (ETH Zurich) / Institute for Chemical and Bioengineering. For over a decade, long-chain perfluoroalkyl carboxylic acids (PFCAs,  $C_xF_{2x+1}COOH$ ,  $x = 7-13$ ), including perfluorooctanoic acid (PFOA) and perfluorononanoic acid (PFNA), have attracted attention as global contaminants of high concern due to their persistence, bioaccumulative potential and global presence in the abiotic environment, biota and humans. To fully characterize the exposure to PFCAs, an understanding of their cycling in the environment, starting from source identification and emission quantification, is needed. In 2006, Prevedouros et al. estimated the total global historical emissions of PFCAs (1951-2004) and highlighted the significance of direct industrial sources to the presence

and distribution of PFCAs in the environment. However, their work focused mainly on PFOA and PFNA, and a detailed breakdown of PFCA sources on a homologue basis was not provided. In addition, industry has taken action to replace the longer-chain homologues with compounds containing shorter perfluorinated chains in recent years, suggesting that potential emission sources for PFCAs have changed since the review was published. Moreover, new manufacturers have begun to make long-chain PFCAs and their potential precursors. In the current study, we re-evaluated and expanded the work of Prevedouros et al. in the following ways, namely: (a) New emission sources and uses of PFCA homologues ( $C_4-C_{14}$ ) are identified. Interestingly, the short-chain PFCAs ( $C_4-C_7$ ) and their derivatives are revealed to have been manufactured in large quantities for many years before the industry started the transition to alternative substances after 2000. (b) The sources of each PFCA homologue are individually assessed for three periods (1951-2002 (pre phase-out), 2003-2015 (transition after phase-out) and 2015-2050 (prognosis)). Thus, the relative contributions of direct and indirect sources to overall emissions are identified in a homologue-specific and time-specific way. (c) Discussion of environmental release media and geographical distribution of emissions as a function of time is included with special attention given to the macroeconomic trend of manufacturing moving to Asia. (d) Information on new commercial alternatives to the long-chain PFCAs and their potential precursors in various applications (e.g. per- and polyfluoroethers as polymerization aids, fluorotelomer-based surfactants in AFFF, etc.) is compiled.

**308 Microbial Degradation of Commercial Model Fluorotelomer Monomers in Aerobic Soils** L.S. Lee, Purdue University / Dept. of Agronomy Crop, Soil & Environmental Sciences, Purdue University / Dept. of Soil, Crop & Environmental Sciences; K. Dasu, Purdue University / Department of Agronomy, Crop, Soil and Environmental Sciences, NRC Post Doc at US EPA / Office of Research and Development, National Risk Management Research Laboratory, U.S. Environmental Protection Agency / National Risk Management Research Laboratory; L.A. Royer, Exponent, Inc. / Agronomy – Crop, Soil and Environmental Sciences, Exponent Inc; J. Liu, University of Maryland Center for Environmental Science / Chesapeake Biological Laboratory, McGill University / Civil Engineering and Applied Mechanics. The global distribution of polyfluoroalkyl substances (PFASs) continues to be a concern for scientists and regulators alike. Most studies to date focus on fluorotelomer alcohols (FTOHs) and perfluoroalkyl carboxylic acids including perfluorooctanoic acid (PFOA). Probing new potential sources of PFOA is needed. We hypothesize that in aerobic soils, 8:2 fluorotelomer (FT)-based monomers will undergo hydrolytic cleavage to yield 8:2 FTOH as the primary degradation product followed by production of the suite of PFASs observed in aerobic 8:2 FTOH biotransformation. The biotransformation potential of six model 8:2 FT monomers was quantified: fluorotelomer acrylate (FTA) and fluorotelomer methacrylate (FTMA), fluorotelomer stearate ester (FTS), fluorotelomer citrate triester (TBC), an aromatic fluorotelomer diurethane (FTU) and an aliphatic fluorotelomer diurethane (HMU). FT monomers were incubated for ~1 to 7 mo in an agricultural soil or a forest soil. Abiotic controls included solvent (no soil) and autoclave-sterilized soil controls. FT compounds were applied quantitatively either dissolved in acetone or coated on talc to achieve a starting concentration of ~100 to 250 mg/kg soil. At designated sampling times, headspace samples were taken and analyzed for FTOHs, and followed by extracting soils with ethyl acetate, MTBE, or tetrahydrofuran for FT monomers and 8:2 FTOH, and then twice with 90/10 v/v acetonitrile/NaOH (200 mM). PFASs were analyzed by GC/MS or liquid chromatography tandem electrospray ionization mass spectrometry (HPLC/ESI-MS/MS). Degradation rates were affected by the non-fluorinated terminus or backbone, soil type and soil storage time. FTA degraded the fastest with half-lives of ~3 to 5 d followed by FTS (5 to 28 d) and FTMA (~15 d). For the larger FT monomers, biodegradation was slow with  $56 \pm 19$  mol% TBC remaining after 7 mo, 70 mol% FTU after 4 mo, and 73 mol% HMU after 6 mo. PFOA levels reached 1 to 10 mol% observed for the different FT-soil combinations with no apparent plateau in some studies. Storage of the forest soil around 4 °C, which is hypothesized to increase in fungal populations, greatly enhanced degradation rates of FTS. Addition of a non-fluorinated carbon source and re-aeration enhanced PFOA production, but not necessarily monomer degradation. Monomers with slower transformation rates appeared to lead to more irreversible binding of PFASs to soil, thus lower PFOA production and lower overall mass balance.

### 309 Preliminary studies on re-mobilization and metabolism of soil-bound <sup>14</sup>C-labeled 5:3 polyfluorinated acid by earthworm *Eisenia fetida*

N. Wang, DuPont, E.I. du Pont de Nemours & Company, DuPont; L.M. Sulecki, B.W. Wolstenholme, R.C. Buck, J.T. Gannon, DuPont. The 6:2 fluorotelomer alcohol [6:2 FTOH, F(CF<sub>2</sub>)<sub>6</sub>CH<sub>2</sub>CH<sub>2</sub>OH] is a major raw material to replace the 8:2 fluorotelomer alcohol (8:2 FTOH, F(CF<sub>2</sub>)<sub>8</sub>CH<sub>2</sub>CH<sub>2</sub>OH) to produce 6:2 FTOH-based products for industrial and consumer applications. Aerobic biotransformation of 6:2 FTOH in various environmental matrices (e.g., soil, activated sludge, and sediment) leads to two major classes of transformation products: perfluorinated carboxylic acids and 5:3 polyfluorinated acid [5:3 acid, F(CF<sub>2</sub>)<sub>5</sub>CH<sub>2</sub>CH<sub>2</sub>COOH]. The 5:3 acid can be further degraded in diluted activated sludge to 4:3 acid and perfluorobutanoic and perfluoropentanoic acids with a total molar yields of ~21%. In soil, however, the 5:3 acid formed during 6:2 FTOH biotransformation become tightly bound to soil organic components and is not extractable by organic solvent alone and can only be recovered by post-treatment of the organic extracts with strong base plus activated carbon. Also, only about 1 mol% of 4:3 acid is formed during 6:2 FTOH biotransformation, indicating that the soil-bound 5:3 acid was not readily available for further biodegradation. The present study investigated the bioavailability of soil-bound 5:3 acid trying to answer two questions: 1) Can earthworms remobilize the soil-bound 5:3 acid? and 2) can earthworms metabolize the soil-bound 5:3 acid to release free 5:3 acid for further biodegradation? Earth worm (*Eisenia fetida*) colonies were established in clean soil with supplementary diet. Aged soil containing soil-bound <sup>14</sup>C-labeled 5:3 acid was used for the study. The aged soil was extracted at least twice with acetonitrile to remove free 5:3 acid prior to mixing with clean soil. The earth worms were then exposed to the mixed soil for ~5 weeks with minimum diet supplement to encourage the earthworms to consume the soil. LC/MS/MS and LC/ARC (liquid chromatography/accurate radioisotope counting) were used to quantify <sup>14</sup>C-labeled 5:3 acid and potential metabolites. Detailed experimental methods and study results will be presented.

### 310 Estimating pesticide exposure and accumulation in terrestrial phase amphibians

R. Van Meter, Environmental Protection Agency / Ecosystems Assessment Branch; S.T. Purucker, Environmental Protection Agency. Dermal exposure presents a potentially significant but understudied route for pesticide uptake in terrestrial amphibians. Although some toxicity data exists for amphibians, the focus has largely centered on early aquatic life stages. Beyond providing protection and minimizing desiccation, amphibian skin has unique characteristics for gas and water exchange that may make this group very susceptible to contaminants relative to amniotes. Hydrophilic pesticides are very likely to be taken up through amphibian skin and this includes uptake from contaminated soil and foliage by terrestrial amphibians at any life stage. Our study was designed to measure dermal uptake or total body burden of pesticides of varying hydrophobicity through terrestrial exposure to juvenile frogs. In doing so, our goal is to begin to expand on the limited data currently available on toxicity of pesticides through dermal exposure in terrestrial amphibians. During spring and early summer 2012, we collected southern leopard frogs (*Rana sphenoccephala*), American toads (*Bufo americanus*), Fowler's toads (*Bufo fowleri*), gray treefrogs (*Hyla versicolor*) and tiger salamanders (*Ambystoma tigrinum*) from ponds in the University of Georgia's Whitehall Forest protected area. All amphibians were reared on-site at the US EPA in Athens, GA through 60-days post-metamorphosis. Our experimental design was a 4x2 full-factorial design with 5 replicates of each treatment as follows: 3 pesticides plus a control and 2 application treatments (pesticide mixed directly into soil or applied via overspray). Juveniles of each species were placed in glass aquariums lined with 2 centimeters of soil and exposed to pesticides through the application treatments detailed above for 12 hours. At the termination of the study, frogs were euthanized and stored in a -20 °C freezer until whole body tissue analysis was performed on a GC/MS. Tissue analysis is on-going, but preliminary results indicate that terrestrial phase amphibians do readily absorb hydrophilic pesticides from the soil environment. The dermis represents an important pathway for contaminant accumulation in terrestrial amphibians and as such, we plan to use this data to evaluate a proposed EPA dermal uptake screening tool.

### 311 Constructed and natural wetlands as sources of current-use pesticides to amphibians

K.L. Smalling, W. Battaglin, US Geological Survey; R. Reeves, Iowa State University; E. Muths, M. Vandever, M.L. Hladik, A. Gallant, W. Sadinski, D. Kolpin, US Geological Survey. Degradation and

loss of habitat due to agricultural practices are among the primary reasons amphibian populations have declined worldwide. Since the mid-1800s, agriculture has transformed the landscape of Iowa's Des Moines Lobe, the southernmost portion of the Prairie Pothole Region, from grasslands and wetlands to one of the most intensively farmed areas in the world, with only small patches of native vegetation and relatively few wetlands remaining. Despite such dramatic landscape changes, populations of native amphibians continue to persist where combinations of uplands and wetlands enable sufficient survival, reproduction, and recruitment, including areas with constructed wetlands and agricultural ditches. However, the stability of these populations and their long-term persistence in the face of multiple potential stressors is uncertain, which underscores the need for assessing the risks these stressors pose to amphibian fitness. The principal potential threats to amphibian species of the Des Moines Lobe are further habitat loss and degradation due to agricultural practices, climate change, and disease. For this reason pesticides are receiving increasing attention as a potential cause of declines, acting singly or in combination with other stressors such as disease. The current study was designed to focus on the potential exposure and accumulation of agricultural pesticides in native leopard frogs (*Lithobates pipiens*) collected from constructed and natural wetlands located in the Des Moines Lobe in Iowa. Surface water, sediment and frog livers collected throughout the spring and summer of 2012 will be analyzed for over 90 current-use pesticides and pesticide degradates including 34 fungicides using gas chromatography mass spectrometry. Preliminary results from April (prior to major crop planting efforts) indicate that a variety of pesticides were detected in water samples collected from both the constructed and natural wetlands including neonicotinoid insecticides, the herbicides, atrazine and metolachlor, and several fungicides. Pesticide concentrations in surface water from these wetlands ranged from 1 to 200 ng/L with a median of 58 ng/L. The results of the study will provide critical information on the potential for amphibians to be exposed to and take up these compounds and will aid in the assessment of subsequent risks to their fitness and long-term population persistence.

### 312 Acute toxicity of the fungicide chlorothalonil to two amphibians, *Xenopus laevis* and *Spea multiplicata*

S. Yu, Texas Tech University / Department of Environmental Toxicology; M. Wages, Texas Tech University/TIEHH / Department of Environmental Toxicology; G.P. Cobb, Baylor University / Department of Environmental Science; J.D. Maul, Texas Tech University / The institute of environmental and human health, Texas Tech University/TIEHH / Department of Environmental Toxicol. As a broad-spectrum fungicide, chlorothalonil has been widely used in agriculture to protect crops and in urban environments for lawn and garden applications. Despite being one of the most heavily used fungicides, little is known about the effects of chlorothalonil on amphibians. The objective of this study was to determine the acute toxicity of chlorothalonil to African clawed frog *Xenopus laevis* embryos (NF stage 8-11) and tadpoles (stage 45) and New Mexico spadefoot toad *Spea multiplicata* tadpoles (Gosner stage 25). We performed 96-h static toxicity tests and exposed embryos and tadpoles to control and five concentrations of chlorothalonil. At the end of the exposure period tadpoles were euthanized, examined for abnormalities, and morphological measurements were taken. For *X. laevis*, the 96-h LC50s (95% CI) were 42.1 µg/L (39.7-44.9) for embryos and 11.7 µg/L (10.4-12.7) for larvae. The results were confirmed in a second verification experiment with LC50s of 29.3 µg/L (27.1-31.8) and 17.5 µg/L (16.3-19.0) for embryos and larvae, respectively. *Spea multiplicata* tadpoles were more sensitive to chlorothalonil with an LC50 of 8.6 µg/L (7.8-9.5). We compared the LC50s of *X. laevis* and *S. multiplicata* tadpoles to those reported in invertebrates and fish, and amphibians appear to be more sensitive than invertebrates and fish. Chlorothalonil induced gut malformations in *X. laevis* embryos and high concentrations produced significantly smaller tadpoles compared to control ( $P < 0.05$ ). However, the size of *S. multiplicata* tadpoles was not significantly different among treatments. Tail shortening was observed in both *X. laevis* and *S. multiplicata* tadpoles exposed to chlorothalonil; chlorothalonil treated groups had significantly lower tail length to total length ratios ( $P < 0.05$ ). The mechanism of tail shortening induced by chlorothalonil is unclear but alteration in the expression of genes involved in tail resorption during metamorphosis may be an explanation. Although chlorothalonil concentrations in the environment were generally low (< 0.1 µg/L), high concentrations (50-130 µg/L) have been reported in run-off after application by rainfall which could cause high mortality and malformations. Our results suggest that chlorothalonil is highly toxic to amphibians, and can cause tail

degeneration in larvae which may have a significant impact on predator avoidance, the ability to acquire food, and metamorphosis.

**313 An Examination of the Maternal and Paternal Contributions to Responses of Embryonic and Larval Southern Toads (*Anaxyrus terrestris*) to Copper** R.W. Flynn, University of Georgia / Savannah River Ecology Laboratory, Savannah River Ecology Laboratory; D. Scott, S. Lance, University of Georgia / Savannah River Ecology Laboratory. Chemical contaminants, including metals, are common features in many aquatic habitats. Chemical contamination is one of the anthropogenic stressors implicated in global amphibian declines. Often the level of any given contaminant is high enough to reduce population size but not to extirpate the population through direct effects. If heritable genetic differences are associated with differential survival of individuals within a population, selection for tolerance to the given stressor along with any linked traits may occur. Though variation in response to contaminants is well documented, the basis for that variation is rarely investigated and the potential for adaptation is largely unknown. In fact, when geographic variation in tolerance corresponds with current presence/absence of a stressor it has been taken as evidence for local adaptation. These studies are correlative, but continue to demonstrate that variation in tolerance to stressors is common in amphibians. In southern toads, *Anaxyrus terrestris*, we have found substantial within and among population variation in tolerance to copper (Cu). To gain a better understanding for whether that variation has an underlying genetic basis we artificially fertilized eggs of five female southern toads with sperm from four male toads from the same population. This resulted in groups of full siblings and paternal and maternal half siblings. Half siblings allow for analysis of genetic and phenotypic contributions of mothers and fathers individually, as well as the interaction of the two. This is essential to quantitatively determine whether there is heritable genetic variation for tolerance to stressors and other quantifiable traits that could result in adaptation. We exposed embryos to a range of Cu treatments so that maternal, paternal, and maternal x paternal contributions to the response of embryos and larvae could be quantified. Embryonic survivorship was significantly affected by Cu treatment and parentage, with a significant maternity x paternity interaction. The response to Cu was significantly different among families and was affected more by paternity than maternity. In a subsequent trial we chronically exposed larvae for three weeks. We took photographs of each tadpole weekly to examine the effects of paternity, maternity, Cu, and interaction of the three on growth rate and other sublethal endpoints. Upon completion of the trial we collected all tadpoles for gene expression and SNP analysis.

**314 Individual and population level differences in response to chronic copper exposure in southern toads, *Anaxyrus terrestris*** S. Lance, University of Georgia / Savannah River Ecology Laboratory; R.W. Flynn, University of Georgia / Savannah River Ecology Laboratory, Savannah River Ecology Laboratory; K. Jones, University of Colorado, Denver / Biochemistry and Molecular Genetics; M. Erickson, Georgia Southern University / Biology; T. Tuberville, G. Mills, D. Scott, University of Georgia / Savannah River Ecology Laboratory. Environmental contaminants are one stressor implicated in the global decline of amphibian populations. There have been numerous studies examining the lethal or sub-lethal effects of contaminants on amphibians. However, we know relatively little about among individual and among population variation in response to exposure and the potential for local adaptation and population persistence. Understanding what makes some individuals and populations more resilient to anthropogenic stressors is important for conservation biology and is lacking in most ecotoxicological studies. One first step is to further examine how much standing variation in tolerance exists within and among populations prior to exposure to a specific stressor. Metals resist degradation in the environment and thus are likely to act as a chronic stressor that has the potential to expose multiple generations. We examined the effects of Cu exposure on the southern toad, *Anaxyrus terrestris*, a widespread species for which no data on Cu exposure are available. Our objectives were to: 1) examine the effects of acute and chronic Cu exposure, 2) quantify lethal and sublethal effects, and 3) assess variation in tolerance to Cu within and among populations with and without prior Cu exposure. Overall Cu significantly reduces survival through the egg and larval stages. We examined eggs from multiple clutches and source populations and both factors are significant sources of variation in survival. Clutches from populations with prior Cu exposure had the lowest survivorship. Among several source populations with no prior Cu exposure there was still significant variation in response to Cu. Depending upon the source

population survival to the free-swimming stage was significantly reduced at concentrations as low as 10 µg/L and no larvae reached metamorphosis at concentrations above 15 µg/L. Neither time to- or size at-metamorphosis were significantly affected by Cu treatment. In a separate study, to better understand the effects of Cu we used RNASeq to examine gene expression patterns in developing toads exposed to Cu. We compared expression in early development of eggs from 24 to 54 hours post treatment. At 55 hours nearly 200 genes are differentially expressed between control and treatment individuals. We discuss our findings and relate them to potential impacts on population level processes.

**315 Improving reptile risk assessment: relative importance of diet and dermal contaminant exposure in the Western fence lizard (*Sceloporus occidentalis*)** S.M. Weir, The institute of environmental and human health / The institute of environmental and human health, The institute of environmental and human health / Environmental Toxicology; L.G. Talent, Oklahoma State University / Department of Natural Resource Ecology and Management; C.J. Salice, Texas Tech University / Environmental Toxicology, Texas Tech University / TIEHH, Texas Tech University / Department of Environmental Toxicology. Reptile ecological risk assessment is currently limited by a lack of toxicity data for reptiles, and little knowledge of contaminant exposure. Recent advances in the use of the Western fence lizard (*Sceloporus occidentalis*) as a model organism creates opportunities for filling important data gaps. Interest has been growing for including dermal exposure in ecological risk assessments for birds. Because many reptiles spend a large proportion of time in contact with substrate, there is potential for dermal exposure to be important for reptiles. The purpose of this research was to provide insight into the relative importance of diet and dermal contaminant exposure in reptiles. Fence lizards were exposed to phthalate esters by either oral gavage or dermal application. Phthalates were chosen as model chemicals because lipophilicity changes with the length of the side chain allowing relationships between dermal exposure and lipophilicity to be estimated in the absence of overt toxicity. We used di-methyl phthalate (DMP, logKow = 1.6), di-iso-butyl phthalate (DIBP, logKow = 4.0), and di-n-octyl phthalate (DNOP, logKow = 8.0). Lizards from both exposure routes received the same dose (10 µL) of each phthalate. Following 24 or 48 hours, lizards were sacrificed and organs removed for chemical analysis. Dermal exposure was highest for phthalates with greater lipophilicity, but was greatest for DIBP at both 24 and 48 hours. Generally, DMP had lower concentrations for both oral and dermal exposure routes, but had many more detections in oral treatments than dermal. DIBP and DNOP appeared to be significantly absorbed by both dermal and oral exposure. Dietary exposure resulted in significantly greater liver and fat residues for both DIBP and DNOP than dermal exposure. Dermal skin samples had very high concentrations of phthalates indicating that only a fraction of the phthalates applied had crossed the dermal barrier. Realistic assessments of contaminant exposure in reptiles should consider dermal exposure routes, especially because reptiles feed infrequently and have relatively low oral exposure. Future research will repeat this experiment under more realistic dosing scenarios (i.e. contaminated soil and dosed food) followed by field truthing of laboratory results in terrestrial enclosures. Results from this and subsequent empirical research will be used to inform, populate and verify dermal exposure models for use in ecological risk assessments.

**316 AROD Optimization in Chorioallantoic Membranes (CAMs) of Kemp's Ridley (*Lepidochelys kempii*) sea turtles** R.J. Pezdek, Texas Tech University / Institute of Environmental and Human Health, Texas Tech University; D.J. Shaver, US National Park Service / Padre Island National Seashore; M.J. Hooper, R.L. Tillitt, USGS / Columbia Environmental Research Center; J.E. Yacabucci, Texas Tech University / Institute of Environmental and Human Health; J.S. Walker, S.C. Ertolacci, US National Park Service / Padre Island National Seashore; C.J. Godard-Codding, The Institute of Environmental and Human Health/ Texas Tech University / Assistant Professor, Texas Tech University/The Institute of Environmental and Human Health / Assistant Professor, Texas Tech University / Institute of Environmental and Human Health. Reptiles are present worldwide and play a key ecological role in various environments. Previous research on declining reptilian species is minimal and leaves many questions unanswered, such as the effects of environmental contaminants. Sea turtles are a key reptilian species in the marine environment and understanding impacts on their health is crucial to conserving currently declining sea turtle populations. With only seven sea turtles species in the world, all of which

are threatened or endangered, traditional *in vivo* toxicology experiments on this species are prohibited. The chorioallantoic membrane (CAM) is a highly vascularized egg membrane involved in the respiration and waste storage for the developing embryo. The CAM's physiological role has often been compared to that of the liver, and previous studies have shown that contaminant burdens found in the CAM correlate well with body burdens in the embryo. The CAM is attached to the outer shell and surrounds the embryo until hatching, when it remains behind in the eggshell. This makes the CAM an excellent tissue for assessing biomarkers of environmental contaminant exposure and effects for non-invasive wildlife research and a novel research tissue for endangered sea turtles. We collected Kemp's ridley sea turtle CAMs during the 2010 nesting/hatching season from Padre Island National Seashore in Corpus Christi, TX (permit #'s TE840727-3 and SPR-0190-122). Here, we report on the optimization of cytochrome P450 catalytic analyses in CAM for use in alkoxyresorufin O-dealkylation (AROD) assays. We investigated (1) four different homogenization steps (whole tissue homogenization, 300 xg, S9, and microsomal preparation), (2) protein loss between homogenization levels, (3) sonication versus traditional homogenization methods, (4) mean weight of CAM tissue, and (5) mean amount of protein found in CAMs. Our preliminary results indicate that the S9 purification level appears best suited for analyses in CAMs weighing 0.15g or more by providing enough protein for the analyses of the four primary AROD assays: 7-ethoxyresorufin O-dealkylation (EROD), 7-methoxyresorufin O-dealkylation (MROD), 7-pentoxoresorufin O-dealkylation (PROD), and 7-benzoyloxyresorufin O-dealkylation (BROD). Further sample analysis will help elucidate which AROD(s) may be best suited for the detection of cytochrome P450 catalytic activity in sea turtles.

**317 In vitro Toxicity of Perfluorinated Compounds in Loggerhead Sea Turtle (*Caretta caretta*) Primary Skin Cell Cultures** S.J. Webb, Texas Tech University / The institute of environmental and human health, The institute of environmental and human health; B.M. Higgins, NOAA/NMFS; C.A. Godard-Coding, Texas Tech University / The institute of environmental and human health. Perfluorinated compounds (PFCs) are globally distributed contaminants which have been measured in both human and wildlife blood and serum. Sources include polymerization aids, stain repellents, surfactants, and medical devices. These compounds have been shown to cause a variety of adverse health effects in mammals, including the development of tumors in the liver and thyroid, hepatotoxicity, developmental delays, interruption in lipid metabolism and adipogenesis leading to decreased body weight, and a significant increase in both internal and external morphological abnormalities. There is currently no PFC toxicity data available in any reptile species. PFCs are found in loggerhead sea turtle tissues at levels which can cause significant toxicity in mammals. In loggerhead sea turtles perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS) are the dominant PFC compounds found in serum. Here, we report on the use of cytotoxicity assays to assess adverse effects of PFOA in sea turtles. Loggerhead sea turtle primary skin cell cultures which were previously established and characterized in our lab were used for testing. Because PFCs are known to affect mitochondrial activity and lipid production in mammalian toxicity studies, (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and lactate dehydrogenase (LDH) were selected as initial toxicity assays. Initially, a variety of test concentrations (0.05  $\mu$ M, 0.5  $\mu$ M, 5.0  $\mu$ M, 50  $\mu$ M, 500  $\mu$ M) were used, which encompass chemical concentrations found in the environment, in turtle serum, and in prey animals. Significant toxicity occurs at the highest dose (500  $\mu$ M) with cells from n=6 turtles for MTT and n=5 turtles for LDH, a large sample size when working with endangered species. Following initial testing, dose range was narrowed between the highest dose (500  $\mu$ M) and the highest dose showing no significant toxicity (50  $\mu$ M). Both MTT and LDH assays were performed on this second dose range (50  $\mu$ M, 140  $\mu$ M, 230  $\mu$ M, 320  $\mu$ M, 410  $\mu$ M, 500  $\mu$ M). Significant toxicity occurs at 410  $\mu$ M and 500  $\mu$ M with cells in initial testing.

**318 Effect of Sediment Physicochemical Properties on the Bioavailability of Sediment-Associated Uranium to a Model Benthic Organism, *Chironomus dilutus*** S.E. Crawford, L. Doig, K. Liber, University of Saskatchewan / Toxicology Centre. The importance of metal bioavailability in aquatic ecosystems has been well established. However, our understanding of the factors and mechanisms controlling the bioavailability of some metals is still incomplete. In particular, there is limited information regarding bioavailability and toxicity of uranium (U) in freshwater sediment. Mineral coatings on particle surfaces have been shown to adsorb metals. Given that

dissolved U is believed to be the primary bioavailable fraction of U, it is hypothesized that adsorption and interaction of U with various mineral coatings will influence the bioavailability of U in sediment. As such, the goal of this research is to investigate the effects of specific sediment physicochemical properties, mainly clays and organic matter, on the bioavailability of U to a model freshwater benthic organism, *Chironomus dilutus*. Differences in binding capacities and hence changes in bioavailability were examined in a series of 10-d sediment bioaccumulation/toxicity tests, exposing 8-d old *C. dilutus* larvae to different treatments of U-spiked sediment. Test endpoints and measurements included *C. dilutus* survival and growth, and U concentrations in whole organisms, whole-sediment and water (both overlying water and pore water). Studies were conducted with 0 (control), 50 and 200 mg U/kg dry weight (d.w.) spiked into formulated sediments and aged for 20 d. Composition of sediments varied according to the characteristic being examined, but included silica sand as the foundation of the mixtures, along with one of three different types of clay (kaolin, montmorillonite, and illite) added at 0 to 60% of the sediment d.w., or peat moss added as a source of organic matter at 0, 5, or 15% of sediment d.w. Bioaccumulation of U in *C. dilutus* larvae ranged from 10 to 1195 mg U/kg d.w. when exposed to 50 mg U/kg d.w. in sediments containing 0 to 60% clay (d.w.), respectively. Similarly, higher organic matter content was associated with lower amounts of U bioaccumulation in *C. dilutus* larvae, indicating a reduction in U bioavailability. It was also found that U bioavailability differed among the three types of clay minerals examined, with bioavailability decreasing with montmorillonite > illite  $\approx$  kaolin clay. Results from this research will guide future studies with more complex sediment, while also informing risk assessments of U contaminated sites and possibly the development of site-specific sediment quality guidelines for U.

**319 Metal Effects on Benthic Invertebrates in Off-Site Ponds near the Deloro Mine Site (Ontario, Canada)** L.E. Brown, ENVIRON International Corporation; P.C. Fuchsmann, ENVIRON International Corporation, ENVIRON International Corp.; M. Henning, ENVIRON International Corporation. Historical mining and smelting operations at the Deloro Mine Site resulted in elevated concentrations of arsenic, cobalt, copper and nickel in sediments in Young's Creek and associated beaver ponds. We investigated risks to benthic invertebrates in these off-site sediments through a novel application of the sediment quality triad (SQT) approach. In addition to the typical SQT elements – sediment toxicity testing, benthic community taxonomic characterization, and sediment chemistry – bioavailable exposures were evaluated by analyzing metals in amphipod tissues and copper in water overlying toxicity tests. Toxicity tests results for three species tended to over-predict effects compared to the benthic community data; overlying water copper data suggest possible laboratory artifacts (e.g., low dilution compared to field conditions). Consequently, site-specific toxicity reference values (TRVs) were derived from the benthic community data set. Taxa richness, abundance, Shannon diversity, and Hilsenhoff Biotic Index were the most useful metrics for differentiating benthic community quality across sampling locations. The influence of each metal relative to observed effects varied across sampling locations. Therefore, overall benthic quality was ranked, and apparent effect thresholds were identified based on tissue or overlying water exposures. Organic carbon normalization of sediment metal concentrations enabled us to translate the apparent effect thresholds to sediment TRVs, while maintaining accurate predictions of effects. The resulting site-specific TRVs are considerably higher than default sediment screening values, which in turn has large impact on estimated costs to remediate the sediment.

**320 Assessing risk in a contaminated river: links between abiotic and biotic factors as predictors of tissue metal concentrations in a stream biomonitor** M. Hornberger, D. Cain, U.S. Geological Survey / Water Resources Division; M. Croteau, U.S. Geological Survey. Assessments of stream health using dissolved and sediment metal concentrations provide a basis for determining possible adverse effects to aquatic organisms. Tissue residue studies using resident species provide biological relevance because organisms integrate metal from their surrounding environment, thus representing bioavailable metal. Biodynamic models can identify key the physiological processes and exposure routes linking abiotic measures of metal exposure and metal concentrations in resident organisms. This approach is being integrated with long-term monitoring field study to evaluate remediation of mining wastes at an USEPA Superfund site. Field work, laboratory experiments and biodynamic modeling can help identify the mechanisms controlling bioaccumulation, allowing us to 1) quantify the routes of

exposure to a larval insect that is being used to monitor bioavailable metals; 2) identify the time period of exposure represented by tissue concentrations in the biomonitor; and 3) determine exposure scenarios necessary to reach reference values. We present an integrated approach to assessing the success of remediation efforts on a metal-impacted river using the common biomonitor *Hydropsyche* (O: Trichoptera). Physiological processes (uptake and loss), and exposure routes (dissolved and diet) were quantified using an enriched stable isotope tracer ( $^{65}\text{Cu}$ ) and biodynamic modeling. Site-specific geochemical field data were incorporated into a biodynamic model, allowing us to validate the model parameters and predict copper bioaccumulation in *Hydropsyche*. Our findings suggest that dietary Cu influx is ~3-fold higher than dissolved influx and that consideration of dissolved only exposure under-predicts *Hydropsyche* Cu concentrations by ~70%. *Hydropsyche* also has fast uptake and loss rates, which has important implications for monitoring programs. This species can reach steady state in ~30 days, but eliminates 17-25% of its Cu body burden per day if exposure is removed. Fluctuations in river discharge also influence exposure and is linked to the physiological and behavioral mechanisms controlling Cu uptake in *Hydropsyche*. Understanding how these abiotic and biotic factors are coupled will allow us to predict how tissue concentrations will change under different exposure scenarios.

**321 Evaluation of Statistical Bioaccumulation Models for Prediction of Tissue and Sediment Concentrations** N. Judd, J. Toll, Windward Environmental LLC; L. Tear, Windward Environmental. Biota-sediment accumulation factors (BSAFs) or biota-sediment accumulation regressions (BSARs) are statistical tools used to estimate chemical concentrations in tissue from sediment concentrations when empirical tissue data are lacking, estimate tissue concentrations under alternative future conditions (e.g., remedial actions or dredging), or estimate sediment preliminary remediation goals (PRGs) from target tissue concentrations. Scatter plots and linear (or non-linear) models offer managers the ability to explore the relationship between sediment and tissue concentrations at a site and make decisions that acknowledge the shape and uncertainty of the relationship. Data from the US Environmental Protection Agency Mid-Continent Ecology Division's BSAF database were used to explore tissue-sediment relationships. Of the 262 datasets for benthic invertebrates with sufficient data for evaluation, many of the sediment-tissue relationships were negative and about two-thirds of the relationships were very poor and did not meet minimum screening criteria (i.e.,  $r^2 > 0.3$ ,  $p\text{-value} < 0.05$ ). Further evaluation of three of the stronger relationships was performed. BSAFs, linear regressions, Model II regressions, example sediment PRGs, and associated confidence intervals were calculated for each example. The examples illustrate several simple but important aspects of sediment-tissue relationships that should be explored for their effects on BSAR and BSAF applications and on the statistical uncertainty of the relationships: non-zero intercept for the relationship (i.e., accounting for non-sediment sources), the nature and shape of the relationship (e.g., linear, log-linear, or non-linear), and the effect of individual sediment-tissue pairs on the relationship (e.g., the influence of a single high point). Simple models, like BSARs and BSAFs, may continue to be the best options for decision-making in many applications; however, their limitations and uncertainties should be acknowledged and quantified when possible. Some best practices for developing and applying sediment-tissue relationships are also proposed.

**322 Selenium biodynamic modeling: Can it be done? Should it?** S.D. Baker, GEI Consultants, Inc. / Ecotoxicologist/Wildlife Biologist; S.P. Canton, GEI Consultants, Inc. / Ecological Division; E. Smith, C. Claytor, GEI Consultants, Inc.. The U.S. EPA is currently revising the national ambient water quality criteria (AWQC) for selenium (Se). It is expected that the new criteria will include a component based on Se concentrations in fish tissues. Implementation of tissue-based standards would require the collection of tissues from wild populations of fish for water quality criteria attainment assessments, which would be an added expense and potentially difficult for both regulatory agencies and the regulated community (i.e., tissue samples would be required in addition to typical surface water samples). Thus, it is expected the U.S. EPA will include in its criteria document a recommended methodology for back-calculating a protective water column concentration from the tissue-based standard, allowing for monitoring of Se in surface waters instead of tissues. Biodynamic modeling has been proposed (e.g., Presser and Luoma 2010) as a potential method for estimating allowable site-specific surface water Se concentrations that will maintain the protection level intended by a given tissue-based standard. While biodynamic

modeling incorporates important site-specific characteristics, which allows for calculation of relevant water-based standards for a given site, the inherent range of values for model parameters can result in widely variable results. In addition, this data variability complicates model calibration and validation (i.e., using site-specific model parameters to predict known site fish tissue concentrations). In this analysis, we used water, sediment, benthic invertebrate, and fish tissue selenium data from two study areas in Colorado to develop site-specific biodynamic models. Validation of these models was attempted using multiple mathematical approaches, including those suggested by Presser and Luoma (2010). Models developed using site-specific data could not be validated, and depending on how data were used, simple bioaccumulation factor (BAF) calculations were identical to biodynamic model results. These results raise a number of questions, including whether it is worth the time and expense for the additional data collection required to run the biodynamic model and whether it is possible to develop any type of truly predictive site-specific bioaccumulation model for Se. Such a model is necessary before any "back-calculated" water-based standards can be adopted.

**323 The Biodynamic Model: a means to improve sediment bioaccumulation protocols and a potential regulatory tool?** H. Selck, Roskilde University / Department of Environmental, Social and Spatial Change, Roskilde University / Dept. Environmental, Social and Spatial Change; S.N. Luoma, University of California Davis / John Muir Institute of the Environment, U.S. Geological Survey, University of California, Davis; M. Croteau, U.S. Geological Survey. To perform environmental risk assessment and to develop robust predictive bioaccumulation models that can be used in a regulatory context, it is vital that we understand and are able to determine the transfer of contaminants from the abiotic (water, sediment, diet) to the biotic compartment. From a regulatory perspective, accumulation from the sediment compartment is important because sediments act as accumulation sites for metals and hydrophobic compounds, and because increasing evidence shows that particle ingestion is the main route of contaminant uptake in deposit-feeders. Benthic communities are therefore likely to play an important role in the remobilization of sediment-associated contaminants to higher trophic levels (i.e., food web transfer). The standardized test guideline, OECD 315, was developed to determine sediment bioaccumulation in sediment-dwelling benthic organisms. Some of the challenges associated with this test includes the relatively long duration (28d uptake, 10d elimination), the use of artificial sediment, a relatively large amount of sediment per test as well as the use of the oligochaete worm, *Lumbriculus variegatus*, as a representative for deposit-feeding organisms. Here we propose and discuss the biodynamic model as a regulatory tool and as a means to develop an alternative standardized test protocol to determine bioaccumulation kinetics from both water and sediment/diet. One of the strengths of the biodynamic model is that it takes into account all uptake routes and allows capturing the biologically driven processes that govern bioaccumulation among species both for metals and organic compounds. In addition, relatively simple short-term experiments allow determination of the required unidirectional fluxes: influx from water and diet as well as efflux (loss and growth). Each biodynamic parameter is measured without interference from simultaneous processes and is used to determine accumulated whole body concentrations (i.e., balance between these opposing fluxes). An important capacity of the model, in a regulatory context, is the potential to include site-specific concentrations, geochemical conditions and species-specific comparable rate constants to predict contaminant bioaccumulation.

**324 Assessment of the Relative Contribution of Ongoing Water Column Versus Sediment Sources of PCBs to Dungeness Crabs From Victoria Harbour, BC** W.R. Hovel, Weston Solutions, Inc., Anchor QEA; E.M. Lamoureux, Anchor QEA, LLC, Anchor QEA; M. Larsen, Anchor QEA; G. Watson, Transport Canada / Environmental Officer; E. Shankie, Public Works Government Services Canada; P. Allard, Azimuth Consulting Group; G. Mann, Azimuth Consulting Group, Inc.. A Dungeness crab hepatopancreas consumption advisory is currently in effect for Victoria Harbour, British Columbia as a consequence of elevated concentrations PCBs, dioxins, and furans. In addition to localized areas of sediment contamination, elevated concentrations of PCBs have been measured in stormwater; however, prior to this study, the relative contribution of these contaminants from ongoing water column sources (i.e., stormwater) versus localized sediment sources to the Victoria Harbour food web was unknown. The current study objective was to evaluate the relative contribution of water column

PCB sources to the crabs through data analysis and bioaccumulation modeling to develop long-term management alternatives for Victoria Harbour. A targeted sampling program was conducted to assess concentrations of PCBs and other site-specific physical and chemical parameters in water, sediment, and representative organisms from Victoria Harbour. Delta  $^{15}\text{N}$  and  $^{13}\text{C}$  stable isotope data collected as part of an earlier study were used to characterize the food web and diet of key organisms. The Arnot and Gobas (2004) AQUAWEB v1.2 bioaccumulation model was used to evaluate the relative contribution of sediment and water PCBs to the Harbour food web. Modeling results provided a reasonable fit to empirical data for the PCB compounds evaluated: the whole Harbour model demonstrated more accuracy in predicting crab PCB concentrations than subarea models and average model bias for crab in the whole Harbour was approximately 1.25, with the 95% LCL and UCL within a factor of 2. The subarea PCB models demonstrated reasonable prediction of perch PCB concentrations. Modeling of paired sediment-clam data indicated that the model was accurately predicting PCB concentrations for clams. Sensitivity analyses demonstrated the importance of sediment and water PCB concentrations, and diet of perch and crab on model outputs. The largest sources of uncertainty to the model included limitations in data used for model inputs and high variability of sediment exposure concentrations. Results suggested that risk management alternatives for the Harbour should include the consideration of ongoing water column sources of PCBs, in addition to localized sediments sources, to PCB tissue concentrations.

**325 Towards ecologically relevant sediment quality criteria** F.A. Gobas, Simon Fraser University / School of Resource and Environmental Management (Faculty of Environment), Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment, Simon Fraser University; J. Arblaster, Simon Fraser University / Resource & Environmental Management; P. Wing Ho Luk, Simon Fraser University / Biological Sciences; J.A. Arnot, ARC Arnot Research & Consulting Inc., University of Toronto Scarborough / Department of Physical and Environmental Sciences. Sediment quality criteria for contaminants are widely used to conduct risk assessments, to develop goals for remediation and to set permit levels for ocean disposal of contaminated sediments. In most cases, the sediment quality guidelines are based on toxicity information for benthic invertebrates and aim to protect benthic invertebrate populations. The sediment quality criteria are in most cases not suitable to protect other organisms such as fish, crabs, marine mammals, birds and human populations who consume various organisms through fishing, crabbing and other forms of hunting. This study reports on the development and application of quantitative modeling and empirical approaches to describe the relationship between contaminant concentrations in sediments, water and biota of complex food-webs for the purpose of risk assessment and the development of ecologically and human health based sediment quality criteria for contaminants that aim to protect wildlife species as well as human populations who consume wildlife. The application of the methodologies for the development of sediment quality guidelines and disposal permits for PCBs and PBDEs in marine habitats of killer whales, Steller sea lions, salmon and human consumers of wildlife is illustrated.

**326 Oil spills from pipelines – why we should be concerned?** P.V. Hodson, Queen's University / School of Environmental Studies; L.L. Williams, U.S. Fish & Wildlife Service. The traditional image of an oil spill involves sinking ships or oil rigs, crashing waves, sticky shorelines, and wildlife destruction in marine ecosystems, as exemplified by the Exxon Valdez and Deepwater Horizon incidents. However, major oil spills at sea account for only a small percentage of the total spilled annually; more than 50% is spilled on land because of a high frequency of small accidents due to transportation, production, refining, and use of oil and oil products. Pipelines may be the safest way to transport large volumes of oil, but the extensive network of pipelines, many of them aging, results in frequent spills that have the potential to cause extensive damage, as exemplified by spills to the Kalamazoo River, MI (2010) and the Pine River, BC (2005). The volumes of spilled oil often exceed 1,000,000 L, but are generally smaller than in marine ecosystems. Nevertheless, the consequences can be far more serious and long-lasting because of the high ratio of river banks to water mass, lower dilution ratios, the propensity of oil and diluted bitumen to sink in fresh water, the extent to which sediments and riparian lands are contaminated, the lack of appropriate clean-up methods, and habitat destruction caused by clean-up. We explore the challenges of exposure, hazard, and risk assessment

for freshwater and terrestrial receptors exposed to pipeline spills and identify critical research needs to improve response capabilities.

**327 Forensic Identification And Quantification of Oil Sands-Based Diluted Bitumen Released Into a Complex River Environment – The Kalamazoo River Spill** G. Douglas, NewFields Environmental Forensics / Environmental Monitoring & Analysis; B. Hollebhone, Environment Canada / Emergencies Science & Technology. Accurate identification and quantification of spilled petroleum in marine and aquatic sediments is a critical component of the Natural Resource Damage Assessment process. The Kalamazoo Oil Spill represents a unique opportunity to investigate the transport and fate of low API gravity Canadian tar sands bitumen/condensate mixture within a river environment that has a substantial background hydrocarbon signature from other petroleum releases, atmospheric deposition, biogenic sources, and land runoff. Once released to the Kalamazoo River, the light condensate was rapidly lost through evaporation and the remaining oil formed small droplets or globules in the water column that settled out in the river bed sediments. Poling, a process of disturbing the sediment bottom to assess the level of sediment contamination produced light, moderate, heavy surface sheens at water temperatures greater than 60°F, a temperature below which the oil forms a semi-solid. The ability to identify and quantify this oil in the river however, was confounded by the high level of background hydrocarbons, and the remediation method of mixing the upper several feet of sediment to release the trapped oil for recovery. In this work, we document a technical approach to 1) identify the chemical signature of the spilled oil in the mixed sediment layer, and 2) quantify the amount of spilled oil in the sediment. Three types of samples were collected to perform this analysis, oil globules in the sediment core, whole sediment and sheen from the surface water. These sediment samples were analyzed by high resolution gas chromatography with mass spectrometry (GC/MS) and flame ionization detection (GC/FID) for polycyclic aromatic hydrocarbon (PAH) /sulfur heterocyclics /biomarkers and alkanes/total petroleum hydrocarbons (TPH) respectively. The chemical signatures were evaluated using a normalized mixing model relative to the source oil, oil globule, sheen and whole sediments where the sediment specific oil signature was extracted from the whole sediment signature, generating a residual hydrocarbon distribution consistent with sediment background. These results will be used to support the NRDA and to accurately delineate the extent of oil transport and degradation in the river sediments.

**328 Fate of the Enbridge Line 6B oil in the Kalamazoo River** M. Boufadel, New Jersey Institute of Technology / Civil and Environmental Engineering; K. Lee, Department of Fisheries and Oceans; R. Zelt, F. Fitzpatrick, I. Cozarella, USGS. The rupturing of the Enbridge Line 6B pipeline at Marshall, Michigan resulted in the spillage of a million gallon of heavy crude. The spill contaminated approximately 40 miles of the Kalamazoo River reaching to Morrow Lake. As of May 2012, efforts were still ongoing to restore the river to its prior recreational usage. The binding of heavy bitumen oil with fines in the Kalamazoo River made this spill highly challenging in terms of the transport and fate of oil. We provide a brief overview of the spill and we focus on the fate of oil buried in the streambed, which is affected by the environmental conditions and local hydraulics. We report measurements of environmental conditions and the hydraulics at select locations in the streambed, both are affected by groundwater flow (hyporheic flow) and stream hydrodynamics.

**329 Immediate Assessment for Impacts to Natural Resources During a Pipeline Oil Spill into the Kalamazoo River** S. Millsap, U.S. Fish & Wildlife Service / US EPA LLRS; L.L. Williams, J. Haas, U.S. Fish & Wildlife Service; S. Hanshew, J. Wesley, Michigan Department of Natural Resources; W. Taft, M. Walterhouse, Michigan Department of Environmental Quality; J. Winter, NOAA / Office of Response and Restoration; R.T. Williamson, Match-E-Be-Nash-She-Wish Tribe of Pottawatomie; D. Beltman, A. Ebbets, K. Ritter, Stratus Consulting; D.E. Tillitt, D.M. Papoulias, U.S. Geological Survey / Columbia Environmental Research Center, USGS / Columbia Environmental Research Center; D. Nicks, USGS; P. Badra, Michigan State University. When a pipeline ruptured near Marshall, Michigan, in July of 2010 and discharged tar sand crude oil into a wetland, through Talmadge Creek, and into the Kalamazoo River, federal, state, and tribal resource agencies began almost immediately to assess impacts to natural resources from the spill. Impacts from this spill extended well into the floodplain because the river was flooded at the time of the spill and included

sediments because a significant amount of this oil sank. Federal and state biologists worked with the owners of the pipeline and their contractors to survey for and collect oiled wildlife, and then rehabilitate and release them whenever possible. Released birds were banded and turtles were PIT tagged to monitor survival and dispersal. State biologists led fish kill investigations and monitored immediate water quality. For benthic invertebrate community assessments and fisheries surveys, they were able to implement standard protocols at locations that allowed data to be compared with previous years and reference locations. Trustees for Natural Resource Damage Assessment (NRDA) worked with the pipeline owners to quickly plan and implement additional ephemeral data collection efforts. Water and sediment sampling was conducted in ecologically important locations and with an extended analyte list relative to the sampling being performed for the spill response. NRDA ephemeral data collection in the first year following the spill also included sampling of fish (including bile) and mussels, surveys for extent of oiling in floodplain habitats, monitoring vegetation for impacts, recovery and invasive species, repeated fish and invertebrate community assessments, and assessments of physical impacts of the response. Response and assessment work are continuing in 2012.

**330 Turtle Stories – Wildlife Response on the Kalamazoo River** B. Doherty, Enbridge Energy; J. Otten, Stantec, Inc.; L.L. Williams, U.S. Fish & Wildlife Service. The release of crude oil into Michigan's Kalamazoo River in July 2010 led to an unprecedented wildlife response involving the collection and care of nearly 6300 animals over a 20 month period. Of the collected animals, 5121 were turtles, representing nearly all of the estimated population within the approximately 40 miles of affected river. Issues faced in saving this many turtles included the need for multiple capture methods, addressing the effects of ongoing cleanup operations, finding effective ways of cleaning oiled turtles, treating varied medical conditions, housing and care for large numbers of turtles, overwintering turtles, finding suitable release locations, and caring for gravid turtles and hatchlings in captivity. Eight species of turtles were captured using hand nets, crab traps, and fyke nets: Spotted (*Clemmys guttata*), Blanding's (*Emys blandingii*), Eastern Box (*Terrapene carolina*), Common Musk (*Sternotherus oderatus*), Common Painted (*Chrysemys picta*), Spiny Softshell (*Apalone spinifer*), Common Snapping (*Chelydra serpentina*), and Northern Map (*Graptemys geographica*). Oiled turtles were cleaned using a variety of techniques and tools such as scrapers, scouring pads, mayonnaise, and dish soap. Medical conditions encountered included skin burns, esophageal corrosion, enlarged livers, shell lesions, and infections. Release locations for the affected animals changed over the course of the response from locations outside the spill zone but within the watershed to locations in the affected stretches of river as the cleanup became more focused. Collection late into the fall of 2010 resulted in the overwintering of 472 turtles in the wildlife center due to a concern about displacing turtles immediately prior to hibernation. A lesser number of turtles were overwintered in 2011. A number of the overwintered females were gravid, resulting in a need for special nesting tanks and incubators. In total, 158 hatchlings were born in the wildlife center and released to the wild. Overall, the survival rate for animals collected during the Kalamazoo River wildlife response was 96.3 percent, and 97.9 percent for turtles (not including the hatchlings).

**331 Bridging Oil Spill Response and Scientifically Supported Information: A Net Environmental Benefit Analysis for the Kalamazoo River Oil Spill** A.C. Bejarano, Research Planning Inc. / Research Planning Inc., Research Planning, Inc. / Department of Environmental Health Sciences Public; J. Michel, Research Planning, Inc.; F. Fitzpatrick, U.S. Geological Service; M. DeGraeve, Great Lakes Environmental Center; L.L. Williams, U.S. Fish & Wildlife Service; M. Alexander, Michigan Department of Environmental Quality; S. Hamilton, Michigan State University; J. Chapman, U.S. Environmental Protection Agency. On July 26, 2010, a pipeline rupture released ~1M gallons of diluted tar sands crude oil into Talmadge Creek and the Kalamazoo River, MI (USA). The spill happened during a flood and impacted over 30 miles of the river including channels, backwaters, wetlands, forested floodplains, and impoundments where an unknown fraction of the oil became submerged. The submerged oil recovery process in 2010-11 included a variety of methods to agitate sediments and recover the resultant sheen. Because of continued issues with submerged oil, a multidisciplinary group was formed to weigh the potential environmental effects of removing the remaining oil or leaving it in place. A Net Environmental Benefit Analysis (NEBA) was used to assess the potential ecological

consequences of oil cleanup options, including consideration of plants, invertebrates, fishes, amphibians, and reptiles in eight major riverine and wetland habitats along the Kalamazoo River. Critical to this assessment was the analysis of sediment chemistry and toxicity testing with *Chironomus dilutus* and *Hyalella azteca*, turbidity data from sediment agitation techniques extensively used for oil recovery in 2011, and a literature review of impacts of sediment agitation. The Equilibrium Sediment Benchmark Toxic Unit approach was used to assess risks from PAH mixtures to benthic organisms. Of the 20 sites chosen for toxicity testing, two heavily oiled and one lightly oiled site posed adverse risks to benthos. However, acute sediment toxicity results did not show significant reductions in survival, growth or biomass relative to a field reference. Based on the weight of evidence, residual oil in the most heavily oiled areas may pose some risks to benthic receptors. Comparison of turbidity data collected during sediment agitation and turbidity levels associated with ecological effects in fish indicated that increased turbidity from agitation may pose moderate (sublethal) effects to juvenile and adult fish species. Post-spill turbidity does not appear to exceed the historical range of turbidity values in the river. Sediment agitation, especially the direct physical impacts, potentially results in mortality of benthic invertebrates, eggs and larvae of bivalves and fish, and destruction of aquatic macrophytes. Overall, the NEBA indicated that, with the exception of certain sites along the river, natural attenuation with monitoring and sheen collection was the alternative expected to have the least ecological impacts.

**332 Oil spill response implications of fate and effect knowledge gaps for diluted bitumen pipeline spills** E. DeCola, Nuka Research and Planning Group. Several new projects have been proposed to transport tar sands oil in the form of diluted bitumen through North American pipeline systems. While pipelines in general are one of the safest means of oil transportation, it is impossible to completely eliminate oil spill risks. The nature of diluted bitumen presents challenges to oil spill responders, due to its physical and chemical properties. These challenges became apparent during the 2010 diluted bitumen pipeline spill in Marshall, Michigan. While that experience yielded some advances in diluted bitumen oil spill cleanup, significant knowledge gaps remain. Hydrocarbons behave in different ways when spilled to land or water, depending on the chemical composition and the environment to which it is spilled. It is critical to garner the best possible understanding of how a potential spill could behave in order to plan and prepare for an effective response. In particular, it is important to anticipate whether the spilled oil will float, submerge, or sink, and over what time periods and in what conditions. Sunken or submerged oils pose different environmental risks and require different oil spill containment and response strategies. In addition to challenges in predicting the fate and behavior of diluted bitumen spills, the actual cleanup of bitumen spills, particularly when the product sinks or submerges, is extremely cumbersome and often ineffective. The state of knowledge for responding to spills of diluted bitumen is still very immature. Containing submerged oil is more challenging than when the oil floats, and requires different equipment and techniques. Recovery of submerged oil on the bottom requires multiple systems for picking up the oil, separating the oil, water, and sediments, and treating the waste streams. Different techniques have been used, with varying success. Nearly all are extremely labor intensive. One commonality among most submerged oil detection, containment, and recovery methods is that they are extremely intrusive. Some techniques may actually cause more harm than good, and ecological risk assessment is a component of submerged oil response operations that should be addressed in the planning phases. This paper will explore the state-of-knowledge and technology for responding to diluted bitumen spills, and will identify significant knowledge gaps that impact oil spill response.

**333 Mitigation of Oil Spills** M. Gordon, M.R. Gordon & Associates Ltd. / Aquatic Resources & Env. Consultant; G. Bakker, M.R. Gordon & Associates Ltd.. The terms "mitigation" or "mitigate" are used often in environmental assessment (EA) or impact assessment reviews. In this context, mitigation is typically assumed to include cleanup of the spill, restoration of habitat and the regeneration of the native species that relied on the affected habitat. After participating in a number of EA reviews and reviewing the after-effects of various oil spills, it is apparent that references to mitigation may not adequately account for the scope of habitat conditions or the timeframe required to restore habitat and regenerate resources. This degree of uncertainty in turn directly impacts those that have relied on the affected resources. Watersheds vary widely depending on several variables: climate,

topography, water chemistry, soil chemistry and local meteorological conditions. This in turn relates to river flow, river substrate, lake depth and other characteristics that influence how an oil spill behaves in the environment. The diversity of habitat conditions that may be encountered when an oil spill occurs creates a high degree of uncertainty and poses significant challenges for cleanup strategies and engineering solutions. The ability to determine what restoration is needed depends on a good understanding of the resource abundance and diversity in the watershed. Using examples from oil spills, this presentation will discuss how effective mitigation strategies have been and what specific elements need to be considered to ensure that mitigation is successful. A basis for detailing the scope and timeframe for successful mitigation will be presented.

**334 Commemorating the 50th Anniversary of Silent Spring** B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / USGS, USGS-Patuxent Wildlife Research Center / Beltsville Laboratory, USGS-Patuxent Wildlife Research Ctr / Beltsville Laboratory; N.H. Golden, U.S. Fish & Wildlife Service / Environmental Contaminants Program, U.S. Fish & Wildlife Service. The publication of *Silent Spring* in 1962 resulted in revolutionary changes in public opinion and government policy. Author Rachel Carson presented and discussed pesticide effects beyond target organisms. New technology for controlling pests had failed to give sufficient consideration to direct and indirect effects of pesticides on non-target invertebrates, fish, and wildlife, human health, and the environment. Carson described ecological imbalances, surface and ground water contamination, inadequate treatment of drinking water, persistence and trophic transfer of chlorinated hydrocarbons, use of natural products for biological control, human safety, and pesticide resistance. *Silent Spring* has been ranked by some as one of the 25 most important science books of the 20<sup>th</sup> century. It helped bring about new environmental laws and the establishment of government agencies to protect the environment. To some, Rachel Carson was one of the most influential Americans of all time, “the mother of the environmental movement”, and shaped the attitude of modern day society toward nature. To others, the charges made in *Silent Spring* lacked scientific rigor and created an unfounded fear of pesticide use that exists to the present day. The life of Carson, the content of *Silent Spring*, and the events and controversy that followed will be reviewed.

**335 Fifty years of POPs: Have we achieved our objectives?** K. Solomon, University of Guelph / School of Environmental Sciences, University of Guelph / Centre for Toxicology, School of Environmental Sciences. Environmentalism had its roots in ancient Greece where scholars, such as Hippocrates, linked diseases of humans to airs, waters, and places. However, this was in the absence of data and mechanistic understanding, science only arrived on the scene with the work of James Snow on cholera in London. Rachel Carson was one of the founders of modern environmentalism and the legacy that *Silent Spring* brought to the general public was an understandable explanation of the behavior of persistent and bioaccumulative substances in the environment. *Silent Spring* begat many progeny; the most globally important of these being the Stockholm Convention on Persistent Organic Pollutants (POPs), but this was not the first step in the science of POPs. Observational and experimental measurement of bioaccumulation in food chains was driven by better techniques of analysis and the use of radiolabelled tracers in the laboratory. The Stockholm Convention was grounded in the understanding of the classical POPs at that time (1995). These were the dirty dozen, the DDT, dioxins, furans, and other halogenated pesticides. These compounds were identified empirically on the basis of observed persistence, bioaccumulation, and toxicity (PBT). More recent programs have expanded the concepts that Rachel Carson highlighted to chemicals in general via TSCA in the US, the DSL in Canada, REACH in the EU and similar legal instruments in other jurisdictions. In this process we have learned that POPs do not have to share all the properties of the dirty dozen to present a risk to the environment. Persistence itself is not necessarily a ticket to a ban; this must be accompanied by partitioning into biota. Experience with the perfluorinated compounds in the environment showed that persistence is still key but that incorporation into the food chain does not require partitioning into lipids associated with compounds of high KOW. Even compounds with high KOW may not be problematic if other properties such as KAW result in partitioning into the atmosphere where rapid degradation occurs. We have learned to proactively instead of reactively but there is a danger that the pendulum will swing the other way

and we will be tempted to extreme precaution that will lead to the unnecessary regulation of too many false positives.

**336 50 Years after Silent Spring: Have Organophosphate and Carbamate Pesticides Met the Challenge?** A. Fairbrother, Exponent / EcoSciences, Exponent, Inc. / EcoSciences. Use of organophosphate and carbamate insecticides increased during the 1970s and 1980s, following the banning of DDT and reduction in use of organochlorine pesticides. Their short environmental half-lives and low chronic toxicity in people, plus the availability of a treatment antidote for accidental acute poisoning, made them a reasonable solution to some of the concerns raised in *Silent Spring*. However, birds are particularly sensitive to cholinesterase inhibitors and continue to experience acute poisonings. A large die-off of Swainson's hawks in Argentina in 1996 following a monocrotophos application for grasshopper control alerted the wildlife community to the potential for large-scale wildlife poisonings, either from direct exposure to spray or from eating contaminated prey. Other products, notably carbofuran, are used illegally to purposefully kill wildlife for predator control, crop protection, or food. There is concern that the cumulative use of multiple pesticides may affect populations of endangered salmon. These pesticides also may cause sublethal effects at low concentrations in both people and wildlife, such as acting as androgen receptor antagonists. Because these products are inexpensive relative to newer pesticides that have fewer nontarget effects, and because they are still effective for controlling a broad-spectrum of common agricultural pests, they remain an important component of large-scale agriculture. Rachel Carson noted “[We are] challenged as mankind has never been challenged before to prove our maturity and our mastery, not of nature, but of ourselves.” If we are to continue to use toxic, broad-spectrum pesticides, we can demonstrate our maturity by acknowledging that they are only one of a larger set of tools for integrated pest management (IPM); by treating them with respect as highly toxic substances and restricting access to only those who need them; and by maintaining an awareness of local wildlife vulnerabilities.

**337 Fate and Effects of the Phenyl pyrazole Insecticide, Fipronil, on Benthic Arthropods; What have we learned since Silent Spring?** D. Schlenk, University of California-Riverside / Department of Environmental Sciences. Fipronil is a phenylpyrazole insecticide that is currently used in a number of field and urban applications. The mode of action of it is based upon its arthropod-selective inhibition of the GABA chloride channel. Although this effect allows the compound to have relatively limited effects in mammals and vertebrates, impacts on target and non-target arthropods can be severe. One of the unique features of the molecule is that its transformation products have a similar or in some cases greater potency and have equivalent if not longer persistence particularly in sediments. Because of this behavior, benthic arthropods, particularly foraging detritivores, may be very susceptible to the acute and chronic effects of fipronil and its degradates. With regard to fipronil, significant progress has been made since *Silent Spring* with studies specifically focused on the chronic impacts of fipronil on arthropod populations and studies have incorporated stereoselectivity in the assessment of its fate and effects. However, understanding the potential for trophic and dietary exposure from sediment and detritus consumption by benthic arthropods is still under appreciated with regard to exposure assessments. *Silent Spring* supports the risk assessment of not only the parent compound but also pesticide degradates and forces us to better characterize the fate of fipronil and its degradates in the environment. And like DDTs and other OCs, it opened up the possibility that fipronil may have endocrine and chronic impacts to non-target organisms outside of simple acute toxicity.

**338 Nothing in Nature Exists Alone: Understanding the Effects of Pesticides on Amphibians in the Presence of Natural and Anthropogenic Factors** M.D. Boone, Miami University / Department of Zoology. When Rachel Carson published *Silent Spring*, she could rightly label many contaminants “elixirs of death,” because direct, lethal toxicity to non-target wildlife was readily apparent. Environmental concentrations of modern pesticides appear safer than early organochlorines, but the effects of modern pesticides are more subtle and can change with environmental conditions. Toxicity testing, however, focuses on lab studies designed for control in simplified environments, which does not account for important environmental variation that alters toxicity. Studies with amphibian communities in the lab and field have highlighted Carson's theme that “nothing in nature exists alone” in

that change in one species can have ramifications throughout the food web. For instance, insecticides can reduce sensitive members of a community like invertebrates, which can have divergent impacts on a community. Exposure to sublethal concentrations of insecticides can affect salamander larvae predation: invertebrate prey sensitive to contaminants may be eliminated or reduced by insecticides, while vertebrates like small tadpoles may persist with exposure, but suffer higher mortality through increased predation by salamanders. Alternatively, invertebrate predators of amphibians can suffer from insecticide exposure resulting in reduced predation, which can benefit amphibians through increased survival, which can consequently lead to greater levels of competition. Timing of exposure during the life cycle can also influence the impact of a pesticide with early life stages appearing to be most sensitive for some species, while others appear to subsequently suffer consequences of exposure later in life cycle. Finally, environmental factors, like temperature, ultraviolet radiation, presence of competitors or predators, presence of other pesticides, and amount of nutrients in the environment, can alter toxicity—in some cases changing the impact of the same concentration of pesticide from positive to negative. Regulation of pesticides on the road forward should involve incorporating important environmental factors into the regulatory process across multiple life stages. The ideal impact of pesticides to non-target wildlife is “no effect,” a goal that remains almost more elusive 50 years after Carson’s publication as we gain a greater understanding of the complexities with which a pesticide can influence individuals in a food web.

**339 Influence of Silent Spring on the U.S. Crop Protection Industry** S.R. Mortensen, BASF Corporation; J.D. Wisk, BASF Corporation / Ecotoxicology, BASF Corporation / Global Risk and Issues Management; M.F. Leggett, CropLife America; L. Guinessi, CropLife Foundation. The 1962 release of Rachel Carson’s book *Silent Spring* launched a public debate on chemical pollution, the use of pesticides, as well as mankind’s relationship with, and responsibility to, the world around us. The decade prior to the release of this book marked the beginnings of the Green Revolution in agriculture; a time when chemical use was responsible for unprecedented gains in pest control. When *Silent Spring* was published, the widespread use of synthetic chemicals for pest control was a relatively new practice. Industry’s initial reaction to *Silent Spring* was defensive, viewing the book as an attack on all pesticide use. But it was not. Rachel Carson advocated the integrated use of pest control methods, in harmony with nature in an era where use of technology to control man’s surroundings was ‘in vogue’. The debate regarding *Silent Spring* led in part to the creation of the U.S. Environmental Protection Agency and development of a regulatory system for pesticide registration and use. While many of the tools that would enable Ms. Carson’s vision to become a reality were already in development, current research and development efforts have shifted towards chemicals with more specific targets, lower persistence and lower environmental impact. Today pest control has embraced principles outlined in *Silent Spring* in the form of adoption of Integrated Pest Management strategies in forests, the public health sector and on farms. A strong network has developed for scouting pest pressure, and determining what needs to be sprayed when and where. Chemicals are rotated to manage resistance and reduce environmental impact. Efficiency advancements have been made in the targeting of applications. Integration of chemical herbicides with biological traits has enabled development of conservation tillage regiments on farms. The combination of agro-ecological knowledge with targeted inputs and seed technology has resulted in large gains in farm yields. These agricultural strategies have enabled North America to be a net food exporter while placing more land under conservation. Environmental gains since *Silent Spring* are due in large measure to formalized environmental policies, improved resource management, and the implementation of emerging technologies in pest control, which are all part of the enduring legacy of Rachel Carson.

**340 What effect do pesticides have on honey bee health?** R.M. Johnson, The Ohio State University – OARDC / Department of Entomology. Insecticides are, by definition, poisons intended to kill insects. The honey bee (*Apis mellifera*) is an insect, so it would seem logical to conclude that insecticides kill honey bees. This assumption is implicit in Rachel Carson’s “Silent Spring”, and this line of reasoning has led many people to assume that insecticides are the primary cause of Colony Collapse Disorder, the mysterious disappearance of honey bees first reported in 2006. However, the real relationship between honey bees and insecticides and other pesticides is far more complicated, and the issues have only become more complex since

“Silent Spring” was written. Modern analytical chemistry methods have demonstrated that a vast array of pesticides are present in bee hives, but the effects chronic low-level exposure to many different pesticides is not clear. Application methods, formulations and label restrictions have reduced bees’ exposure to the most toxic pesticides, but while the active ingredients in these formulations have changed, they are just as toxic to bees as the active ingredients used 50 years ago. The use of systemic pesticides has expanded, which protects bees from inadvertent contact exposure during pesticide application, but may lead to chronic oral exposure through pollen and nectar. Undoubtedly the biggest change is that beekeepers have started to apply pesticides directly inside beehives. With the introduction the *Varroa* mite, a devastating parasite of honey bees, beekeepers have begun using acaricides to stop these mites from killing honey bees. While honey bees clearly benefit from reduced parasitism after acaricide application, exposure to these pesticides may also affect bee health. In summary, insecticides continue to be toxic to bees, just as they were 50 years ago, and indiscriminate insecticide use continues to result in obvious mass killings of bees – though these events are rare. Instead, it is bees’ continual exposure to sublethal doses of many different pesticides, including pesticides applied by beekeepers, that may affect bee health in more subtle ways. Characterizing the effects of bees’ real-world pesticide exposure, that is chronic exposure to sublethal levels of mixtures of pesticides, is the challenging future of toxicological research on honey bees.

**341 Facilitating Management Decisions through Pesticide Sensitive Crops and Habitats Registry Outreach Programs** L. Hahn, Office of Indiana State Chemist / Water Quality/Endangered Species Program Specialist; L. Theller, Purdue University / Ag and Biological Engineering; B. Engel, Purdue University / Agricultural and Biological Engineering; A. Reimer, Purdue University / Natural Resources Social Science Lab, Department of Forestry and Natural Resources. The Driftwatch.org Pesticide Sensitive Crop and Habitats Registry was developed through a collaboration of producers of pesticide sensitive specialty crops, stewards of at-risk habitat (including pollinators) and pesticide applicator communities. The Drift-Watch Registry assists producers in mapping their field(s) and identifying their specialty crop type on the publicly accessible website [www.driftwatch.org](http://www.driftwatch.org). A second registry enables automated pesticide applicator notifications. Pesticide applicators can view sensitive fields and contact information in the area of their scheduled applications. Nearby habitats of endangered species are displayed, as are other themed data such as watersheds with public drinking water intakes. The goal of the developers of the registry is to facilitate effective communication between the specialty crop grower, pesticide applicator and stewards of surrounding at risk habitat. This presentation will highlight (1) current measures of website communication effectiveness of participating states; (2) social science survey outcomes measuring attitudes, motivations and behaviors of commercial pesticide applicators towards natural resource concerns and use of the website; and (3) selected examples of (state) progress in the management of pesticides.

**342 Characterizing soil-to-vegetation transfer factors (TFs) and quantifying uncertainty for uranium TFs in Grand Canyon area terrestrial habitats** G. Linder, USGS/BRD/Columbia Environmental Research Center, HeronWorks Field Office, USGS/BRD/CERC / HeronWorks Field Office; J. Hinck, USGS/BRD/CERC; S. Finger, USGS/BRD/CERC, Geological Survey NRDAR Coordinator / Columbia Environmental Research Center; E.E. Little, USGS/BRD/CERC, Ecology Branch Chief / Columbia Environmental Research Center; D.E. Tillitt, U.S. Geological Survey / Columbia Environmental Research Center, USGS / Columbia Environmental Research Center. Exposures of terrestrial biota to naturally occurring uranium have reappeared as a concern in northern Arizona adjacent to Grand Canyon National Park (GCNP). Whether we consider exposures of terrestrial biota to uranium linked to soils or atmospheric dusts, relationships between these exposure matrices and vegetation are generally characterized by relatively few empirical data. Furthermore, we are uncertain of the relationships between TFs for uranium that are frequently applied in the literature, or to those TFs characteristic of soil-vegetation systems in the vicinity of GCNP. Here we focus on a nested analysis of TFs compiled from existing literature and project-specific uranium concentrations in soils collected from locations near GCNP. Based on this nested analysis, we characterized soil-to-vegetation TFs used for screening level evaluations of risks linked to dietary exposures to uranium in terrestrial biota typically encountered in habitats of GCNP and environs. Soil-to-vegetation TFs are simple ratio estimators that describe the

relationship between the concentrations of a constituent, here, uranium in soil and the concentrations of that same constituent in vegetation growing in that soil. To characterize uranium TFs for areas in the vicinity of GCNP, we completed a literature search and compiled existing data for soil-to-vegetation TFs for uranium, then assembled various data subsets sufficient to characterize TFs based on geographic or vegetative characteristics. Simple distribution plots and distribution-fitting methods were initially used to graphically characterize these data assemblages. Then, we estimated uranium soil-to-vegetation TFs using tools from exploratory data analysis, as well as bootstrap derivations of 95% confidence interval (CI) for 50%-tile estimates of TFs and bootstrap-implemented quantile regression estimates of 50%-tile with 95% prediction intervals (PI). For example, bootstrap estimates of median TF values were 0.042 (CI: 0.026-0.15), whereas quantile regression estimates for TF median values were 0.042 (PI: 0.029-0.10). Thus, if soil U concentration was 50 mg U/kg dry weight we would estimate a concentration of 2.1 mg U/kg dry weight in vegetation. The quantitative uncertainty estimates of TFs, if incorporated into dietary exposure equations, can contribute to sensitivity analyses subsequently completed during characterization of risks associated with uranium exposures in soils or dusts under field settings.

**343 Derivation of soil thresholds to protect chisel-toothed kangaroo rat from uranium mine waste in northern Arizona** J. Hinck, US Geological Survey / Columbia Environmental Research Center; G. Linder, US Geological Survey; J. Otton, US Geological Survey (retired); S. Finger, E. Little, D. Tillitt, US Geological Survey. The ecotoxicological risks of uranium mining in the Grand Canyon region are largely unknown, and chemical concentration data in biota inhabiting the region is lacking. Many species such as the Arizona chisel-toothed kangaroo rat (*Dipodomys microps leucotis*) have specialized life history strategies and physiological adaptations that allow them to survive in the region's arid environment but may also increase their exposure to mine-related contaminants. Chemical data from soils and waste rock samples collected from five uranium mines (3 reclaimed, 1 left on standby and not reclaimed, and 1 never mined) were used in a screening level risk analysis. Dietary toxicity reference values based on lowest observed adverse effect levels from the scientific literature were used to estimate soil thresholds representing risk to kangaroo rats. Concentrations of arsenic, cadmium, copper, lead, nickel, thallium, uranium, and zinc were approximately an order of magnitude greater in soils at the non-reclaimed mine than those from reclaimed mines. Sensitivity analyses indicated that body weight critically affected outcomes of exposed-dose calculations; juvenile kangaroo rats were more sensitive to the inorganic chemical toxicities than adults. Given the natural history of kangaroo rats, consensus-based toxicity thresholds (e.g., EcoSSLs) were overly conservative and overestimated risk. Therefore, we derived soil thresholds to protect kangaroo rats for arsenic (273 mg/kg), cadmium (39 mg/kg), copper (1827 mg/kg), lead (2286 mg/kg), nickel (3854 mg/kg), thallium (6.4 mg/kg), uranium (1513 mg/kg), and zinc (3653 mg/kg) using toxicity reference values that more closely replicate field exposure of kangaroo rats. Inorganic contaminants in soils in and near the mine areas generally posed minimal risk to kangaroo rats. Most exceedences of soil thresholds were for arsenic and thallium and were associated with mine waste rock; few exceedences occurred for cadmium, copper, lead, nickel, uranium, and zinc. Management goals to protect kangaroo rats from arsenic may also protect them from the individual chemical toxicities of other inorganic constituents but would not account for additive, antagonistic, or synergistic effects of chemical mixtures. Studies to establish chemical toxicity thresholds using kangaroo rats and other burrow-dwelling desert mammals are warranted to better characterize risk to species that have evolved and thrived in desert conditions.

**344 Estimating population exposure to ionizing radiation caused by the Fukushima Daiichi nuclear disaster** M. Takagi, National Institute for Environmental Studies; A. Takeuchi, National Institute for Environmental Studies / Central Research Laboratory; A. Tanaka, H. Nitta, National Institute for Environmental Studies; S.F. Nakayama, National Institute for Environmental Studies / Centre for Environmental Health Sciences, National Institute for Environmental Studies / Center for Environmental Health Sciences. The 9.0-magnitude undersea megathrust earthquake occurred on 11 March 2011 in the north-western Pacific Ocean with its epicenter approximately 70 km east off coast of Tohoku, Japan. The earthquake triggered huge tsunami waves that reached heights of up to 40 m and travelled up to 10 km inland. The earthquake and tsunami caused more than 15,000 deaths

and 27,000 injured with over 3,000 people still missing, which also brought substantial economic impacts. The destructive tsunami waves disabled the reactor cooling systems, resulting in nuclear radiation leaks, hydrogen explosions and partial nuclear meltdowns. This largest nuclear disaster since Chernobyl of 1986 released significant amounts of radioactive materials, including iodine-131, caesium-134 and caesium-137, into the atmosphere and ground/ocean waters. Radioactive fallout caused significant public concern, leading voluntary but unnecessary evacuation, reputation risk of locally produce foods and delay in disaster waste disposal. The Japanese government and other governmental and academic institutions carried out measurements of radioactivity nationwide, of which data are available through many web sites. However, to date systematic exposure assessment has not yet been performed to our knowledge. In order to perform comprehensive risk assessment, it is important to estimate general population's exposure to ionizing radiation caused by the nuclear disaster. In this study, built was a model combining external and internal radiation exposure. For external exposure, the model included airborne radiation measurement data, radiation shielding rate and time spent outside by each age category. The internal exposure model consisted of inhalation doses, market-basket data, food consumption rate, dust and soil data and behavioural patterns of each age category. Using SAS "rand" function, performed was Monte Carlo simulations with 500,000 iterations. The model revealed no one had external exposure to more than 1 mSv during the first year since the disaster except Fukushima Prefecture (median < 0.1 mSv). Further details of the model and its result will be shown in the presentation.

**345 Gamma radiation-induced damages in the monogonont rotifer, *Brachionus koreanus*** J. Lee, Hanyang University / Dept of Chemistry, Hanyang University Graduate School / Dept of Chemistry; J. Han, Hanyang University. To investigate the impacts of gamma radiation on aquatic organism, we tested the monogonont rotifer, *Brachionus koreanus* as a model species. Several parameters including 24-h toxicity test, population growth rate, and intracellular reactive oxygen species (ROS) level were measured after exposure to a wide range of gamma radiation dose. To check the transcriptional change of important inducible genes such as glutathione S-transferase (GST) genes, heat shock protein (Hsp) genes, DNA repair-related (e.g. replication protein A; RPA, DNA dependent protein kinase; DNA-pk, Ku70/80) and DNA damage response genes (e.g. p53, Bcl-2) after gamma radiation, we measured dose- and time-dependency at 0, 50, 150, 200 Gy by using the quantitative real-time RT-PCR. Results showed that gamma radiation induced gradual growth retardation of *B. koreanus* at 150, 200 Gy. But 24-h toxicity test of *B. koreanus* was not observed at all doses. The level of ROS was high at 50, 100, 150, 200 Gy, suggesting that all the doses would be already toxic. The expression of GSTs, Hsps, DNA repair-related and DNA damage response genes mRNA was up-regulated in a dose- and time-dependent manner. Of all genes, RPA1 and p53 transcripts levels were observed up to about 50 and 40 folds relative to the control 1h after gamma radiation (200Gy), respectively. This result indicates that gamma radiation can induce growth retardation with up- or down-regulation of important genes in DNA replication, chaperoning and repair process. Our studies are helpful in expanding knowledge of the molecular mechanisms on impacts of gamma radiation in aquatic organisms.

**346 Long-term fate simulation of radioactive cesium by multimedia fate model in Fukushima region in Japan** N. Suzuki, Y. Imaizumi, National Institute for Environmental Studies; Y. Morino, National Institute for Environmental Studies; T. Ohara, National Institute for Environmental Studies. Long-term multimedia fate of radioactive cesium species in Fukushima and surrounding region in Japan is simulated by multimedia fate model methodology. Radioactive nuclides emitted into atmosphere by the accident of Fukushima nuclear power plant were transported in the atmosphere from the plant to the Fukushima and surrounding region within a few hours after the emission. Part of transported radionuclides, especially those with lower volatility are considered to be deposited onto surface through wet and dry deposition processes. In this study, long-term fate of radioactive cesium species in the region after the short-term atmospheric transport is simulated by the combination of atmospheric transport model CMAQ and multimedia fate model G-CIEMS, on the former which is already reported by co-authors in elsewhere. Here the latter of the process after deposition of radioactive cesium species onto surface is reported. Accumulation of cesium species in soil, transport of them to the river through erosion and runoff processes, transport by river flow networks and fate between their sediments,

similar processes in lakes and sediments, and final output to sea are connected by the G-CIEMS. Based on the original feature of the G-CIEMS, GIS-based real river network segmented by approximately 5 km paths and their topological connections are used to simulate the transport along river flow. Runoff from river catchment to river segment is calculated based on the runoff processes in combination of soil erosion and water runoff. Using this simulation framework, long-term fate of levels of cesium species during 20 years after approximately 1 month emission period is simulated in soil, river water and sediments, and fluxes among those media. As a result, it is revealed that total amount of cesium species existing in soil compartment could be declined slightly faster than expected radioactive decay, because of the impact of runoff processes. Levels in soil and river sediments are simulated roughly comparable ranges compared to the observed levels. Amount existing in river networks is small compared to the soil compartment; however, the declining trend of the media might be slower than soil compartments, maybe because of the combined mass-balance impact of runoff, sedimentation, partitioning and outflows from the river system. Partitioning parameter of cesium species between soil and water may have major impact on the runoff processes of cesium in the regional fate system.

**347 Providing access to environmental radioactivity measurements during crisis and in peacetime : two tools developed in France by IRSN** E. LEPIEUR, Institute for Radioprotection and Nuclear Safety / Radiation Protection Division; g. Manificat, IRSN-Institute for radioprotection and nuclear safety / Environmental radioactivity study and monitoring department. All over the French territory, thousands of radiological environmental measurements are carried out each month, whether by IRSN, operators of nuclear facilities or other public, private or non-governmental organizations. In the event of a radiological accident, many additional measurements would also be performed. This multiplicity of actors makes data collection difficult and consequently these monitoring data are not easily accessible to experts and policy makers, but also to the general public. To solve this problem, two projects were launched by IRSN with the aim of developing tools to centralize information on environmental radioactivity in normal situation (RNM project for "Réseau National de Mesures" – National network of radioactive measurements) and during a radiological crisis (CRITER project for "CRIse et TERrain" - Crisis and field). The RNM network is created to contribute to the estimation of doses from ionizing radiation and to inform the public. To achieve this goal, the network collects the results from the different French stakeholders of environmental radioactivity measurements obtained in normal situation. In addition the RNM network is accessible for the public through the Internet. In the event of an radiological emergency, IRSN's mission is to centralize and manage – at national level – all the results of measurements or analysis performed by all the stakeholders, in order to accurately and permanently determine the radiological state of the environment, before, during and after the accident. The CRITER project involves data collection from all potential sources, their transmission, their organization, and the publication of the measurements during the crisis or post-accident situation. For all events with possible radiological health and environmental consequences requiring the activation of an emergency response organization, a specific CRITER database is created. For example, a CRITER IT system was implemented after the Fukushima accident in March 2011. Both projects have developed complementary tools with compatible data repositories, allowing not only to form a national reference database with measurements taken in normal situation from all environmental compartments and around each nuclear facility, but also a crisis database able to quickly centralize the new measurements available from all those on the affected area and give access to these data for all decision-making bodies.

**348 Summary of field ecological studies conducted to assess exposure to radionuclides at the Los Alamos National Laboratory** R.T. Rytz, Neptune and Company, Inc.. Field studies have been used as one line of evidence to assess the potential for ecological risk from radionuclides and other contaminants. This paper summarizes field studies conducted at the Los Alamos National Laboratory (LANL) in New Mexico, USA. Although both terrestrial and aquatic studies have been conducted at LANL, this paper summarizes information on the terrestrial environment. Key radionuclides measured in LANL plants and animals are cesium-137, strontium-90, plutonium-238, and plutonium-239/240. Uranium has been measured as a metal and as isotopic uranium (uranium-234, uranium-235, and uranium-238). Wildlife studies have focused on the small mammal community although some broad-ranging mammals (like elk and deer) or birds have been sampled.

Some of the studies have evaluated tissues separately from pelts to better understand exposure pathways and contaminant transport. It is important to understand the spatial scale of the contamination, the residence time of the wildlife and their home range to interpret the results of such studies. Lastly, recommendations for improvements to plant and wildlife radionuclide monitoring are presented.

**349 Tissue radionuclide concentrations in water birds and upland birds on the Hanford Site (USA)** D.A. Delistraty, Washington State Department of Ecology / Hazardous Waste and Toxics Reduction Program; S. Van Verst, Washington State Dept. of Health. Historical operations at the Hanford Site (Washington State, USA) have released a wide array of non-radionuclide and radionuclide contaminants into the environment. As a result, there is a need to characterize contaminant effects on site biota. Within this framework, we evaluated radionuclide concentrations in bird tissue, obtained from the Hanford Environmental Information System (HEIS). The database was initially sorted by avian group (water bird [WB] vs. upland bird [UB]), radionuclide (over 20 analytes), tissue (muscle, bone, liver), location (onsite vs. offsite), and time period (1971-1990 vs. 1991-2009). For this presentation, the purpose of our study was to compare concentrations of Co-60, Cs-137, and Sr-90 in WB vs. UB on the Hanford Site, as well as to compare Sr-90 concentrations in muscle vs. bone in birds at Hanford. Onsite median concentrations in WB were significantly higher (Bonferroni  $P < 0.05$ ) than those in onsite UB for Cs-137 in muscle (1971-1990) and Sr-90 in bone (1991-2009). These observations may be linked to behavioral, habitat, or trophic differences between avian groups. As expected, median concentrations of Sr-90 in bone were significantly higher (Bonferroni  $P < 0.05$ ) than those in muscle for both WB and UB. This presumably relates to Sr-90 serving as a calcium analog, preferentially depositing in bone. Overall, our results contribute toward ongoing efforts to characterize ecological risk at the Hanford Site.

**350 NOAA Talks Turtle** M. McDaniel, McDaniel Lambert Inc.. BP's oil flowed unchecked for over 105 days after the tragic Deepwater Horizon explosion that killed 11 workers on April 20, 2010. The oil soiled the waters, shores, livelihood and sense of well-being of those who lived and worked in five states on the Gulf coast. The 24-hour Internet news cycle, awash with twitter feeds, independent bloggers and professional journalists flooded the waves with verified and unverified news, pictures and videos. BP's every move was broadcast at high speed and in full color, revealing their lack of crisis management as they stumbled through high-scale efforts to stop the leak. It was within this climate that a little known branch of the National Oceanic and Atmospheric Administration (NOAA) scientists began to explain their incredibly technical process. This group manages the National Resource Damage Assessment (NRDA) program that assesses ecological damage and loss of human use of natural resources. Although ultimately geared to "make the stakeholders whole," NRDA's very structure—a multi-year, multi-trustee, polluter cooperative and lawyer-heavy process—worked against communication. Realizing they were hopelessly technical, the smart NOAA scientists were quick to identify their crisis communication weakness would be more of an Achilles heel in this process than NRDA itself. They undertook a series of risk communication trainings to better prepare team members for community outreach. Ultimately NOAA scientists learned their success relied on not hiding behind the data. They developed techniques to explain technical information clearly and accurately to communities of non-technical, outraged, and disadvantaged stakeholders. They gained insights into dealing with outrage and how risk perception magnifies or diminishes risk. They consistently got information out promptly. The scientists also learned how to let their passion for the natural resources of the Gulf become the bridge that connected them to local communities. NOAA couldn't change the arduous legal process or scientific rigor of NRDA, but they worked hard to earn trust and credibility with a skeptical public. And it worked.

**351 An Education Initiative Program as a Risk Communication Tool at TVA Kingston** S. Young, ARCADIS, ARCADIS / Environmental; D. Jones, R. McKinney, ARCADIS; N.E. Carriker, TVA Kingston Ash Recovery Project / Kingston Fly Ash Recovery Project. The December 2008 Kingston ash release discharged approximately 5.4 million cubic yards of coal slurry into the surrounding environment. This event raised concerns of resident health and safety within the community and spawned predictions of dire effects on the aquatic ecology as a result of bioaccumulation

of ash-related constituents. As TVA worked with federal and state agencies to clean up and restore the area surrounding the Kingston Fossil Plant, the agency interacted with local, state, and Federal (USEPA) officials to create a forum for residents to voice their concerns and provide input into the cleanup process. TVA also recognized the opportunity to contribute to the academic and personal growth of local students. As a result, TVA developed an Educational Initiative to inform students about the scientific investigations that were taking place at the release site. The Educational Initiative included three separate information sessions presented to more than 1,000 students at high schools in Roane County, TN. These were designed to teach students about the causes of the spill; describe the immediate response and on-going efforts to repair the damage; and introduce the engineering and scientific disciplines being applied to the cleanup and environmental monitoring that will continue for years to come. Students participated in hands-on lessons about chemical elements that affect their daily lives, the air they breathe and the water they drink. They also learned about various animals, fish and bugs that comprise the food web, as well as the materials and methods scientists use when studying living creatures. This presentation highlights some of the lesson material used in the sessions, including video clips recreating the initial failure, live footage of different sampling methods used for abiotic and biotic media, and quizzes given to students to test their knowledge. This highly successful program helped this generation of students better understand the event and how it relates to their daily lives. Further, the Education Initiative helped foster the relationship and trust between TVA and the affected community, which is the cornerstone of risk communication.

**352 Fishing for S.T.E.M. Literacy Initiative: A National Science Foundation Proposed Project for Increasing Informal Science Education** R.S. Grippio, Arkansas State University / Department of Biological Sciences, Graduate Program in Environmental Science; A.A. Gill, Arkansas State University / ASU Center for Digital Initiatives; R. Johnson, Arkansas State University / Biological Sciences; J.T. Kennon, Arkansas State University / Dept of Chemistry & Physics; T. Risch, Arkansas State University / Department of Biological Sciences. The National Science Foundation (NSF) Directorate for Education and Human Resources is tasked to build a globally competitive, diverse science, technology, engineering and mathematics (STEM) workforce that will engage the public as science learners, allowing citizens to address societal changes including environmental challenges. The NSF Informal Science Education (ISE) program is part of this Directorate and supports innovation in anywhere, anytime, lifelong learning outside formal school settings through investments in research, development, infrastructure and capacity-building. Promotion of a STEM workforce is especially important to SETAC because these are the disciplines from which most members are drawn. Thus, developing informal science learning in STEM areas will increase the awareness and support of SETAC mission and activities. Fishing is a popular recreational activity in Arkansas. However, many participants do not have the background knowledge required to understand the complex STEM concepts underlying a healthy aquatic system and sustainability of the natural resources they are using. To address this, we propose the Fishing for STEM Literacy ISE initiative utilizing an angling platform. After a year of planning, the implementation of five pilot studies will be undertaken to collect data and allow program evaluation. This will include pre- and post-survey data derived from paper and virtual environments. These will evaluate the understanding of STEM concepts underlying the sustainability of healthy aquatic resources and fisheries, attitudes toward science and the environment, parental perceptions of their children's STEM abilities, and levels of involvement in fishing and water quality activities. This program builds on existing knowledge and interest in a rural youth population to increase understanding of STEM concepts including food chains, water quality and chemistry, aquatic life, population biology, taxonomy and conservation of resources. A target audience of 10-15 year olds and their parents will foster career aspirations in children at an age at which commonly there is a departure from STEM career interests.

**353 Working Towards Agreements: Three Rules for Effective Risk Communication** A. Chun, The Chun Group. The goals of risk communication range from successfully relaying complicated technical information to gaining the public's approval of decisions based on complicated technical information. The latter is the subject of this presentation and is a complex negotiation or risk management process. Public approval depends on the ability of a risk communication program to inform, engage, and respond.

Successful risk communicators require a negotiator's attitudes and skills for identifying and understanding the interests of different stakeholders and for building trusting relationships. One must also appreciate how different perspectives can influence risk perception and people's willingness to negotiate. Three key rules are: Expect the unexpected and know how to respond effectively. Discuss difficult problems privately first. Always be nice and respectful. For resolving ecological or human health problems, the differences are in the stakeholders and their interests, but all three rules apply. An example from a risk communication effort involving the USEPA's Superfund Program will be used to demonstrate this.

**354 Use and misuse of Risk-Based Screening Levels** A. Guiseppe-Elie, DuPont Company / Corporate Remediation Group; E. Quinn, US Environmental Protection Agency / Region III; T. Bingman, DuPont Company / Corporate Remediation Group; R.G. Stahl, DuPont Company / Corporate Remediation Department, DuPont Company / Corporate Remediation Group, DuPont Company / DuPont Corporate Remediation Group. Risk-based Screening Levels (RSLs) have been developed for various media (e.g., surface water and biological tissues). These values are important in a tiered approach to human and ecological risk assessments as they serve a triage purpose in determining which potential exposure situations need further evaluation versus those that are of lesser concern. RSLs tend to be calculated in a conservative manner in a way that affords protection to sensitive human and ecological receptors for the particular exposure scenario. However, RSLs can be misused. In this case, we highlight why a fish-tissue mercury screening level should not be applied to waterfowl, and offer an alternative approach that would be more appropriate for determining potential exposure/risk concerns for hunters. Waterfowl might be a potential mercury source to hunters because of their proximity to the water bodies where mercury contamination exists. While it might be tempting to apply fish-tissue screening levels to waterfowl, the derivation of these are based on significantly different exposure assumptions than appropriate for waterfowl hunters. For example, EPA's water quality criterion is set to be protective of the general population, includes other dietary and non-dietary sources of mercury, and assumes a daily food ingestion rate that is inconsistent with hunting patterns. While, it is appropriate to consider the potential for exposures to hunters who may consume waterfowl, this evaluation is best done on a site-specific basis rather using a fish advisory level.

**355 Post Mortem of an Effective Risk Communication Effort – The Sierra-Crete® Case** T. Bingman, A. Guiseppe-Elie, DuPont Company / Corporate Remediation Group; R.G. Stahl, DuPont Company / Corporate Remediation Department, DuPont Company / Corporate Remediation Group, DuPont Company / DuPont Corporate Remediation Group. Effective risk communication can occur only once an open and honest dialogue between stakeholders develops. Risk communication pioneers, such as Sandman and Covello have described the concepts of outrage factors and source-message-channel-receiver models, respectively, as important elements in this discipline. By anticipating potential outrage factors within the receiving community and developing an approach to openly engage community stakeholders, it is possible to develop a risk communication strategy that effectively meets the needs of all parties. For this presentation, we provide a post mortem of such an example using Sierra-Crete®. This road sub base material, which had been used in several residential communities, was shown to contain trace levels of dioxins and furans. Following a risk assessment that demonstrated a lack of health risks in the community, the challenge of informing the community of the situation began. In this case study, we will examine how outrage factors such as dread, trust, control and children's issues can all be effectively addressed to contribute to the success of the risk communication effort.

**356 Environmental Awareness and Public Communications at U.S. Army Aberdeen Proving Ground: 35 Years of Lessons Learned** M. Ciarlo, EA Engineering, Science, and Technology, Inc., EA Engineering, Science, and Technology; K. Stachiw, Kenneth Stachiw; J. Weintraub, U.S. Army Aberdeen Proving Ground Department of Public Works. The U.S. Army Aberdeen Proving Ground has been a center for testing, training, and research since 1917. It has been home to landmark programs in the nation's defense, many of which were conducted prior to the current era of environmental awareness. APG is located alongside the Chesapeake Bay and contains thousands of acres of wetlands, forests, and natural resources. The environmental management history at APG is overall a success story,

with decades of work with hazardous materials and waste offset by decades of intense environmental scrutiny and protection. This history includes landmark environmental projects and policy with unique and precedent-setting challenges and solutions. The past 100 years – and especially the last 35 – at APG provide lessons learned that are of great potential and may help inform future environmental management. This presentation focuses on the relationship that has developed over the past 35 years between APG and its stakeholders for hazardous waste and environmental clean-up. These years represent a period of intense change during which significant effort was put forth to develop collaboration and cooperation in addressing hazardous waste issues. This presentation briefly outlines this aspect of APG's history and identifies a number of important lessons learned.

**357 Methods and Tools of Effective Communication during Emergency Response Actions** P. Kurzanski, CSX Transportation; J.R. Clarkson, Arcadis U.S., Inc. / Senior Vice President, ENVIRON, ENVIRON. September 28, 2012 marks the 30-year anniversary of the Livingston Train Derailment. This has been called the 'worst chemical transportation accident in the state of Louisiana history' and also 'the best managed chemical transportation accident.' For two weeks, the energies and expertise of eleven state agencies, six federal agencies, and five non-governmental entities, as well as the civic resources of the town of Livingston and neighboring communities, were focused on the mitigation of this chemical transportation accident. Protection of the health and welfare of human and ecological life and the effective management of the emergency were outcomes of federal and state legislative action and comprehensive hazardous materials spills emergency planning within the state of Louisiana. The effective management of this environmental crisis was documented in a film produced by the United States Environmental Protection Agency, which was used for many years to train first responders at the Environmental Response Team center in Edison, New Jersey. Many of the lessons learned during this incident have also been incorporated into the federal emergency management system for mitigating chemical emergencies in the United States. Communication and education about human health and ecological risk were critical to the effective management of this emergency response. Through the use of this example and several others, the presentation will highlight methods and tools of communication that were effective 30 years ago and have stood the test of time and are still effective today. This presentation will also highlight several methods and tools that are no longer successful given the explosion of internet access, social networking sites, and 24/7 news cycles of recent years. Possible alternative methods to meet these communication challenges will also be presented.

**358 Incorporating bioavailability into risk assessment for metal mixtures: Results of a comparative evaluation** E.J. Van Genderen, International Zinc Association / Assistant Manager, Environment, International Zinc Association / Manager, Environment & Sustainability; E.C. Rogevich-Garman, NiPERA / Ecotoxicologist; R.L. Dwyer, International Copper Association; J. Gorsuch, Copper Development Association. While the concepts encompassing mixture toxicity and modeling have been around for decades, only recently have new approaches ("bioavailability models") been expanded to consider metal mixture scenarios. Although current environmental regulations rarely require assessment of chemicals mixtures, the metals industries consider research on mixtures in the environment and development of efficient and economic science-based risk assessment approaches for metals mixtures essential to preparing for future regulatory demands and vital for ensuring adequate environmental protection. To this end, a comparative modeling evaluation was commissioned by the copper, nickel and zinc industries in an attempt to compare and contrast the available approaches for modeling metal mixtures in fresh water using the principles of bioavailability. Four international research groups, who are actively developing, testing and publishing a range of bioavailability-based approaches, were each provided the same mixture dataset (nearly 2500 metal mixture and associated single-metal exposures) to which they applied their respective modeling approaches. The dataset included toxicity exposures for seven metals in various binary, ternary and quaternary combinations using both spiked (laboratory and field waters) and ambient (field waters) experimental designs. Results of the comparative evaluation demonstrated that despite representing the spectrum of modeling complexity, the various modeling approaches each provided consistent conclusions concerning interaction types and importance of accounting for bioavailability in metal mixture risk assessments. Similarly, all of the modeling approaches

were challenged by metal combinations where significant deviation from concentration addition hypotheses occurred. Overall, approaches have been successfully developed to incorporate bioavailability into metal mixtures risk assessment. In addition, this evaluation illustrated the importance of incorporating variability into effects predictions and the need to emphasize the science behind modeling biological complexity when communicating risk.

**359 From substance- to societal solutions in risk assessment and sustainable risk reduction** L. Posthuma, RIVM / Lab. for Ecological Risk Assessment, RIVM / LER; D. De Zwart, RIVM / Lab. for Ecological Risk Assessment; D. Sijm, J. Verhoeven, RIVM / Substances Expertise Centre; S. Dyer, Procter & Gamble; K. Kapo, Montani Run, LLC; A. Burton, University of Michigan / School of Natural Resources & Environment and Cooperative Institute for Limnology & Ecosystem Research. Environmental quality criteria are critical in ecological risk assessment and risk remediation of chemicals. But: criteria exceedance signals regulatory problems and a potential for impacts, but not problem-solving solutions. Situations are multi-faceted: acute or chronic exposures, habitat alterations and presence/absence of refugia may occur, to mention a few. To illustrate that a multi-pronged solution-oriented approach works, we provide 3 case studies. First, in chemical regulation (e.g., REACH), PNEC-exceedance for a compound triggers a restriction evaluation of that compound, with optional replacement by an alternative chemical. Restriction follows when the use of the alternative results in lower impact. The final solution involves an evaluation of the trade-offs of chemical performance, information needs and risk per use category. Second, chronic impacts of multiple stress, including mixtures of toxicants, are to be expected within river catchments. Emissions of agriculture, industry and waste waters cumulate, while other stressors also vary. Impact diagnostics help to optimize impact reduction measures, brought together in river basin management plans. By developing innovative, landscape-level diagnostic techniques, the impacts of mixtures can be disentangled from influences of habitat deterioration, which improves the efficacy of river basin management. An Ecosystem Reality Check needs to be made before focus is put to a single stressor. The final solution involves pragmatic yet synthetic river basin management. Third, natural disasters occur, partly associated to massive unintended release of chemicals. Our common 'safe concentrations' need be replaced by 'impact distances', since the latter are key to prioritize impact reduction efforts in disaster events. Impact distances are needed quickly for direct exposures of man as well as for the environment, the latter related to ethical issues as well as to key ecosystem services to man, such as the provision of food. An approach to provide these distances has provided a pragmatic and implementable solution that optimizes impact reduction for humans and ecosystems. Solution-oriented risk assessment triggered innovative steps in risk assessment, partly re-using existing methods. Relevance of this way of working will be illustrated via the cases. Surprisingly, an unintended extra use has evolved: the safe distance model has improved disaster preparedness around the globe.

**360 Environmental Risk Assessments: The Value in Using Decision Analytic Methodologies** C. Stahl, U.S. EPA Region III, U.S. Environmental Protection Agency, Region III / Environmental Assessment and Innovation Division, U.S. EPA Region III / Environmental Assessment and Innovation Division, U.S. EPA Region III / Air Protection Division; J. Babendreier, U.S. Environmental Protection Agency / Office of Research and Development; A. Cimorelli, U.S. Environmental Protection Agency, Region III; J. Kremer, U.S. Environmental Protection Agency, Region III / Environmental Assessment and Innovation Division. Many current approaches often implicitly integrate many different pieces of information to arrive at an assessment conclusion or actionable decision without taking advantage of more transparent and robust decision analytic methodologies. Therefore, even when explicit decision making is not a goal, the integration of multiple criteria to create a biological index or arrive at an assessment conclusion can benefit from the use of good decision analytic techniques. This presentation will describe the feasibility of robust analyses using currently existing technologies and concepts using specific applications as examples – and the benefits of applying decision analytic techniques to environmental assessments that require integration of multiple endpoints and the potential dangers of using un-integrated or implicitly-integrated analyses in arriving at assessment conclusions. Current commonly-used approaches tend to focus on single disciplines or media, even when the larger environmental system is acknowledged, and present these narrowly-focused assessments as complete assessments of the environmental problem. This presentation will include

examples where the environmental assessment can support alternative conclusions even when the same data, but differently organized and differently valued, are used. Data, model and decision uncertainty impact the environmental assessment conclusions and these can be explored through the use of decision analytic methodologies; providing assessment analysts and decision makers a more robust analysis. Disclaimer: Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

**361 The need for more ecological realism in Ecological Risk Assessment procedures** M. Vighi, University of Milano Bicocca / Department of Environmental Sciences, University of Milano / Department of Environmental Sciences. In the last few decades, ecological risk assessment was based on simplified tools in order to provide methods suitable to be applied in support of chemical regulations. This pragmatic approach produced transparent and easy methods, applicable using the reduced information available, and allowed the development of many international regulatory tools. Chemical control in the last few decades substantially changed environmental and pollution problems in developed countries. In spite of their practical usefulness, these tools, mainly based on laboratory toxicological tests, suffer for a lack of ecological realism. Their capability to describe and predict the actual consequences on structure and functions of natural ecosystems is poor. Therefore, there is the need for the development of new tools capable to accounting for the complexity of communities and ecosystems. In the frame of scientific committees of the European Commission (SCHER, SCENHIR, SCCS) a Working Group is ongoing on "Addressing the New Challenges for Risk Assessment". The environmental subgroup highlighted a number of relevant issues worth to be developed: Increasing the ecological realism of exposure assessment. Assessing the effects of highly time-variable exposure. Covering the gap between effects at cellular or individual level and consequences for ecologically relevant end points. Assessing the vulnerability of natural biological communities and ecosystems. Assessing the role of indirect ecological effects of stressors. Assessing the interactions between combined stressors and environmental factors. Developing Trait-based risk assessment. Improving Ecological Modelling. Improving the scientific bases for the development of extrapolation approaches. A short overview is given on the main issues and on their realistic applicability (in the short, medium and long time) in risk assessment procedures for regulatory purposes.

**362 The future of risk assessment at regional scales with multiple sources, stressors and endpoints in the 21st century** W.G. Landis, Western Washington University, Institute of Environmental Toxicology. Risk assessment in the last century primarily consisted of a single stressor, usually a chemical, acting on a few endpoints at relatively small scales. Often the scale was limited to a contaminated site, although some of these were relatively large. The methods used were often simple risk quotients although some investigators did pioneer the use of spatially explicit techniques. In the early part of the 21<sup>st</sup> century investigators in the United States, Australia and in Europe started to conduct risk assessments that clearly involved multiple stressors at the watershed (catchment scale). As of the spring of 2012 these types of assessments can be found examining landscapes in Australia, China, South Africa, United States, and Chile. Some of these assessments use the relative risk model; some Bayesian networks of their own design and others are adapting the relative risk model to a Bayesian network format. In other words there has become an international effort to examine the risks due to multiple stressors on multiple endpoints at very large scales. The stressors being examined are also inclusive. Chemicals of various classes can be included, but non-indigenous species, habitat alteration, and changes in climate are incorporated into the quantitative risk assessment. In many parts of the world regional risk assessment is regarded as a planning tool for the long-term management of important resources. It is also possible to use risk assessment to calculate management scenarios that result in low-risk outcomes to the various endpoints. Recently, application of regional risk assessment has been extended by efforts of the US Forest Service to forest management and to non-indigenous species. My mid 21<sup>st</sup> century the type of risk assessment outlined here will be integrated into a broad environmental assessment, restoration and management scheme incorporating all potential sources, stressors, environments and ecological services. The limitations appear to regulatory and cultural, not that the underpinnings are already there.

**363 Regional Risk Assessment of the Puyallup River Watershed and Low Impact Development (LID) to Meet Management Goals** E.E. Hines, Western Washington University / Institute of Environmental Toxicology, Huxley College of the Environment; S. Edwards, Western Washington University / Institute of Environmental Toxicology; W.G. Landis, Western Washington University, Institute of Environmental Toxicology. Relative risk assessment is a tool to calculate the likelihood of effects to endpoints when multiple stressors occur in complex ecological systems. Here we use Bayesian network (BN) models derived from the relative risk assessment framework. We created a model that can evaluate the risk Low Impact Development is able to reduce in the Puyallup River Watershed for ecological endpoints. The BN structure comprises of three tiers of nodes: landscape stressors, habitats, and ecological endpoints of interest to local managers. Each tier links nodes to lower-tiered nodes when spatial and ecological relationships exist. Four potential discrete states exist for all parameters: zero, low, medium, and high with numeric scores of 0, 2, 4, and 6 respectively. As a first step in model creation, conceptual models show causal pathways between stressors and endpoints. A conceptual model for the endpoint of prespawn mortality in coho salmon (*Oncorhynchus kisutch*) has been created. In the next step, a BN structure has been created for this endpoint, demonstrating causal pathways between the endpoint and the stressors pesticides, polycyclic aromatic hydrocarbons (PAHs), copper, and ecological modifications. The adaptability of using BNs for a relative risk assessment provides opportunity for the model created to be adapted for other watersheds in the Puget Sound region with the same restoration goals. If our model finds Low Impact Development is able to reduce risk, the goal of this model will be to create a relative risk model that may be used in future watershed restoration to determine what types and where Low Impact Development should be implemented.

**365 Accurate bio-activity and toxicity prediction technology based on three-dimensional docking to pocket ensembles and ligand fields** R. Abagyan, University of California, San Diego / Skaggs School of Pharmacy and Pharmaceutical Sciences, University of California San Diego; F. McRobb, Y. Chen, I. Kufareva, University of California, San Diego; M. Totrov, Molsoft LLC. Recognizing a possible endocrine disruptor or a toxic compound among tens of thousands of man-made compounds already present in the environment is vital. Alerting about potential dangers long before a new chemical is developed or released, ideally even before it is synthesized, is an even more important task. Until recently most of the computational models for predicting endocrine disruption were based on quantitative structure-activity relationship models in which a model is 'trained' on a set of chemicals with a certain activity. However, rapid progress in molecular biology, physiology and toxicology allows us to relate many of the effects to direct interactions of compounds with the ligand binding sites of certain receptors, such as nuclear receptors, G-protein coupled receptors, kinases etc. Here we present two three dimensional docking-based technologies, along with the benchmarking, validation and application, which achieve high accuracy of activity prediction without (or with substantially reduced) dependence on "training" on large collections of active chemicals. These unbiased docking based models of several nuclear receptors, including the estrogen receptor, can be now expanded to a sizeable fraction of the comprehensive collection of 3D pockets and co-crystallized ligands, a.k.a. the Pocketome.

**366 Design Guidelines for Minimal Aquatic Toxicity Based on Experimental Spectroscopic Characterization** A. Voutchkova-Kostal, Yale University / Center for Green Chemistry and Green Engineering, George Washington University, George Washington University / Chemistry; N. An, George Washington University / Chemistry. In light of the increasing number of new commercial chemicals that are likely to exert ecotoxicity, the need to *rationally* design chemicals with minimal biological activity is clear. Tools and guidelines must be developed that allow molecular designers to incorporate considerations of minimizing toxicity during the design and synthesis stages. These strategies must be easy to implement alongside traditional chemical synthesis and characterization. The interpretation of chemical characterization data, such as NMR, IR and UV-visible spectroscopy, is second nature to chemists. If such data could be used to inform the likely toxicological hazard of chemicals, the approach to chemical design for minimal hazard could be transformed. Previously we have shown that HOMO-LUMO energy gaps and octanol/water partition coefficients are directly informative of acute and chronic aquatic toxicity. We now show that NMR and UV-visible data can be used in place of calculated properties

to identify chemicals that exhibit high acute and chronic aquatic toxicity. Aquatic toxicity data for *P. promelas*, *D. magna*, *O. latipes* and *P. subcapitata* (72-hr LC50 and NOEC values) were obtained from the U.S. E.P.A. and the Japan Ministry databases, while experimental spectroscopic data were obtained from the NIST database or predicted. We show that although this goal is tremendously challenging, it is feasible and worthwhile of future research efforts.

**367 Designing Benign Chemistries** J. Zimmerman, Yale University; P. Anastas, Yale University / Center for Green Chemistry and Green Engineering. The potential threat that commercial chemicals with unintended biological activity can pose to our society and the environment has become increasingly clear in recent years. While chemists and engineers have developed considerable expertise in designing chemicals to have specific industrial or biological functions, thus far little or no consideration has been given to minimizing the undesired and adverse human health and environmental impacts of commercial chemicals. This work will present strategies and tools to address this critical gap by systematically developing an anticipatory, cohesive molecular strategy for hazard reduction that can readily be 1) implemented in the design stages of a commercial chemical, 2) used by regulatory bodies to evaluate new and existing chemicals to inform design-making on potential hazards, and 3) utilized as the basis for engaging, effective educational materials that ensure molecular designers consider hazard reduction as well as performance criteria. Work has focused on linking physicochemical properties of chemicals to acute ecotoxicological effects. This effort will expand this methodology to extrapolate findings and approaches to broader hazard concerns and endpoints to potentially include chronic and human health endpoints as well as global and physical hazards.

**368 New Computational Toxicology Resources for Green Chemistry** R. Boethling, US Environmental Protection Agency / Office of Pollution Prevention and Toxics; C. Baier-Anderson, E. Sommer, US Environmental Protection Agency; R. Judson, US Environmental Protection Agency / Office of Research and Development; D. Reif, I. Shah, US Environmental Protection Agency; P. Howard, J. Adams, W. Meylan, SRC Inc.. Green chemistry encourages the design or selection of chemicals and chemical processes that reduce or eliminate negative human health and environmental impacts. Principle 4 of the green chemistry principles, "Design safer chemicals," stresses preserving useful function while minimizing toxicity, persistence or other undesirable effects. A principal impediment to its implementation has been the difficulty of finding and retrieving the toxicology, environmental fate and chemical property data required for a holistic perspective of intrinsic hazard. In its Aggregated Computational Toxicology Resource (ACToR), EPA has compiled data from hundreds of sources. ACToR largely solves problems resulting from toxicity data residing in a wide variety of specialized databases, different and often incompatible formats, and different locations. ACToR is being expanded to include data on environmental fate and persistence of chemicals by including the specialized sources and functionality of EPA/SRC's FatePointer tool. In addition to resources already available in ACToR (e.g. ToxCast), users will have easy access to fate data, enabling inclusion of these data alongside toxicity endpoints in alternatives assessment and chemical design. EPA also plans to develop UNIX and web-based versions of EPI Suite™, a tool that predicts chemical properties and fate from chemical structure. The web-based version of EPI Suite™ will be incorporated into customized decision-support tools to enable the integration of chemical property and fate predictions with other types of data and models. Decision-support tools under development include "dashboards", which are tool-based websites tailored to specific subjects or clients; e.g., a web page that allows convenient access to, and application of, the varied resources needed for informed substitution in green chemistry. To illustrate application in chemical or product design, data are retrieved for a series of synthetic musk fragrances, and used to compare alternative structures on the basis of both toxicological and environmental endpoints.

**369 Probabilistic Assessment of Sustainable Molecular Design Guidelines: Exploring Chemical Outliers and Chemical Classes** K.A. Connors, Baylor University / Institute of Biomedical Studies, Baylor University / Department of Environmental Science; A. Voutchkova-Kostal, Yale University / Center for Green Chemistry and Green Engineering, George Washington University, George Washington University / Chemistry; P. Anastas, J.B. Zimmermen, Yale University; B.W. Brooks, Baylor University

/ Environmental Science and Biomedical Studies, Baylor University / Department of Environmental Science. One of the Twelve Principles of Green Chemistry emphasizes the need to synthesize safer chemicals. These chemicals should be capable of performing their desired function but would be designed to elicit minimal toxicity. In support of this effort, two recent studies have explored the relationships between chemical properties and acute or chronic toxicity as measured through standardized OECD and EPA protocols. Mechanistically-rationalized guidelines were derived resulting in two practical design guidelines: acute and chronic toxicity could be minimized if compounds had an octanol-water partition coefficient (log P) below 2 and highest occupied molecular orbital (HOMO)-lowest unoccupied molecular orbital (LUMO) gap (eV) greater than 9 eV. We employed a probabilistic hazard assessment approach to examine the likelihood of encountering industrial chemicals within regulatory toxicity categories (e.g., high, moderate, low toxicity). If these two design guidelines are employed, the present study estimates that acute toxicity to the fathead minnow model could be reduced for over 10% for industrial chemicals classified with 'High' acute toxicity. We further examined chemicals, modes of action and chemical classes for which these property guidelines did not reduce aquatic toxicity. For example, in the absence of chemical design guidelines, our model predicts that 27.6% of chemicals acting through an electrophile reactivity mode of action in the fathead minnow model would be classified as 'High' concern for acute toxicity. When both guidelines are obeyed, only 14.5% of chemicals with an electrophilic MOA would be classified at this level. Ongoing efforts are developing additional design guidelines for chemicals remaining in 'High' toxicity categories.

**370 Quantum-Mechanical Approach to the Prediction of Olefin and Epoxide Mutagenicity** J. Kostal, Sustainability A to Z; A. Voutchkova-Kostal, Yale University / Center for Green Chemistry and Green Engineering, George Washington University, George Washington University / Chemistry; J. Zimmerman, P. Anastas, Yale University. Computational modeling of molecular interactions has found extensive applications in drug discovery; however, its application to the rational design of minimally toxic commercial chemicals has not yet been explored. Present study demonstrates the feasibility of developing computer-aided predictive *in silico* methods for prioritizing chemicals of high concern for human toxicity on the example of epoxide-opening reactions. Epoxides are known for mammalian mutagenicity and carcinogenicity; these toxic endpoints have been attributed to the ability of epoxides to covalently bind to DNA via ring-opening reactions. Activation barriers ( $\Delta G^\ddagger$ ) and free energies of reaction ( $\Delta G_{\text{rxn}}$ ) for the  $S_N2$  ring openings of 13 mono and disubstituted epoxides were computed at the MP2/6-31+G(d,p) levels of theory in the gas phase and in aqueous solution. This study finds an aqueous-solution  $\Delta G_{\text{rxn}}$  threshold value of -15 kcal/mol can be used to discern mutagenic/carcinogenic epoxides ( $\Delta G_{\text{rxn}} < -15$  kcal/mol) from non-mutagens/non-carcinogens ( $\Delta G_{\text{rxn}} > -15$  kcal/mol). The computationally modeled reactivity of epoxides is thus proposed as a viable *in silico* screen for potentially toxic epoxides.

**371 Understanding the Impact of SWNT Aggregation on Toxicity to Inform Greener Nano Design** L. Pasquini, S. Hashmi, M. Elimelech, J. Zimmerman, Yale University. Functionalized SWNTs (fSWNTs) are a unique class of emerging nanomaterials that offer simultaneous enhancement of SWNT applications and reduction of their negative human health and environmental implications. Here, the percent cell viability loss of *Escherichia coli* K12 resulting from exposure to nine fSWNTs is explored. Three of the fSWNTs exhibit statistically significant decrease in percent cell viability loss. Various characterization techniques were employed to characterize the fSWNTs and identify the physicochemical properties associated with the observed trend in bacterial cytotoxicity. Light scattering results, both static (SLS) and dynamic (DLS), elucidated aggregate morphology and provided the distribution of diffusion time of fSWNT aggregates under experimental conditions. Individually, DLS and SLS do not explain the observed trend in cell viability loss, but combined it becomes clear that compact monodispersed fSWNT aggregates result in reduced cytotoxicity. This is the first study that takes a systematic approach to determine fSWNT physicochemical properties that result in the observed trend in cytotoxic behavior fSWNTs. The targeting of specific properties is intended for future design and manufacture of safer SWNTs.

**372 Greener Organocatalysis: Toxicity and Biodegradation studies in tandem with Green Chemistry Metrics analysis** [N. Gathergood](#), Dublin

City University / School of Chemical Sciences; S. Connon, University of Dublin, Trinity College / School of Chemistry; R. Gore, Dublin City University / School of Chemical Sciences; L. Myles, University of Dublin, Trinity College / School of Chemistry; T. Garcia, IQAC-CSIC / Department of Surfactant Technology. The research project combines two fields of green chemistry, ionic liquids and catalysis. Our study is directed towards ionic liquids which can also catalyse reactions. This overlap between organocatalysis and ionic liquid research enables us to design low toxicity and potentially biodegradable catalysts based on the extensive biological screening data of ionic liquids. Assessment of the performance of a new catalyst, in tandem with the (eco)toxicity screening and biodegradation testing allows the chemist to develop green synthetic methods. We have designed a library of aprotic ionic liquids which can act as Brønsted acid catalysts with low antibacterial and antifungal activity. Preliminary studies of the toxicity of all the ionic liquids were performed to establish the influence of the ester or amide group in the cation. Antifungal and antibacterial toxicity studies demonstrated that the ionic liquids did not inhibit the growth of any organism screened at concentrations of 2.0 mM. Biodegradation of all novel ionic liquids was investigated in "CO<sub>2</sub> Headspace" test (ISO 14593). Our latest studies (including Green Chemistry metrics feedback) investigate the effect of substitution on the imidazolium ring on biodegradation and activity of the catalyst. Acetalisation and thioacetalisation reactions of a variety of aldehydes have been studied at room temperature and low catalyst loadings (0.05 mol%). The study demonstrated the excellent catalytic activity of these aprotic molecules as active Brønsted acids in the presence of protic media. The most active catalyst has been recycled 15 times without any loss of catalytic activity.

**373 CECs – Why the Big Fuss?** S. Aminzadeh, California Coastkeeper Alliance. Contaminants of emerging concern (CECs) are increasingly detected at low levels in California's waterbodies. Some CECs are similar to conventional toxic pollutants in that they are associated with industrial releases, whereas many others are used by the general public in pharmaceuticals and personal care products. CECs are released directly to the environment after passing through wastewater treatment processes, which are typically not designed to remove CECs from the effluent. These contaminants are relatively unmonitored and found to occur at trace levels in wastewater discharges, ambient receiving waters, and drinking water supplies. Many CECs are so new that standardized measurement methods and toxicological data for interpreting their potential human or ecosystem health effects are unavailable. This lack of basic information and technology to efficiently measure CECs hampers California's ability to assess their potential risks and develop regulatory protocols. The discharge of CECs to California's receiving waters occurs on a daily basis due to recycled water. As recycled water becomes an increasingly important part of California's water supply portfolio, the State faces the challenge of monitoring and regulating the discharge of CECs into surface and groundwater. Many streams in southern California are effluent-dominated streams with 80-95% of dry weather flows coming from recycled water discharges, and many northern California streams receiving recycled water effluent interact regularly and closely with groundwater. As such, the importance of monitoring for CECs is absolutely critical to identify risks posed to public health and aquatic life. Some CECs have been shown to cause endocrine disruption after being released to the environment, as they interfere with the action of reproductive hormones such as estrogen and testosterone. CEC standards are critical to build public confidence in the use of recycled water; and the absence of monitoring data for CECs is an impediment to the promotion of recycled water as a sustainable water supply for California.

**374 Regulatory Aspects of Managing CECs in California Waters** J. Bishop, California Water Resources Control Board. California recycles approximately 650,000 acre-feet of water per year, but has identified the potential to reuse an additional 1.5 million acre-feet in the future. To encourage expanded reuse in a state that experiences periodic water shortages, the California State Water Resources Control Board (SWRCB) adopted a Recycled Water Policy in 2009 intended to provide permitting clarity for recycled water projects. One challenge in developing that policy was how to address new classes of chemicals, such as pharmaceuticals, current use pesticides, and industrial chemicals, collectively referred to as chemicals of emerging concern (CECs). Many CECs are potentially present not only in recycled water, but also in ambient waters that receive discharge of treated municipal wastewater effluent and stormwater runoff. After discharge to receiving waters, CECs may have direct impacts to aquatic life, or may associate with particles, accumulate in sediments and work their way up the food chain to higher biota, including humans. The mission of the SWRCB is to protect beneficial uses of water resources in California through promulgation of water quality standards and monitoring requirements for permitted discharges, ground and surface waters. To address the different challenges that CECs present, the Water Board also supports research and technology development that facilitates science-based decision and policy making. One such example is the development of bioanalytical screening tools, a means for detection of many known and unknown chemicals based on their mode of biological action, thus de-emphasizing the need to develop chemical specific analytical methods for the next generation of CECs.

**375 Monitoring CECs in San Francisco Bay** M. Sedlak, D. Yee, J. Davis, San Francisco Estuary Institute. The Regional Monitoring Program for Water Quality in the San Francisco Estuary (RMP) has been investigating contaminants of emerging concern (CECs) since 2001 and developed a formal workgroup to address the issue in 2006. The RMP Emerging Contaminants Workgroup (ECWG) includes representatives from RMP stakeholder groups (wastewater, stormwater, and industrial dischargers, dredgers, and regulatory agencies) and an advisory panel of expert researchers that work together to address the workgroup's guiding management question – Which CECs have the potential to adversely impact beneficial uses in San Francisco Bay? The overarching goal of the ECWG is to develop cost-effective strategies to identify and monitor CECs so that potentially problematic chemicals can be identified as early as possible and thus minimize impacts to the Estuary. The ECWG works toward this goal by evaluating available information on chemical occurrence, fate,

toxicity, volume use, and potential sources, and then recommends CECs for investigation in special studies. Each year the highest priority studies are conducted, and the results guide whether or not these CECs are added to routine monitoring by the RMP. Using this process, the RMP has generated one of the most comprehensive datasets for CECs in an aquatic ecosystem. CECs investigated to date include perfluorinated compounds, alkylphenols, more than 100 pharmaceuticals and personal care product ingredients, and a variety of flame retardants including polybrominated diphenyl ethers and their replacements. This presentation will summarize results from the CEC studies conducted to date and highlight the ECWG approach to prioritizing CECs for monitoring.

**376 CA Science Advisory Panel recommendations for CEC monitoring in recycled water** P. Anderson, Ohio EPA; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology; J. Drewes, Colorado School of Mines / Environmental Science and Engineering; K.A. Maruya, SCCWRP, Southern California Coastal Water Research Project; A. Olivieri, EOA, Inc.; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; G.I. Scott, National Ocean Services / Center for Coastal Environ. Health & Biomolecular; S. Snyder, University of Arizona / Chemical and Environmental Engineering. The paucity of information on the occurrence and potential impacts of chemicals of emerging concern (CECs) in natural and treated waters currently limits our ability to define and, thus, manage risks associated with CECs. In response, the State of California tasked Southern California Coastal Water Research Project (SCCWRP) to convene an expert panel to provide recommendations for effective monitoring of CECs in recycled water. Through an open and transparent process, SCCWRP convened a panel of six national experts in the fields of chemistry, biochemistry, toxicology, epidemiology, risk assessment and engineering, with more than 100 years of combined experience investigating CEC issues. The Panel was asked to address five charge questions. They held several meetings during which they considered a wide range of CECs and identified the scenarios most likely to be associated with exposure to CECs. The Panel created a framework to prioritize CECs based on occurrence and toxicological relevance, applied this framework using statewide data and provided recommendations for monitoring of high priority CECs and treatment performance indicators and surrogates. In addition, the Panel identified data gaps, research needs and programmatic issues that would result in future improvements to the framework and increase the overall relevance and effectiveness of CEC monitoring in recycled water.

**377 Monitoring Strategies for Chemicals of Emerging Concern (CECs) in California's Aquatic Ecosystems Recommendations of a Science Advisory Panel** D. Schlenk, University of California-Riverside / Department of Environmental Sciences; K.A. Maruya, SCCWRP, Southern California Coastal Water Research Project; P. Anderson, Ohio EPA; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology; A. Olivieri, EOA Inc.; J. Drewes, Colorado School of Mines / Environmental Science and Engineering; G. Scott, NOAA; S. Snyder, University of Arizona / Chemical and Environmental Engineering. Contaminants of emerging concern (CECs) represent a challenging problem for regulators to address, owing to limited scientific knowledge about their sources, fates, and effects. The State of California convened a panel of experts to provide recommendations on how current knowledge of CECs should influence their regulatory activities, beginning with recycled water applications, and with support from the David and Lucile Packard Foundation, continuing with ambient waters receiving treated wastewater effluent and stormwater discharge. The Panel delivered a risk-based framework and monitoring approach which included a list of priority CECs, appropriate methods and interpretive guidelines for monitoring data. To make future monitoring more relevant and efficient, the Panel recommended the development of bioanalytical tools that integrate the response of high priority CECs.

**378 Developing bioanalytical techniques to address water quality** N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology; P. Anderson, Ohio EPA; J. Drewes, Colorado School of Mines / Environmental Science and Engineering; A. Olivieri, EOA, Inc.; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; G.I. Scott, National Ocean Services / Center for Coastal Environ. Health & Biomolecular; S.

Snyder, University of Arizona / Chemical and Environmental Engineering; S. Westerheide, University of South Florida; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP. Standard methods to evaluate occurrence of chemicals in surface waters or reused water currently involve a chemical-by-chemical approach using mass spectrometry. However most of the analytical methods that exist in the commercial sector are primarily for select groups of chemicals that have previously been identified as chemicals that should be regulated. This includes high volume pollutants and legacy pesticides. In the past several decades, it has become apparent that additional chemicals, typically referred to as chemicals of emerging concern (CECs), including many pharmaceuticals and personal care products may also appear in surface waters that receive treated sewage influents; however, analytical methods for CECs are scant and not standardized. While many of the CECs can be predicted to be in the waters based on their physical-chemical properties and their volume of production and use, there are other CECs which may be present but which we cannot predict and consequently for which we do not have any analytical methods. These are the "unknown unknowns", i.e., chemicals which we do not anticipate being in the water and for which we have no analytical methods. This group may include additional pharmaceuticals, by-products of disinfection, or novel replacement pesticides, among others. It is possible to measure occurrence of these chemicals by their molecular activities, using high throughput bioanalytical assays. Of special concern are chemicals that may be additive (or synergistic) in their molecular activities and which may activate adverse outcome pathways, leading organisms towards decreased growth, decreased reproduction, increased susceptibility to disease or even death. We are using these high throughput assays to determine chemical equivalencies (for example, total estrogen equivalency) and comparing the bioanalytical measurements with traditional mass spectrometry methods.

**379 The Role of Non-Targeted Analyses in the Evaluation of CECs** S. Snyder, University of Arizona / Chemical and Environmental Engineering; S. Merel, A. Jia, University of Arizona; N. Dodder, Southern California Coastal Water Research Project; K.A. Maruya, SCCWRP; Southern California Coastal Water Research Project. The vast majority of analytical techniques applied in the environment are designed to identify and quantify specific targeted contaminants. However, targeted analytes provides only limited resolution regarding the actual occurrence of environmental contaminants. Moreover, many targeted analytes are transformed by natural and/or engineered processes to generate transformation products of unknown structure and toxicity. The use of bioassays provides tremendous advantage in screening for wide ranges of contaminants with specific biological activity. Yet, bioassays are generally unable to distinguish the specific contaminants responsible for observed bioactivity. Non-targeted analytical techniques are critical in identification and new environmental contaminants, transformation products, and natural products in complex environmental matrices. For instance, time of flight mass spectrometry is capable of provide high mass accuracy valuable in calculation of molecular formula. Sample preparation and separation technologies including on-line SPE and GCxGC/LCxLC techniques are robust technologies for identifying non-targeted contaminants. Beyond analytical instruments, advanced software platforms are capable of complex statistical analyses which can differentiate unique peaks within multiple matrices. Lastly, coupling in vitro bioassay techniques with non-targeted analyses provides for a bio-directed analytical approach that has been successfully applied to estrogenic and genotoxic environmental contaminants. We will provide specific examples of non-targeted analyses successfully employed for identification of environmental contaminants in fish tissues, water, and sediments.

**380 Development of Standardized Methods for Assessing Antibiotic Resistance Risks** G.I. Scott, National Ocean Services / Center for Coastal Environ. Health & Biomolecular; M. Fulton, J. Moore, NOAA/NCCOS; S. Norman, M. Uyaguari, University of South Carolina; D. Schlenck, University of California; N.D. Denslow, University of Florida; P. Anderson, ARCADIS and Boston University; J. Drewes, Colorado School of Mines; A. Olivieri, EOA, Inc.; S. Snyder, University of Arizona; K. Maruya, Southern California Coastal Water Research Program. Chemicals of Emerging Concern (CECs) may include a wide variety of chemicals such as flame retardants, contemporary use pesticides, newly developed commercial products (e.g. nanomaterials) and pharmaceutical/personal care products for which there are often incomplete ecotoxicity data. Antibiotics are CECs that have received significant attention due to their potential to

cause development of bacterial resistance at very low concentrations and/or development of resistance genes that may be exchanged (e.g. plasmids) among bacteria. Between 100 to 200 million kg of antibiotics are consumed annually worldwide, while in the US, more than 22 million kg of antibiotics are produced annually for animal (40%) and human (60%) use. Most antibiotics are poorly absorbed, resulting in 25 – 75% of the consumed product being released unaltered in feces or urine, which may be discharged into sewerage treatment plants (STPs). STPs concentrate and treat human waste, ultimately releasing treated wastewater into local environments. While STPs efficiently remove most biosolids, many antibiotics and antibiotic resistant bacteria often survive the treatment process and may be discharged into the environment. High levels of antibiotic resistance have been reported among bacteria in water, sediments and biota in aquatic ecosystems as a result. Antibiotics may adversely affect bacteria resulting in death at high therapeutic doses [Minimum Inhibitory Concentrations (MICs)] while at lower doses bacteria may survive and adapt to exposure by mutations which may result in development of antibiotic resistance (ABR). MICs are generally the antibiotic concentrations that cause bacterial death and are routinely reported for every antibiotic. Published MIC data for *E. coli* or other commonly used bacteria in water quality monitoring or research were used to determine toxicity thresholds for antibiotics that have been measured in monitoring studies conducted throughout the US. A process was developed to assess the potential for development of ABR which compared MICs for antibiotics under a variety of exposure conditions. The ratio of Standard and Resistant MICs was then used as an estimate of the potential for enhancement of ABR within the environment and safety factors were applied to deal with uncertainty. Methods for assessing the potential for developing ABR from low levels exposure of antibiotics versus exchange of genes from plasmids among resistant bacteria will be discussed.

**381 Algal blooms in European lakes: overview of assessment methods and a modelling case study** J. Moe, Norwegian Institute for Water Research (NIVA) / Climate and environmental modelling, Norwegian Institute for Water Research / Climate and environmental modelling, Norwegian Institute for Water Research / Section for Freshwater Biodiversity, Norwegian Institute for Water Research (NIVA) / Section for Climate and Environmental Modelling; D.N. Barton, Norwegian Institute for Nature Research (NINA); B. Skjelbred, A.L. Solheim, Norwegian Institute for Water Research (NIVA). Eutrophication (excessive nutrient enrichment) is one of the greatest environmental problems for inland waters of Europe, especially in agricultural areas. High nutrient concentrations (phosphorus and nitrogen) in lakes promote algal blooms, and thereby increase the risk of toxin-producing cyanobacteria. In addition, climatic change such as increased temperature tends to favour growth of harmful cyanobacteria relative to other algae. Environmental legislation in the European Union (The Water Framework Directive) requires that the frequency and intensity of algal blooms in lakes are only "slightly higher" than in comparable undisturbed lakes. A research challenge across Europe has been to quantify an acceptable "slight increase" of blooms and other metrics describing of the phytoplankton community, and to relate this management goal to nutrient pressures in different geographic regions and for different lake types. This presentation will give an overview of current assessment methods for cyanobacteria and other phytoplankton metrics for European lakes. A case study from the eutrophic Lake Vansjø in Norway will also be presented. This lake has experienced cyanobacteria blooms for decades, in spite of considerable nutrient abatement measures. The blooms occasionally cause production of toxins (e.g. microcystin) which are harmful to people, and result in restrictions on recreational use of the lake. We use a Bayesian network modelling approach to integrate information on climatic variables, nutrient concentrations, algal biomass etc., and simulate impacts of alternative abatement measures on levels of cyanobacteria under different climatic conditions.

**382 Harmful Algal Bloom Toxins in Inland Waters: Perspectives on Assessment and Management of these Environmental Contaminants of Emerging Concern** B.W. Brooks, Baylor University / Environmental Science and Biomedical Studies, Baylor University / Department of Environmental Science. Environmental science and management continuously faces emerging challenges associated with contaminants for which limited information is available for their fate and effects. Regulatory programs have developed approaches to characterize risks from chemicals and chemical management programs; however, such approaches are not as widely defined or employed, however, for harmful algal blooms (HABs), whose increase

in frequency and magnitude over the past few decades has occurred at the global scale. Factors leading to development of HABs vary, but climate change and urbanization are common influences on such increases of HABs. Though much attention has been given to coastal HABs, inland waters often experience HABs, which can be exacerbated by anthropogenic activities. For example, harmful blooms of cyanobacteria receive unprecedented attention due to impacts on fisheries, linkages to terrestrial poisonings, and public health concerns associated with drinking water contamination. A number of *Prymnesium parvum* (golden algae), an invasive haptophyte historically observed in estuarine and coastal habitats, have increasingly produced devastating fish kills in inland waters of the United States. Managers no longer stock sport fish in some impoundments due to repeated, fish-killing *P. parvum* blooms, and seasonal *P. parvum* blooms in water supply reservoirs have resulted in cessation of municipal drinking water withdrawals. This presentation critically examines HAB toxins as contaminants of emerging concern, and provides specific recommendations within the framework of water quality assessment and management as mandated by the Clean Water Act.

**383 Influence of Spatiotemporal pH Variability on Site-specific Water Quality Assessments** W.C. Scott, Baylor University / The Institute of Ecological, Earth, and Environmental Sciences; K.N. Prosser, Baylor University; B.W. Brooks, Baylor University / Environmental Science and Biomedical Studies, Baylor University / Department of Environmental Science. Water chemistry gradients can develop along longitudinal and vertical axes in aquatic systems due to natural and anthropogenic activities. Gradients of pH, temperature and salinity, for example, can form longitudinally and vertically in both inland and coastal systems. In particular, production: respiration dynamics and the formation of thermal stratification can cause pH levels to vary through a water column. Such changes in pH can influence the ionization state and bioavailability of ionizable compounds, resulting in differential spatiotemporal bioaccumulation and toxicity of these contaminants. The objective of this study was to develop an understanding of spatiotemporal pH variability in surface waters to support future hazard assessments of contaminants exhibiting pH-dependent toxicity. We selected three coves in Lake Granbury, a continuous level impoundment of the Brazos River located in central Texas, USA, for initial studies during Winter and Spring 2012. Our observations revealed that the mean change in pH through a water column more than doubled in all three coves sampled from February to April, and in some cases varied by 2 orders of magnitude. Furthermore, the magnitude of vertical pH gradients appeared to decrease with distance upstream from the main channel as depth decreased. Harmful blooms of *Prymnesium parvum* blooms are more toxic at higher pH and primarily occur in the winter and early spring months in Texas. February studies on Lake Granbury revealed uniformly high pH throughout the water column, whereas April studies showed deep zones of water with lower pH that could potentially serve as a refuge from toxicity. Criterion Maximum Concentrations (CMC) and Site Specific Potency Ratios of ammonia and pentachlorophenol varied significantly with depth between February and April across all three coves. Mean surface and bottom CMC for ammonia in the three coves were predicted to be 15.50 and 17.77 TN/L, respectively, for February, and 4.17 and 8.54 TN/L for April. Likewise, mean surface and bottom CMC for pentachlorophenol for the three coves in February were predicted to be 24.56 and 22.53 ug/L, respectively, and 30.73 and 19.93 ug/L for April. Ongoing research of Lake Granbury will extend to summer and fall sampling events, and further expand this study to include rivers flowing to Gulf Coast estuaries to better understand temporal patterns of pH gradients and how they may impact the hazards of ionizable contaminants.

**385 Neurotoxic effects of saxitoxins in freshwater fish: in vivo and in vitro studies** C.A. da Silva, Federal University of Paraná / Ecology and Conservation Post-graduate Program; E.T. Oba, Federal University of Paraná / Department of Pharmacology; E.C. Morais, M.D. Moura Costa, Federal University of Paraná / Department of Basic Pathology; J.C. Ribas, I.C. Guiloski, Federal University of Paraná / Department of Pharmacology; W.A. Ramsdorf, Federal University of Paraná / Department of Genetics; S.M. Zanata, Federal University of Paraná / Department of Cellular Biology; M.M. Cestari, Federal University of Paraná / Department of Genetics; C.A. Oliveira Ribeiro, Federal University of Paraná / Department of Cellular Biology; V.F. Magalhaes, Federal University of Rio de Janeiro / Carlos Chagas Filho Institute; H. Silva de Assis, Federal University of Paraná.

Cyanobacteria blooms saxitoxin (STX) producers such as *Cylindrospermopsis raciborskii*, has become a serious environmental concern, especially in southern Brazil, where this species has already been dominant in public water supply reservoir. STX is a naturally produced neurotoxin that blockage the sodium channel in the neurons cells leading animals to death. However, the bioaccumulation in trophic chain and their neurotoxicological effects in fish are not acknowledged completely. To better understand the potential of bioaccumulation of STX, the freshwater fish *Hoplias malabaricus* was submitted to a trophic bioassay (0.08 µg/100 g of STX equivalents) using individuals of *Astyanax sp.* as vehicle during 20 days with feeding every 5 days. The biomarkers as activities of acetylcholinesterase (AChE), superoxide dismutase (SOD), catalase (CAT), glutathione S-transferase (GST) and glutathione peroxidase (GPx), the concentration of glutathione (GSH), lipoperoxidation (LPO), protein carbonylation (PCO), and comet assay were analyzed in the brain. Muscle was collected for STX chemical analysis. To evaluate neurotoxic effect directly in the target cell, a new protocol was established using primary culture of neurons from *H. malabaricus*. The cells were incubated at 24°C, 1.7% CO<sub>2</sub> for 24h and the medium was changed to a new one without and with STX (0.3 µg/L and 3 µg/L) for 24h. Isolated cells were immunocytochemistry marked. Cell viability, oxidative stress, apoptosis and genotoxic effects were analyzed. The results of the bioassay suggested an oxidative stress and genotoxicity. However, it was not observed STX contents in muscle samples. The in vitro protocol showed that a culture medium enriched with fibroblast growth factor and nutritional supplements such as B27, and the use of papain, as well as substrate coating appropriate as poly-L-Lysine and segregation gradients cells, allowed a cellular culture with good cell viability. After the neurons exposure to STX cytotoxicity, oxidative stress, and genotoxicity were observed. It was not noticed apoptosis in the exposed group. Although STX effects are reported as reversible, the time exposure and concentration of STX suggested cellular damage which can lead to neuropathology. In addition, the establishment of neurons culture primary protocol enables new applications in fish ecotoxicology in the assessment of neurotoxic substances in the target cells.

**386 State of the Art and Research Needs on the Management of Harmful Cyanobacterial Bloom** S. Merel, The University of Arizona / Chemical and Environmental Engineering; D. Walker, The University of Arizona / Environmental Research Laboratory; R. Chicana, Cesar Vallejo University / School of International Business; S. Snyder, The University of Arizona; O. Thomas, French School of Public Health / Environment and Health Research Laboratory. Cyanobacteria are ubiquitous microorganisms considered as important contributors to the formation of Earth's atmosphere and nitrogen fixation. However, they are also frequently associated with toxic blooms. Indeed, the wide range of hepatotoxins, neurotoxins and dermatotoxins synthesized by these bacteria is a growing environmental and public health concern. This study provides a state of the art on the management of harmful cyanobacterial blooms in surface and drinking water, including economic impacts and research needs. Cyanobacterial blooms usually occur according to a combination of environmental factors e.g., nutrient concentration, water temperature, light intensity, salinity, water movement, stagnation and residence time, as well as several other variables. These environmental variables, in turn, have promoted the evolution and biosynthesis of strain-specific, gene-controlled metabolites (cyanotoxins) that are often harmful to aquatic and terrestrial life, including humans. Cyanotoxins are primarily produced intracellularly during the exponential growth phase. Release of toxins into water can occur during cell death or senescence but can also be due to evolutionary-derived or environmentally-mediated circumstances such as allelopathy or relatively sudden nutrient limitation. Consequently, when cyanobacterial blooms occur in drinking water resources, treatment has to remove both cyanobacteria (avoiding cell lysis and subsequent toxin release) and aqueous cyanotoxins previously released. Cells are usually removed with limited lysis by physical processes such as clarification or membrane filtration. However, aqueous toxins are usually removed by both physical retention, through adsorption on activated carbon or reverse osmosis, and chemical oxidation, through ozonation or chlorination. While the efficient oxidation of the more common cyanotoxins (microcystin, cylindrospermopsin, anatoxin and saxitoxin) has been extensively reported, the chemical and toxicological characterization of their by-products requires further investigation. In addition, future research should also investigate the removal of poorly considered cyanotoxins (β-methylamino-alanine, lyngbyatoxin or aplysiatoxin) as well as the economic impact of blooms.

**387 The Prevalence of Cyanobacteria and Cyanotoxins in Southern California Waterbodies**

M. Howard, Southern California Coastal Water Research Project; R. Kudela, University of California, Santa Cruz; M. Suttle, E. Stein, Southern California Coastal Water Research Project; L. Busse, San Diego Regional Water Quality Control Board; D. Greenstein, S. Bay, Southern California Coastal Water Research Project; T. Magrann, Saddleback College. Cyanobacterial blooms are a global problem and have been documented throughout California in estuarine, brackish and fresh water habitats. Blooms of cyanobacteria cause a variety of water quality problems such as impaired recreational waterbodies, influenced biological index score, reduced aesthetics, lower dissolved oxygen concentrations, taste and odor problems in drinking water and the production of toxins (cyanotoxins) which have caused wildlife mortality and are associated with liver cancer and tumors in humans. The impact of cyanotoxins can extend well beyond freshwater systems and have created a land-sea connection by causing mortality in California sea otters. Despite the health risks associated with cyanotoxins, little is known about the predominance of cyanotoxins in southern California waterbodies. The prevalence of cyanobacteria and cyanotoxins and the potential environmental drivers of cyanotoxin production were evaluated in a variety of southern California waterbodies using conventional monitoring methods combined with a newly developed monitoring tool, SPATT (Solid Phase Adsorption Toxin Tracking). Cyanotoxins and associated chemical and biological constituents were measured including nutrients, pH, alkalinity, electrical conductivity, total dissolved solids, dissolved oxygen, chlorophyll *a* and algal pigments from over 60 depressional wetlands, lakes, ponds, bays and lagoons in southern California. Laboratory studies were conducted to evaluate the potential effects of cyanotoxins on benthic species used in standard toxicity tests.

**388 Algal toxins and human health: A brief overview and notes on needed research directions**

N. Chernoff, United States Environmental Protection Agency / Toxicology Assessment Division; NHEERL, ORD. Marine and freshwater algae, both algae and cyanobacteria, are known to produce a wide variety of toxins that have caused severe adverse health effects in humans and other vertebrate species. There is general agreement that there is currently an increase in the incidence of hazardous algal blooms (HABs), the periods of occurrence, and their geographical range. The primary reasons for these changes include eutrophication of water bodies, climate change, global spread of individual species, and their intrinsic adaptability. Some toxins are known to be produced by only a small number of organisms while others (e.g. cylindrospermopsin (CYN) and saxitoxin) are generated by multiple species in evolutionarily distant groups. The toxins in HABs may induce general effects (CYN) or may target specific organ systems like the liver (microcystins) or the central nervous system (anatoxin-a, saxitoxin). Poisoning episodes involving severe toxicity and/or lethality have been recorded in humans after exposure to the above toxins as well as many others. Laboratory animal models have been developed for many of the toxins and there is excellent agreement in the types of toxicity observed across mammalian species. Lower vertebrates and invertebrates, however, often show different spectrums of toxicity and may display significant bioaccumulation of toxins. Many fundamental areas of research require additional work. The toxicity of mixtures is a critical data gap because exposures to single toxins rarely, if ever, occur. Reasons for this include the fact that during blooms, other species producing different toxins may be present; many species produce more than one toxin during a bloom; and blooms often occur sequentially in terms of the predominant species, and exposure to liver toxins may, for example, be followed by neurotoxin exposure. Additional underemphasized research areas include mechanism studies, and both developmental toxicology and long-term exposure studies (including carcinogenic potential) in susceptible organisms. The possible role of picoplankton in the production of toxins needs investigation as some types have been shown to produce microcystins. There is a need for a reliable biomarker of exposure in humans. Finally, interdisciplinary work is necessary in comprehensive toxicology studies. Information on bloom taxonomy, conditions and toxin production, and toxin analyses are essential to maximize the relevance of laboratory data to environmental HAB exposures.

**389 Commercial Nanosilver Applications and Their Potential for Environmental Release**

J.A. Steevens, U.S. Army Engineer Research & Development Center / Waterways Experiment Station; A. Kennedy, M. Chappell, F. Hill, A. Poda, D. Johnson, US Army ERDC. Historically silver has found a wide range of applications including its use as an antimicrobial

agent. More recently, nanoscale silver has been explored for use in washing machines, water treatment, catalysis, medical applications, and sensors. The antibiotic applications of nanosilver include use to kill bacteria, fungi, and viruses. The greatest potential for commercialization exists through use of nanosilver (< 50 nm) as a component of self-decontaminating surfaces and fabrics. Many of these antibiotic applications require a composite of NP silver with other metals such as titanium dioxide for water and air purification. The mechanism of action for nanosilver is through silver ion release and surface charge interactions that result in free radical generation and membrane disruption. To understand the environmental releases of nanosilver, the technologies can be evaluated through a life-cycle approach where releases can be examined throughout development, manufacture, use, disposal, and recycling. Because nanosilver is incorporated in a surface, fabric, or composite releases must occur from the technology. The releases can occur through passive release from an unstable matrix or by release through abrasion, dissolution, thermal and chemical decomposition, or biotic transformation. Nanosilver technologies often require direct contact with water (i.e., washing, fabric, water treatment) therefore several investigators have described or quantified releases through wastewater treatment plants. The estimates made to quantitatively predict the quantity of nanoscale materials released to the environment have a high degree of uncertainty and remain very dynamic due to the increasing number of producers, applications, and unknown nature and stability of the NP in the technology. This presentation will provide an introduction to nanoscale silver technologies and describe approaches used to decrease uncertainty in the estimates of environmental release.

**390 Fate and effects of silver nanoparticles in terrestrial environments**

J.M. Unrine, University of Kentucky, University of Kentucky / Department of Plant and Soil Sciences, University of Kentucky / Department of Plant & Soil Sciences, University of Kentucky / Savannah River Ecology Laboratory, University of Kentucky / Department of Plant and Soil Sciences, University of Georgia / Savannah River Ecology Laboratory; P. Bertsch, O. Tsyusko, University of Kentucky; W.A. Shoults-Wilson, Roosevelt University; G.V. Lowry, Carnegie Mellon University; B.P. Colman, E.S. Bernhardt, Duke University. Terrestrial environments are likely to be the ultimate sink for the majority of manufactured silver nanoparticles (AgNPs). As nano-Ag products are used and particles enter wastewater streams, they ultimately partition into sewage sludge, the majority of which is used as a soil amendment in agro-ecosystems. This raises several important questions. First, how are AgNPs transformed during wastewater treatment? How do the speciation and distribution of AgNPs change over time in biosolid amended soils, and how does this affect their bioavailability and toxicity? Finally, can simple laboratory toxicity assays predict ecological consequences in real-world exposures? We have found that AgNPs are extensively transformed during wastewater treatment, with sulfidation playing the most important role. These transformations dramatically alter the behavior of AgNPs in soil pore-water, and decrease the role of the original manufactured coating. For example, for freshly synthesized particles, citrate-coated AgNPs remained stable in soil pore water for up to six months while polyvinylpyrrolidone-coated AgNPs rapidly partitioned into solid phases. However, when pre-incubated with biosolids, the presence of free AgNPs in soil pore water was dramatically reduced for both coatings. Several studies have investigated the toxicity of unsulfidized AgNPs to earthworms in soil. The most sensitive endpoint measured to date was behavioral avoidance, which occurred at AgNP concentrations that were similar to estimates of Ag concentrations already present in some biosolids. Fewer toxicity studies have been conducted using exposures with sulfidized Ag MNMs, and fewer still in natural soils and sediments. Simple laboratory assays indicate that the solubility of sulfidized AgNPs is dramatically decreased as is toxicity. However, in natural soils and sediments Ag<sub>2</sub>S solubility may be enhanced, possibly due to microbial activity or redox coupling with other mineral phases. A recent mesocosm study using AgNPs pre-incubated in sewage sludge indicated that in more realistic, multi-species exposures, unpredicted indirect effects may occur, with effects on plant and microbial communities being detected at µg/kg concentrations in soil. Major efforts are currently underway regarding risks of nano Ag in terrestrial environments that will help to answer these basic questions.

**391 Ecotoxicological Effects of Nanosilver on Soil Microorganisms**

X. Lu, Peking University / Lab for Earth Surface Processes, College of Urban and Environmental Sciences; C. He, F. Gao, Z. Hou, S. Zhang, J. Yang,

Peking University / College of Urban and Environmental Sciences. With the rapid development of nanotechnology, manufactured nanomaterials are increasingly used and may contaminate the soil during the process of their use. Nanosilver is widely used due to its unique biocompatibility and antibacterial properties. The toxic impacts of nanosilver on microbes have been revealed by some researchers, but these researches were mainly based on pure cultures other than microbes in complicated matrix. This study aimed at investigating the ecotoxicological effects of nanosilver on soil microorganisms. Fresh soil from a hillside was collected for the experiment. Nanosilver with particle diameter of 15 nm and purity of 99.99% was purchased from a company. Using self-designed apparatus, the nanosilver was mixed with the soil at concentration of 1 mg nanosilver per gram of fresh soil and then split into 18 Erlenmeyer flasks. Fresh soil without nanosilver was used as control and also split into 18 Erlenmeyer flasks. All the flasks were covered with gauze and incubated in a cool and dark closet. Periodically, distilled water was added to each of the flasks to maintain the soil water content at about 5%. Every four weeks, three flasks of the nanosilver treated soil and three flasks of the control soil were taken to analyze different ecotoxicological parameters including microbial biomass, biochemical processes (respiration and ammonification), activities of enzymes (dehydrogenase and fluorescein diacetate esterase) and community structure. After near five months of experiment, the results showed the activities of both dehydrogenase and fluorescein diacetate esterase were inhibited by nanosilver; respiration of the soil microorganisms was not influenced by the nanosilver, while ammonification was stimulated by the nanosilver in the beginning but inhibited later on; no significant differences in microbial biomass and community structure was observed between the nanosilver treated soil and the control soil. The study results will be discussed in detail in terms of the experiment design, the parameter sensitivities, and the mechanisms involved in the ecotoxicological effects.

**392 Bioaccumulation and Toxicity of Silver Nanoparticles to Benthic Organisms** H. Selck, Roskilde University / Department of Environmental, Social and Spatial Change, Roskilde University / Dept. Environmental, Social and Spatial Change; G. Banta, Roskilde University / Environmental, Social & Spatial Change (ENSAPC); V.E. Forbes, University of Nebraska Lincoln / School of Biological Sciences. Nanotechnology is expanding rapidly, thus increasing the release of engineered nano-particles (NPs) to the aquatic environment. Sediment is likely to be the environmental compartment that is most exposed to metal-bearing NPs, and organisms that feed on sediment are likely to be particularly at risk from metal-NP exposure. Due to their increased surface area and reactivity, NPs may be more bioavailable and toxic than their macroscale counterparts. However, very little is known about the environmental impact of NPs and whether they behave similarly in the environment compared to their macroscale counterparts, and these factors make it difficult to perform environmental risk assessments and to set quality standards for NPs. Some of the questions we are facing are whether nano-specific properties lead to unexpected and new biological effects? If so, is the potential for such effects diminished when NPs are introduced to a complex environment such as the sediment compartment? Acknowledging that we are not yet able to characterize NPs once they have been introduced to the sediment compartment, we used a comparative approach to assess toxicity and bioavailability of Ag NPs. This presentation will show that by using realistic exposure scenarios, applying different well-characterized forms and sizes of Ag to the sediment compartment, and examining subsequent bioavailability and toxicity, we found evidence that bioavailability was affected by the Ag form introduced even though metal inevitably will change speciation once it enters the sediment compartment. The effect and importance of metal form added to sediment for metal bioavailability and subsequent toxicity is not straightforward, however, and depends both on biological factors, such as digestive complexity, and physical-chemical factors affecting the fate and speciation of metals in the sediment compartment. To better understand these mechanisms we need to focus future research efforts on developing methods to characterize nanomaterials in complex environments, including sediment, soil and diet, that are robust, reliable and yet relatively easy to implement in a standard laboratory.

**393 Uptake, elimination, and relative distribution of total silver in various tissues of Common Carp (*Cyprinus carpio*) after aquatic exposure of silver nanoparticles** M. Jang, J. Park, J. Oh, Y. Lee, Korea Institute of Toxicology / Future Environmental Research Center; S. Lee, Korea Institute of Toxicology / Future Environmental Research Center, Korea Institute of

Toxicology / Ecotoxicology Laboratory. Despite increasing application of silver nanoparticles (NPs) in industry and consumer products, relatively little research has been conducted on the fate, behavior and bioavailability of the materials in the water column. To investigate the fate and effects of silver NPs in fish, common carp (*Cyprinus carpio*) were exposed to water treated with silver NPs. A semi-static test system was used to expose common carp to either a freshwater control, or 0.5 mg l<sup>-1</sup> silver NPs for up to 7 days followed by 2 weeks depuration period. Uptake into the gills, brain, fillet, gastrointestinal tract, liver and blood was quantified by inductively coupled plasma-optical emission spectrometry (ICP-OES) after acid digestion (with combination of concentrated HNO<sub>3</sub> and hydrogen peroxide). Prior to experiment, recovery efficiency of silver NPs during acid digestion was tested and the percent recoveries from tissue extracts ranged from 90.9 to 111.4 %. Over the exposure period, the concentrations of total silver were stable in water as the measured concentration of silver, 0.62 ± 0.12 mg l<sup>-1</sup> (mean ± SD) was slightly higher than the nominal concentration, 0.5 mg l<sup>-1</sup>. During the uptake periods, the highest concentrations of total silver was found in the liver (5.61 mg kg<sup>-1</sup>), indicating that it is the target organ for silver NPs exposure. The concentration of total silver in gill, gastrointestinal tract, brain, fillet and blood was 3.32, 2.93, 0.14, 0.18, and 0.02 mg kg<sup>-1</sup>, respectively. After 14 days of depuration, silver were not detected in the fillet, blood and brains, however there were still detections of total silver in the liver, gastrointestinal tract, and gills. The concentrations of total silver in each tissue after 14 days of depuration were 4.22, 1.26, and 0.77 mg kg<sup>-1</sup>, respectively. These results contribute to a better understanding of the potential health effects of exposure to manufactured nanomaterials on species in aquatic ecosystems.

**394 Mechanism of Nanoparticle Silver Accumulation in *Daphnia pulex*** E. Costa, Wilfrid Laurier University; J. McGeer, Wilfrid Laurier University / Department of Biology. This research aims to understand the acute and chronic uptake and toxicity of nanoparticle forms of silver (nAg) to *Daphnia pulex* through comparisons to ionic silver (Ag<sup>+</sup>). A three-step approach considered toxicity, solution characterization, and physiological effects to determine if nAg toxicity is due to individual particles or particle dissolution to Ag<sup>+</sup>. Acute and chronic toxicity tests were standard 48 h and 21 d exposures, respectively, to determine 25% (EC25) and 50% effect concentrations (EC50). Using filtration and dissolution techniques, solutions at these concentrations were measured for size fractions (e.g. Ag content in < 450nm, < 100nm, < 10nm, and < 1nm fractions) and assessed for the relative content of nAg and Ag<sup>+</sup> associated with effects. The size fractionation and dissolution assessments were done on three solutions: water only, water + neonates (acute simulation), and water + adult *Daphnia* + food (chronic simulation). To assess physiological effects, 6 d old *Daphnia* were exposed to the chronic EC25 (0.4 µg/L Ag) to measure short-term (3 h) and long-term (48 h) bioaccumulation as well as <sup>22</sup>Na influx (to determine if nAg disrupts Na balance). Acute (EC50 0.8µg/L) and chronic (EC25 0.4µg/L) toxicity is similar for Ag<sup>+</sup> as well as three forms of nAg. However, uptake kinetics (3 h and 48 h) differed compared to Ag<sup>+</sup> as did Ag induced Na disruption (compared to Ag<sup>+</sup> and among nAg forms). Exposure solution characterization revealed that dissolution of nanoparticles to form ionic silver in solution does not play a significant role in nAg toxicity. Size fractionation of nAg particles revealed that particle size distribution is influenced by food and the presence of test organisms. This research was supported by the NRC-NSERC-BDC Nanotechnology Initiative.

**395 Silver Nanowire Toxicity on *Daphnia magna*** L.D Scanlan, U.C. Berkeley / Molecular Toxicology, U.C. Berkeley / graduate student; R. Reed, Colorado School of Mines; B. Gilbert, LBL Earth Sciences Division; N. Karunaratne, M. Eng, T. Cun, U.C. Berkeley; C. Higgins, J. Ranville, Colorado School of Mines; C. Vulpe, University of California, Berkeley / Nutritional Sciences and Toxicology. The use of nanomaterials and their subsequent release into the environment is increasing and it is therefore important to understand the toxicity of nanomaterials in ecological indicator organisms such as *Daphnia magna*. Silver nanowires (AgNW) are a high aspect ratio nanomaterial that are toxic to *Daphnia magna*. Previous experiments showed AgNW with poly(vinyl pyrrolidone) (PVP) or inorganic amorphous aluminum-doped silica (SiO<sub>2</sub>) coatings that were either 2 µm x 30 nm or 20 µm x 60 nm have toxicities in the 4 – 500 µg/L range. AgNW were detected inside *Daphnia* hemolymph following a 24-hour exposure, indicating absorption across the gut or gill epithelia. Furthermore, irregular shaped nanorods were detected in the hemolymph,

which may have formed from proteins interacting with silver species *in vivo*. To investigate environmental effects on the toxicity of AgNW, we exposed daphnids to AgNW in *Daphnia* growth media with high (8.8) and low (6.5) pH or with high (20ppm) or low (2ppm) levels of dissolved organic carbon. We also performed single particle inductively coupled plasma mass spectrometry (spICPMS) on hemolymph extracted from the *Daphnia* to verify AgNW uptake into the hemolymph and to quantitate internal silver levels. spICPMS was done on silver and AgNW-exposed animals following a post-exposure gut clearance depuration period with or without food. We found that changes in environment can affect LC<sub>50</sub>. We also found no difference in silver load between animals fed or not fed during the 1.5-hour gut clearance, which indicates the silver detected in hemolymph is not a result of puncturing the gut during hemolymph extraction. spICPMS also detected larger silver species in *Daphnia* following Ag<sup>+</sup> exposure, which indicates the animals may form biological silver nanoparticles *in vivo*.

**396 Assessing the Ecological Risk of Nano Silver: A Perspective Based on Current Knowledge** S.A Diamond, U.S. EPA / MED, U.S. EPA / Mid-Continent Ecology Division, U.S. EPA / MED. The development of nanotechnology has led to the creation of a variety of materials having unusual and potentially beneficial properties. Among these materials, nano-silver (n-Ag; having approximate dimensions between 1 and 100 nm) shows particular promise due to its ease of incorporation into fabrics, polymers, porous silica and other materials, where its antimicrobial activity can be of great economic, environmental, and societal benefit. In addition, n-Ag has relatively large surface area per volume, the potential for tightly controlled release of free silver, and exhibits novel quantum properties including strong absorbance and fluorescence signatures that indicate the potential for its use in a broad range of applications other than antimicrobial. These properties also suggest a capacity for production of ROS in some systems. Recent ecotoxicological research indicates that, in many systems (particularly aquatic) degradation of n-Ag (release of free Ag species) is the primary pathway for exposure and effects, suggesting that fate processes elucidated for ionic silver can accurately predict hazard where rates of degradation are defined. Generation of ROS has also been shown to contribute to toxicity. Fate studies have defined degradation rates and also demonstrated the concomitant generation of peroxide; which might explain ROS-related toxicity for n-Ag. All of these processes have been shown to be strongly dependant on the form or structure of n-Ag, e.g. coated, embedded, functionalized, or varying in crystal structure. These and other key risk assessment issues and regulatory challenges associated with n-Ag will be discussed relative to recent research findings.

**397 Characterization of freshwater natural dissolved organic matter (DOM): quality perspectives for direct and indirect interactions with organisms** H. Al-Reasi, McMaster University / Department of Biology; S. Smith, Wilfrid Laurier University / Department of Chemistry, Wilfrid Laurier University / Chemistry; C.M. Wood, McMaster University / Department of Biology. Direct and indirect influences on aquatic organisms in the presence of different sources of dissolved organic matter (DOM) have been revealed, but many have exhibited unexplained, source-dependent variability. As an attempt to understand the role of DOM quality, various freshwater DOMs were characterized by absorbance and fluorescence spectroscopy and potentiometric titration. Specific absorptivities at 254, 340 and 436 nm (SUVA<sub>254</sub>, SAC<sub>340</sub>, and SCOA<sub>436</sub>) were indices of aromatic carbon composition and colored content. Absorbance ratios of Abs<sub>254/365</sub> and Abs<sub>octanol 254</sub>/Abs<sub>water 254</sub> were used as molecular weight index and as octanol solubility index of DOMs, respectively. Fluorescence index was employed to classify DOMs and the excitation-emission fluorescence spectra were resolved by parallel factor analysis (PARAFAC) resulting in four fluorescent components (humic-like, fulvic-like, tryptophan-like, and tyrosine-like). Magnitude of all measures varied widely between DOM samples, indicating substantial differences in term of compositional and molecular nature and corroborating the use of absorbance and fluorescence measurements in addressing the issue of quality of heterogeneous DOMs. Aromaticity (SAC<sub>340</sub> and SUVA<sub>254</sub>), content of colored moieties (SCOA<sub>436</sub>) and the relative concentration of humic-like fluorophore showed an ascending source dependent continuum from autochthonous to terrigenous DOMs, molecular weight index (Abs<sub>254/365</sub>) and the relative concentration of fulvic-like fluorophore demonstrated a descending trend. Autochthonous DOMs had relatively higher magnitudes of octanol solubility, tryptophan- and tyrosine-like composition than the terrigenous isolates. Acid-base

titrations revealed the dominance of carboxylic and phenolic ligands with a trend for more autochthonous source to have higher total proton binding capacity. With the introduction of a summary parameter, referred to as the tridentate index, it is possible to directly relate optical characteristics, i.e., SAC<sub>340</sub>, and chemical (proton) reactivity. Metal reactivity is related to proton reactivity; thus, the tendency observed in the literature that darker organic matter is more protective in metal toxicity studies can now be rationalized on a mechanistic basis. The optical indices described above may provide clues for justifying the unsolved variations of direct and indirect influences on aquatic organisms in the presence of DOMs.

**398 Does ecosystem disturbance influence the toxicity mitigation quality of natural organic matter?** K.C Livingstone, J. McGeer, Wilfrid Laurier University / Department of Biology. Natural organic matter (NOM) has an important role in the recovery of damaged aquatic systems, particularly those impacted by metals. This aim of this study is to examine the influence of NOM source quality on acute Cu toxicity to the freshwater amphipod *Hyalella azteca*. Acute toxicity tests (96h) were done according to standard (Environment Canada) methods, with tests being completed in duplicate using 10 *Hyalella* (2-9d) added to solutions of Cu (0-4µM) and NOM sources at a DOC concentration of 5 mg C/L. NOM was collected by reverse osmosis from sites that had been disturbed by logging, fire, or long term smelter emissions. Culture and test solutions were kept at pH 7.1±0.1, 20-21°C, and hardness of 13 mg CaCO<sub>3</sub>/L. The LC50s for Cu-NOM solutions were significantly different, indicating variation in quality among NOM sources. Disturbed sites offered less protection against Cu toxicity than reference sites. Short-term (6h) Cu bioaccumulation studies were conducted to compare the effect of DOC (5 mg/L) on uptake; which varied in the severity of disturbance (undisturbed, fire, or logging). High levels of Cu were accumulated when no NOM was present and less was accumulated with NOM. The undisturbed site NOM was most effective in reducing short term Cu bioaccumulation while NOM from fire damaged and logging damaged sites were less effective, implying that both the type and severity of ecosystem disturbance has an influence on the protective capacity of NOM. Tests to compare the quality (based on toxicity mitigation) of NOM sources demonstrated clear differences that could be related to optical characteristics measured by absorbance and excitation emission matrix spectroscopy (EEMS). The absorbance of NOM sources at 340nm provided a clear correlation with the LC50 and may act as a rapid method for predicting NOM quality. EEMS, in conjunction with PARAFAC analysis, has been found to be useful in terms of modeling by taking into account the relative composition of each NOM source. Characterization of Cu-NOM solutions by ion selective electrode was used to establish links between the binding capacity and affinity of each NOM source in order to understand the role of ecosystem disturbance in protecting against Cu toxicity. An improved understanding of NOM quality can be useful in improving predictions of Cu toxicity in freshwater systems. This project is part of the TALER Research Program supported by NSERC, Vale and Xstrata.

**399 Investigations into the mechanisms of chronic nickel toxicity to freshwater pulmonate snail, *Lymnaea stagnalis*** S. Niyogi, University of Saskatchewan / Department of Biology; K.V. Brix, M. Grosell, RSMAS, University of Miami. The freshwater pulmonate snail, *Lymnaea stagnalis*, is known to be extremely sensitive to multiple metals including Ni. An EC10 of < 2 µg l<sup>-1</sup> Ni for juvenile snail growth has recently been estimated for this species, which is well below the current USEPA chronic water quality criterion for Ni. We characterized ionoregulation and acid-base balance in juvenile (~10 day post-hatch) *L. stagnalis* to understand the potential mechanisms of chronic Ni toxicity. Individual snails were exposed to an increasing range of waterborne Ni concentration (0, 1, 2, 4, 8 and 16 µg l<sup>-1</sup>, n=10 per treatment) in 150 ml polythene containers for 24 days. The exposure water was exchanged fully every day, and the snails were supplied daily with a piece of fresh lettuce as food. The results showed a dose-dependent decrease in average growth rate (g wet weight per day), with approximately 3-fold reduction at the highest exposure dose during day14-21. The net Ca<sup>2+</sup> flux rate also remained suppressed at concentrations >2 µg l<sup>-1</sup> Ni during the entire exposure period, and this effect was most pronounced on day 14 with a 55% reduction at 16 µg l<sup>-1</sup> Ni exposure. Snails were sacrificed at the end of the exposure, and hemolymph and soft tissue were collected for the analysis of essential ions, acid-base parameters (pH and total CO<sub>2</sub>), and Ni accumulation. A dose-dependent decrease in hemolymph Ca<sup>2+</sup> concentration was observed at the end of the exposure, however hemolymph Mg<sup>2+</sup> and Na<sup>+</sup>

levels remained unaltered. In contrast, both  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  concentrations in the soft tissue decreased by 25-35% at  $>4 \mu\text{g l}^{-1}$  Ni exposure. In addition, a marked dose-dependent increase in hemolymph pH was recorded, indicating alkalosis of extracellular fluid in juvenile snails following Ni exposure. In agreement with this observation, a concurrent increase in hemolymph total  $\text{CO}_2$  level was also observed at  $2\text{-}16 \mu\text{g l}^{-1}$  Ni exposure. Finally, Ni accumulation in soft tissue increased in a dose-dependent manner, and exhibited a strong negative correlation with the hemolymph  $\text{Ca}^{2+}$  level. Interestingly though, analogous experiments suggested no direct interaction of water-borne  $\text{Ni}^{2+}$  and  $\text{Ca}^{2+}$  uptake in *L. stagnalis*. Although the basis of Ni/Ca interaction remains to be elucidated, our findings suggest that Ni causes chronic toxicity to *L. stagnalis* by inducing ionoregulatory and acid-base disturbance.

#### 400 The toxicity of aluminum to 6 different aquatic species, at a pH of 6

**B.A. Stubblefield**, Oregon State University, Oregon State University / Environmental and Molecular Toxicology; **A.S. Cardwell**, Oregon State University / Faculty Research Assistant; **B.J. Adams**, Rio Tinto / Product Stewardship; **B.W. Gensemer**, GEI Consultants / Ecological Division; **E. Nordheim**, EAA; **R.C. Santore**, HDR|HydroQual, Inc. An extensive number of studies were undertaken to assist with the assessment of the impact of water chemistry on the toxicity of soluble aluminum salts. The studies consisted of a series of chronic toxicity tests conducted with freshwater organisms. Aluminum toxicity is a function of its speciation and this is a function of water pH. Previous chronic toxicity tests with aluminum were typically conducted under acidic test conditions and few studies have been conducted at pHs more typical of natural surface waters. These studies investigated the chronic toxicity of aluminum at pH 6.0 to six freshwater species. The species tested were the great pond snail (*Lymnaea stagnalis*), a rotifer (*Brachionus calyciflorus*), an aquatic oligochaete (*Aeolosoma sp.*), an aquatic plant (*Lemna minor*), and two fish, the fathead minnow (*Pimephales promelas*) and zebrafish (*Danio rerio*). Chronic test durations ranged from 48 hours to 35 days. The most sensitive species was the zebrafish ( $\text{EC}_{10}$  150.1  $\mu\text{g/L}$  total aluminum; in water of a hardness of 100  $\text{mg/L}$  as  $\text{CaCO}_3$  and dissolved organic carbon of 0.51  $\text{mg/L}$ ) based on growth effects. The least sensitive species was *Lemna minor*, with an  $\text{EC}_{10}$  of 2175  $\mu\text{g/L}$  total aluminum (in water of a hardness of 32  $\text{mg/L}$  as  $\text{CaCO}_3$  and dissolved organic carbon of  $< 0.50 \text{ mg/L}$ ) as total dry weight. The results of these tests will contribute to a greater understanding of aluminum toxicity at circumneutral pH ranges in surface waters.

#### 401 Understanding the importance of latent toxicological effects: embryonic cadmium exposure produces less fit adults in a freshwater snail

**D.A. Kimberly**, Texas Tech University / Environmental Toxicology, Texas Tech University / TIEHH; **C.J. Salice**, Texas Tech University / Environmental Toxicology, Texas Tech University / TIEHH, Texas Tech University / Department of Environmental Toxicology. Latent effects are defined here as adverse effects in juvenile or adult stages as a result of early development exposure. These effects have been documented in a multitude of taxa after exposure to toxicants including metals and pesticides. However, the extent to which latent effects alter natural populations are largely unexplored. One unexplored avenue of research is how exposure to toxicants during early development influences subsequent responses to stress in later life stages. The objective here was to understand how early life stage exposure to cadmium influences later life stage exposures to either cadmium or temperature stress in the freshwater gastropod, *Physa pomilia*. Thirty  $< 24$  hour old egg masses from laboratory reared *P. pomilia* were divided among three initial treatments including control, 2.5ppb, and 10ppb. At hatching (6-9 days), all snails were transferred to clean water. At 21 days after hatching, snails were divided among four secondary treatments, including control, 50ppb, 150ppb, and 35C. Each secondary treatment consisted of 4 replicates with four snails in each replicate. Time to first reproduction, egg mass density, hatching success and size were recorded. Overall, snails exposed to cadmium initially and temperature secondarily were most adversely affected. For example, time to first reproduction was significantly longer for animals exposed to cadmium and then temperature with the first egg mass observed around 42 days (control snails produced eggs in 30 days) from the start of the experiment. Snails exposed to cadmium initially and secondarily did not exhibit as severe adverse responses as those exposed to temperature but more severe than animals among the cadmium initial/control secondary treatments. Surprisingly, animals exposed to cadmium in the egg mass but nothing secondarily showed significant adverse effects compared to overall

controls indicating an important latent effect of early exposure to cadmium. The effects of embryonic cadmium exposure manifested across all fitness related responses. Our research shows that animals exposed in an early life stage (egg mass) can show significant latent adverse effects. Because most experiments dealing with toxicant exposures make observations over a single life stage, latent effects will go largely unnoticed. As a result, latent effects may have a large impact on future susceptibility to novel stressors and thus influence individual survival and population persistence.

#### 402 Correlating Zn and Cd elimination rate constants across taxonomic groupings

**M.D. Poteat**, North Carolina State University / Department of Environmental and Molecular Toxicology, North Carolina State University / Dept. of Environmental and Molecular Toxicology; **D.B. Buchwalter**, North Carolina State University / Department of Environmental and Molecular Toxicology, North Carolina State University / Department of Environmental & Molecular Toxicology. Biodynamic modeling has emerged as a powerful tool for understanding and predicting metal accumulation in aquatic organisms. Of the parameters that feed biodynamic models, the rate constant of loss ( $k_e$ ) has proven to be the most sensitive factor in determining metal accumulation in organisms. We measured Zn and Cd  $k_e$ 's following dissolved exposures with 65-Zn and 109-Cd in 11 species of aquatic insects representing the families Hydropsychidae and Ephemerellidae. The  $k_e$ 's ranged 9.8-fold for Zn and 14-fold for Cd and were strongly correlated across species ( $r=0.93$ ,  $p<0.0001$ ). The strength of this correlation allowed us to test predictions of Zn elimination in three additional insect species based on pre-existing data for Cd. All measured Zn  $k_e$ 's fell within the 95% confidence interval of the regression with observed values averaging 8% deviation from predicted values. To explore whether this relationship between Cd and Zn  $k_e$ 's was limited to insects, we further explored the correlation of Zn and Cd  $k_e$ 's in reported literature for 17 other species in varying taxonomic groups. A global analysis of all species shows that Zn and Cd  $k_e$ 's are well correlated whether analyzing data with conventional or phylogenetic statistics. Interestingly, different faunal groups had distinct slopes when Zn  $k_e$  was regressed against Cd  $k_e$  (aquatic insects:  $m=0.79\pm0.1$ , bivalves:  $m=1.11\pm0.2$ , and fish:  $m=0.46\pm0.2$ ), yet correlations remained high between the metals within faunal groups. Significant correlations between Cd and Zn  $k_e$ 's were found within bivalves ( $r=0.86$ ,  $p<0.0001$ ) and fish ( $r=0.65$ ,  $p=0.02$ ) when including all possible routes of metal exposure (dissolved, pulse, and dietary exposure). Exposure route appears to be an important consideration however. When only analyzing  $k_e$ 's for all organisms exposed to dissolved Zn and Cd,  $k_e$ 's were strongly correlated ( $r=0.84$ ,  $p<0.0001$ ). However, there was no correlation of Zn and Cd  $k_e$ 's for organisms exposed via diet, nor were trends apparent with respect to the magnitude of dissolved and dietary  $k_e$ 's. Certain species showed unique trends in elimination. In *Daphnia magna*, Zn  $k_e$ 's were an average of 3-fold higher than Cd  $k_e$ 's following dietary exposures and an average of 9.5-fold higher following dissolved exposures. It may be possible to predict the  $k_e$  of one metal from existing data for the other (for Cd and Zn) when taxonomic position and mode of uptake are taken into consideration.

#### 403 Intracellular Speciation of Pb in the Green Alga C. reinhardtii using High Energy Resolution Fluorescence Detected X-ray Absorption Spectroscopy

**T. Stewart**, Swiss Federal Institute of Aquatic Science & Technology / Environmental Ecotoxicology, Swiss Federal Institute of / Aquatic Science & Technology; **J. Szelachetko**, PSI, Paul Scherrer Institute / Bioenergy and Catalysis Laboratory; **R. Behra**, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Ecotoxicology; **L. Sigg**, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; **M. Nachttegaal**, PSI, Paul Scherrer Institute / Bioenergy and Catalysis Laboratory. Metal bioavailability and toxicity can often be predicted by solution chemistry and related to intracellular accumulation. Use of spectroscopic methods like X-ray Absorption Spectroscopy (XAS) can help to determine intracellular metal speciation, furthering insights into mechanisms of toxicity and detoxification. High-energy resolution fluorescence detected (HERFD)-XAS was used to obtain information on the intracellular speciation of Pb in the model green alga, *C. reinhardtii*. Obtaining structural information of Pb complexes with traditional XAS spectroscopy is difficult, as the lone pair of electrons leads to poorly defined Pb-ligand bond distances. With HERFD-XAS the detection of the fine structure in the absorption edge region of the spectrum is possible. A short-term exposure (0.1  $\text{mM Pb}^{2+}$ , 10  $\text{mM MOPS}$ , pH 7) using exponentially growing cells was conducted, and an EDTA wash was used to

remove cell surface bound Pb. PbO, PbS, PbAcetate, Pb(OH)<sub>2</sub>, Pb<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, Pb(NO<sub>3</sub>)<sub>2</sub>, PbGly, PbCys, and PbGSH were used as references for Pb bound to different functional groups. For each compound, the Pb L<sub>3</sub> absorption edge (13000 – 13100 eV) was probed and fluorescence emission, spanning the L<sub>α1</sub> and L<sub>α2</sub> emission energies, was detected yielding full 2-D resonant inelastic X-ray scattering (RIXS) maps. The RIXS maps allow discrimination between O and S ligands. Furthermore, RIXS planes of references show unique features, allowing conclusions to be made about the type of Pb complex. Fitting of reference RIXS plane to the algae sample revealed that intracellular Pb speciation is a mix of S ligands (63%) and Pb<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> (37%). This *in vivo* study suggests the importance of not only S ligands, but also of Pb phosphate in metal detoxification.

**404 Is Pb internalization by *Chlamydomonas reinhardtii* limited by diffusion? Comparison of observations vs. theoretical predictions** P. Sanchez Marin, Institut National de la Recherche Scientifique / Centre Eau Terre Environnement, INRS-ETE / INRS-ETE; C. Fortin, INRS – Eau, Terre et Environnement / Université du Québec, Université de Québec / INRS-ETE; P.G. Campbell, Université de Québec / INRS-ETE. The flux of lead (Pb) internalization by the unicellular alga *Chlamydomonas reinhardtii* has been observed to be surprisingly high for a non essential metal. In the presence of carbonate as an inorganic ligand and for a given [Pb<sup>2+</sup>], Pb internalization was higher than in the absence of binding ligands. Over a common range of free Pb<sup>2+</sup> concentrations, according to the biotic ligand model (BLM), similar uptake was expected. The enhanced internalization in the presence of carbonate was observed only at Pb<sup>2+</sup> concentrations lower than 50 nM. One plausible explanation for these results would be that the uptake of Pb by this alga is limited by the diffusion of Pb<sup>2+</sup> ions towards the cell surface. If the alga takes up Pb<sup>2+</sup> at a higher rate than the rate of supply of free Pb<sup>2+</sup> by diffusion, there will be depletion of Pb<sup>2+</sup> ions in the vicinity of the cell. The presence of complexes that can dissociate in the diffusion layer surrounding the alga would attenuate this depletion, therefore possibly enhancing Pb uptake. In order to check if this process is taking place for *C. reinhardtii*, three different approaches were used: (1) First of all, simple calculations of the maximum diffusive flux of Pb towards the cell surface were made to see if the predicted flux was higher or similar to the observed internalization fluxes; (2) Pb uptake in the presence of other ligands (citrate, iminodiacetate) was evaluated to see if their presence also increased Pb internalization at low Pb<sup>2+</sup> concentrations as observed with carbonate; and (3) A flow-through experiment was performed to evaluate if an increase in flow regimes – and concomitant decrease in diffusion layer thickness – had an effect on Pb internalization fluxes in the absence of ligands. The different Pb complexes tested affected Pb internalization in different ways; some of the ligands increased Pb uptake whereas others did not. The observed results are compared with theoretical predictions of Pb fluxes, considering the degree of lability of the different Pb complexes. This study will contribute to the refinement of predictive models such as the BLM.

**405 Is it time for Environment Canada to turn the page on the *Hyaella azteca* standard method?** L. Taylor, Environment Canada; J. Miller, Miller Environmental Sciences Inc.; L. Van der Vliet, P. Jackman, R. Scroggins, Environment Canada. The Environment Canada (EC) standardized test method for *Hyaella azteca* (EPS 1/RM/33; Biological Test Method: Test for Survival and Growth in Sediment using the Freshwater Amphipod *Hyaella azteca*) was originally published in 1997. Over the past fifteen years, several technical advancements have been made to the 14-day survival and growth test which requires updating the 1<sup>st</sup> edition. Most notably, the EC Atlantic Laboratory for Environmental Testing conducted experiments to refine specific aspects of the new test design for a water-only exposure (note: this type of exposure is completely new to the 2<sup>nd</sup> edition). In addition, new guidance regarding updated statistics, conducting field replicates, barcoding for taxonomic identification, the use of solvent and negative controls and the implementation of water quality thresholds for triggering renewal will be included in the new 2<sup>nd</sup> edition scheduled for release later this year. Aside from these and other technical additions, the method also requires a general overhaul. This includes for example, contrasts to other *Hyaella azteca* methods from different agencies (i.e., US EPA, ASTM, ISO) for harmonization purposes and the mutual recognition of data.

**406 Results of 10, 28, and 42-day feeding trials with *Hyaella azteca* after additions of bromide and chloride to well water** H. Krueger, Wildlife International, LTD / Aquatic Toxicology, Wildlife International, LTD;

S. Thomas, N. Billa, Wildlife International, LTD. Many laboratories are working on feeding trials with *Hyaella azteca* in order to improve survival and growth in the 10-day test and survival, growth, and reproduction in the 42-day test. The *Hyaella azteca* advisory group (HAAG) has been sharing information among labs that are working on improving these endpoints. Our lab has been working on feeding trials in formulated sediment test systems and also in water only exposures. Well water is used in these trials with additions of chloride and bromide. Before these additions were made we did not see good survival, growth, or reproduction in trials. Feeding rates also have been ramped up during trials as suggested by other HAAG trials. We have tested several types of food including YCT and Tetramin flake food in suspension. These diets have been tested with and without supplements of Navicula (a diatom). The additions of bromide to 20 ppb and chloride to 20 ppm in well water, as well as ramping up feeding rates seem to have had the most dramatic effects on survival, growth, and reproduction, since all have been greatly improved regardless of food types. Increases in growth at 10 and 28 days have easily met the new proposed criteria a 2.5x increase in weight at 10 days and a 10x increase in weight at 28 days. Results of past trials and trials currently running will be presented to evaluate the reproducibility of results.

**407 Benefits of biofilm in optimizing survival, growth, and reproduction of the amphipod *Hyaella azteca* in static-renewal, water only exposures** D. Soucek, Illinois Natural History Survey / Illinois Natural History Survey, Illinois Natural History Survey / Illinois Natural History Survey, Institute of Natural Resource Sustainability / Illinois Natural History Survey; A. Dickinson, K. Major, Illinois Natural History Survey. While the amphipod *Hyaella azteca* has been used for decades in toxicity tests, and standardized sediment toxicity testing guidelines have been developed for this species by U.S. EPA and ASTM, no standardized chronic water-only toxicity testing methods have been established. The recommended diet for sediment toxicity testing is a commercially available Yeast-Cereal leaves-Trout chow (YCT) mixture, but a wide variety of foods and test waters are used by toxicology researchers for culturing and testing of this species. This variation may be contributing to a range of culture health conditions that may lead to inconsistencies among laboratory testing results. We conducted nine 42-d static-renewal exposures with *H. azteca* using a variety of different foods as treatments to determine if there is a combination that consistently produces high survival, growth and reproduction. Our first important finding was that Nitex screens covered with a thin biofilm consisting of water mold, green algae, and stalked ciliates consistently produced high survival (>90%), growth (frequently > 0.9 mg dry weight) and reproduction (frequently > 10 young per female) with relatively low coefficients of variation, whereas using clean Nitex screens with no biofilm but otherwise the same diet produced highly variable results. While biofilm appears to be beneficial, standardization would be difficult. Therefore we tested a diet of three commercially available diatoms, added with Tetramin, as an alternative to natural biofilms, and observed survival, growth, and reproduction comparable to and in some cases greater than that observed with the biofilm treatments. The Tetramin plus diatom combination is a good candidate for a standardized diet for *H. azteca* in chronic, static-renewal, water-only toxicity tests.

**408 Evaluation and improvement of sediment and water-only exposure methods for *Hyaella azteca*** D.R. Mount, US Environmental Protection Agency / ORD; T.L. Highland, US EPA / ORD, NHEERL, Mid-Continent Ecology Division; J.R. Hockett, U.S. EPA / Mid-Continent Ecology Division; D. Hoff, US Environmental Protection Agency / ORD, NHEERL, Mid-Continent Ecology Division, Ecotoxicology Analysis Research / Mid-Continent Ecology Division; C. Jenson, U.S. EPA; T.J. Norberg-King, U.S. EPA / ORD, NHEERL, Mid-Continent Ecology Division, US EPA / Mid-Continent Ecology Division; T.W. Valenti, Syngenta Crop Protection LLC / National Research Council, National Research Council / U.S. Environmental Protection Agency. The amphipod *Hyaella azteca* is widely used as a test organism in a variety of short-term and chronic toxicity tests in both sediment and water-only exposures. Many such tests are conducted according to, or using modifications of, sediment test guidelines developed by ASTM and U.S. EPA in 2000. Recently, we have completed a number of experiments evaluating performance under those previous guidelines, and exploring ways to improve and refine test guidelines. Perhaps the most significant finding is that the feeding regime used in the existing guidelines (1 ml of yeast/cereal leaves/trout chow slurry per day per chamber) becomes limiting to *Hyaella* in exposures longer than 10 days, and much

higher growth and reproduction rates can be achieved with larger rations or alternate diets. Multiple experiments were conducted evaluating alternate foods, and various feeding rations. Given that *Hyalella* increase in mass approximately 40-fold during a 42-day chronic test, the traditional approach of feeding a single fixed ration for the entire test seems inappropriate. Using a diet comprised of wheatgrass powder and flaked fish food, we evaluated a number of profiles of increasing ration to determine regimes that would provide high rates of growth while avoiding excess feeding. These alternate feeding schedules are shown to produce considerably higher growth and reproduction rates than were typical under the previous ASTM or U.S. EPA guidance, with 42-d weights of *Hyalella* in excess of 0.8 mg dwt/individual and reproduction well over 10 young per female. Results of experiments evaluating other aspects of test procedures are also discussed and incorporated into recommendations for consideration in the refinement of future test methods for conducting water or sediment exposures with *Hyalella*.

**409 How Good Should Control Sediment Be?** P.J. Lasier, USGS-Patuxent Wildlife Research Ctr. / University of Georgia; M.L. Urich, USGS-Patuxent Wildlife Research Ctr. Acceptable performance of the freshwater amphipod, *Hyalella azteca*, in sediment exposures is based on growth within control treatments that often consist of quartz sand. However with the standard food allocation (1 ml Y-C-T/d), growth using this substrate can be inconsistent and marginal. A week-by-week comparison was conducted over 28 days to determine differences in growth between treatments of sand and sand amended with a small amount of conditioned alfalfa (0.24%), and between treatments of the standard feeding regime and one in which the allocation of food is doubled after two weeks. Length and weight were significantly greater ( $\alpha \leq 0.05$ ) in exposures to the amended sediment, and the increased food allocation resulted in significantly greater weight after 21 and 28 days and significantly greater length after 28 days. Growth of amphipods in sand exposures receiving the standard diet was only slightly above the acceptable minimum. With additional food, amphipod growth increased in sand exposures but remained well below levels observed in the amended-sand treatments. Mean length of amphipods exposed to the amended-sand treatments and fed the standard diet was similar to lengths observed in previous exposures of *H. azteca* to natural sandy sediments with similar organic content. Animals in amended-sand treatments receiving additional food grew the largest. Increasing the food ration will most likely increase amphipod growth in all treatments and maintain the disparity between control and natural sediments. Satisfactory growth that is comparable with exposures to natural sediments can be obtained with the standard diet using amended sand.

**410 Relationship of metals, bifenthrin, habitat, sediment parameters and water quality conditions to *Hyalella sp.* abundance in urban California streams** L.W. Hall, University of Maryland / Wye Research & Education Center; R. Anderson, University of Maryland. The objectives of this study were to determine the relationship between *Hyalella sp.* abundance in four urban California streams with the following parameters: (1) 8 bulk metals (As, Cd, Cr, Cu, Pb, Hg, Ni, and Zn) and their associated sediment Threshold Effect Levels (TELs); (2) bifenthrin sediment concentrations; (3) 10 habitat metrics and total score; (4) grain size (% sand, silt and clay); (5) Total Organic Carbon (TOC); (6) dissolved oxygen and (7) conductivity. California stream data used for this study were collected from Kirker Creek (2006 and 2007), Pleasant Grove Creek (2006, 2007 and 2008), Salinas streams (2009 and 2010) and Arcade Creek (2009, 2010). *Hyalella* abundance in the four California streams declined when metals concentrations were elevated beyond the TEL. There was also a statistically significant negative relationship between *Hyalella* abundance and % silt for these 4 California streams as *Hyalella* were not found in silt areas. No statistically significant relationships were reported between *Hyalella* abundance and metals concentrations, bifenthrin concentrations, habitat metrics, % sand, % clay, TOC, dissolved oxygen and conductivity. The results from this study highlight the complexity of assessing which factors are responsible for determining the abundance of amphipods, such as *Hyalella sp.*, in the natural environment.

**411 An evaluation of the sensitivity of lab-reared and field-collected *Hyalella azteca* to the pyrethroid insecticide bifenthrin** S. Clark, S. Ogle, A. Gantner, Pacific EcoRisk; G. Mitchell, FMC Corporation. *Hyalella azteca* are epibenthic macroinvertebrates commonly used for sediment toxicity studies. *H. azteca* has also recently seen considerable use in toxicity

tests of water samples in California, as the organisms are reported to be more sensitive to pyrethroid insecticides than other routine invertebrate toxicity test species (e.g., *Ceriodaphnia dubia*). Resident *H. azteca* are known to occur, at times in abundance, in some sediments containing pyrethroid pesticides concentrations that are toxic to lab-reared *H. azteca*. This suggests potential significant differences in the sensitivity of lab-reared and resident field populations of *H. azteca* to pyrethroids. The goal of this study was to determine the sensitivity of various *H. azteca* populations, including field populations, to the pyrethroid bifenthrin. For the first phase of this study, *H. azteca* were collected from Pleasant Grove Creek, a Northern California site with a historical record of robust populations of *H. azteca* and which is dominated by residential land use. Lab-reared *H. azteca* were obtained from a widely used commercial vendor, and were 7-14 days old (and within 2 days of age) when initiating testing. Since the field organisms could not be aged, they were sieved to obtain a size close to that of the lab-reared organisms. The *H. azteca* were exposed to nominal concentrations of 0.89, 2.7, 8, 24, and 72 ng/L bifenthrin in water for 96-hours (the reported 96-hr LC<sub>50</sub> for bifenthrin toxicity to *H. azteca* is 7.7 ng/L). The resulting LC<sub>50</sub> was 10.6 ng/L and >72 ng/L for the lab and field *H. azteca*, respectively. Based on these results, a follow-up exposure was performed with higher concentrations of bifenthrin. The resulting LC<sub>50</sub> was 2.7 ng/L and >388 ng/L for the lab and field *H. azteca*, respectively, a difference of greater than two orders of magnitude. These results demonstrate that lab-reared *H. azteca* were far more sensitive to bifenthrin than the field-collected organisms. In order to determine how common such differences in sensitivity are, testing is underway with *H. azteca* collected from additional sites influenced by urban and agricultural runoff, as well as from remote sites that are not expected to receive urban and/or agricultural runoff. In addition, the sensitivity of multiple sources of lab-reared *H. azteca* cultures is being evaluated.

**412 Variation in contaminant sensitivity among *Hyalella azteca* from different sources** D. Weston, University of California / Department of Integrative Biology; H.C. Poynton, US Environmental Protection Agency / Molecular Indicators Research, University of Massachusetts-Boston / Environmental, Earth and Ocean Sciences; G. Wellborn, University of Oklahoma; M. Lydy, Southern Illinois University. There have been reports of water or sediment samples causing toxicity when tested in the laboratory with *Hyalella azteca*, yet the same waterbodies contain thriving populations of the same species. To further explore these reports, the sensitivity of ten populations of *H. azteca* to pyrethroid insecticides was determined. Three populations were from established laboratory cultures, and seven were from wild collections. The three lab cultures, and some of the wild populations, shared comparable sensitivity to pyrethroids, with LC50s within a factor of three of one another. Yet some field populations had LC50s two orders-of-magnitude greater. The relative sensitivity to pyrethroids did not appear to be a function of the extent of prior pyrethroid exposure within the habitat from which they were collected. However, pyrethroid sensitivity was related to the degree of genetic similarity among the populations. DNA sequencing was consistent with previous findings that *H. azteca* represents not a single species, but a species complex. Based on the genetic data, four members of this complex appeared to be represented within the ten populations we examined, and one member in particular was extraordinarily tolerant of pyrethroids. These findings have ramifications for use of *H. azteca* in toxicity testing, related to the source of the animals used, and how cultures are maintained.

**413 Agrichemicals and Sediments: The Hourglass** A.S. Kolok, University of Nebraska Medical Center / Environmental, Agricultural and Occupational Health, University of Nebraska – Omaha / Nebraska Watershed Network, University of Nebraska – Omaha / Department of Biology; S. Bartelt-Hunt, University of Nebraska – Lincoln; M. Sellin, Department of Zoology. Research in two watersheds within Nebraska over the past few years suggests that the fate and transport of agrichemicals is different from that for estrogenic contaminants being released from wastewater treatment plants. Wastewater treatment plants continually release estrogenic compounds into the receiving waters. As such, the endocrine disrupting compounds (EDCs) are pseudo-persistent in the waters downstream from the discharge. These compounds may be subject to biodegradation, however their concentration in the water may not decrease over time, as the compounds are continually recharged by the additional, continuous discharge. As such, the chemical plume may resemble an "eternal flame" of discharge as it moves downstream. In contrast, agrichemical contaminants are only released from fields

during storm events. EDCs will only be found in the receiving streams for only a short time after a storm event. As such, it would seem that the agricultural exposure to the local biota would be limited to a relatively short period of time. Recent research in our laboratory has suggested that in environments with episodic pulses of water-borne agricultural chemicals, the sediment plays a very important role. During the chemical pulse, the sediment loads with agricultural chemical, which then gradually desorbs from the sediment and re-enters the water in a bio-available form. Rather than being pseudo-persistent, chemicals in this environment are only episodically available to the local biota, but this episodic exposure lasts longer than expected due to the role of the sediment as both a sink and a source. Conceptually, the sediment resembles an hourglass, where a storm event can load the sediment with chemical (the resetting of the hourglass) that gradually desorbs and moves downstream (much the same as sand moving from the upper to the lower bulb within an hourglass). Previously published data from our lab and others will be presented to substantiate this conceptual model.

#### 414 An Evaluation of Linking QSARs with Interspecies Correlation Estimation (ICE) Models to Develop Screening Level Water Quality Criteria

**S.D. Dyer**, The Procter & Gamble Company / Central Product Safety, The Procter & Gamble Company / Miami Valley Innovation Center, The Procter & Gamble Company / Miami Valley Labs; S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship Organization, The Procter & Gamble Company / Central Product Safety Department; J. Chaney, M. Fan, The Procter & Gamble Company; K. Mayo, USEPA; S. Raimondo, United States Environmental Protection Agency / Gulf Ecology Division, National Health and Environmental Effects Laboratory, US EPA / Gulf Ecology Division; M.G. Barron, US EPA / Gulf Ecology Division; F. Wu, State Key Laboratory of Environmental Criteria and Risk Assessment. Interspecies Correlation Estimation (ICE) models have been developed and North American species models are publicly available via [www.epa.gov/ceampub/fchain/webice/](http://www.epa.gov/ceampub/fchain/webice/). Until this year, aquatic models were restricted to invertebrates and fish species; however, several algal ICE models are now being added. ICE models provide the unique opportunity to predict several species toxicity values based on a surrogate species toxicity value. Including the predicted species toxicity values in a species sensitivity distribution (SSD), one can predict the 5<sup>th</sup> percentile hazard concentration (HC5). For the first time, HC5s can be developed for all three trophic levels based on ICE models. Furthermore, predicted species values for all 3 trophic levels can be combined to creating an "ecosystem" HC5. In this presentation we specifically explore the use of ICE models for chemicals that are known to be especially toxic to each respective trophic level. While the use of ICE models provides an alternative to deriving predicted no effect concentrations (PNECs) without an assessment factor, the potential to link ICE to QSARs (such as Ecosar) provides another opportunity to explore the development of screening level water quality criteria (PNECs) based on minimal datasets. Here again we explore the use of QSARs that clearly show trophic sensitivity, hence its effect on trophic HC5s and ecosystem HC5s. Since Ecosar provides both acute and chronic values, we compare predicted acute and chronic SSDs and HC5s to measured SSDs and resultant HC5s.

#### 415 All ER Agonists Are Not Created Equal: Weaknesses of *in vitro* EEQs as Predictors of *in vivo* Estrogenic Effects in Fish

**E. Yost**, S.W. Kullman, North Carolina State University / Environmental and Molecular Toxicology. Activation of the estrogen receptor (ER) is a common mode of action for many endocrine-disrupting compounds, including steroid hormones as well as numerous xenobiotics. The estrogenic activity of compounds with this mode of action may be estimated using *in vitro* bioassays, such as the yeast estrogen screen (YES), which utilizes 17 $\beta$ -estradiol (E2 $\beta$ ) as a standard and reports the estrogenicity of a sample in terms of E2 $\beta$ -equivalents (EEQ) based on ligand interaction with the human ER  $\alpha$ . Assays such as the YES are useful as a high-throughput means of screening chemical compounds and environmental samples for estrogenic activity; however, there is concern that there may be a discrepancy between *in vitro* EEQs and actual toxic effects in aquatic organisms. In this study, we tested the hypothesis that YES-derived EEQs should be able to accurately predict the effects of estrogenic compounds on exposed male Japanese medaka, using the expression of estrogen-responsive genes (vitellogenin, choriogenin, and ER  $\alpha$ ) as a measure of estrogenic effects. Male medaka were exposed for 7 days to E2 $\beta$  at a concentration of 200ng/l, or to a suite of steroidal estrogens [estrone (E1), 17 $\alpha$ -estradiol (E2 $\alpha$ ), estril (E3)] or an environmental sample (effluent from an industrial swine operation) at

a YES-derived EEQ of 200ng/l. We found that these exposures did not elicit equal gene expression responses in the male medaka hepatocytes. The expression of estrogen-responsive genes was significantly lower in the E1-, E2 $\alpha$ -, and swine effluent-exposed fish, compared with fish that were exposed to E2 $\beta$  or E3. *Ex vivo* exposure of medaka livers to these same treatments elicited the same hepatic gene expression profiles as the whole-fish exposures, indicating that the discrepancy between the YES-derived EEQ and *in vivo* transcriptional effects in the medaka is likely not attributable to differences in absorption, distribution, metabolism, and excretion (ADME) of these compounds. Alternatively, these differences in gene expression may be attributable to molecular level events associated with differential receptor binding and transcriptional regulation in the Japanese medaka. These data indicate a significant discrepancy between YES-derived EEQs and the ability of to evoke estrogenic responses *in vivo*.

#### 416 Insights into the mechanisms of androgen-induced anal fin elongation in a potential bioindicator organism, the mosquitofish (*Gambusia spp*)

**E.K Brockmeier**, University of Florida / Physiological Sciences; Y. Ogino, T. Iguchi, Okazaki Institute for Integrative Bioscience; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology, University of Florida / Dept. of Physiological Sciences &. Bioindicator organisms can be used as sensitive indicators of the ecosystem level impacts of chemical exposure through the measurement of molecular or physiological endpoints. Currently, there is no bioindicator organism of androgen exposure for use in North America. The Eastern and Western mosquitofish (*Gambusia holbrooki* and *G. affinis*) have the potential to become such a bioindicator, since males have an elongation of the anal fin (gonopodium) whose formation is driven by androgens. Female mosquitofish do not have this anal fin elongation but the gonopodial structure can be induced by androgen exposure. To gain crucial knowledge for bioindicator development, we evaluated the expression patterns of three genes in the anal fins of androgen-exposed female mosquitofish: sonic hedgehog (shh), muscle segment homeobox C (msxC) and fibroblast growth factor receptor 1 (fgfr1). These genes have known roles in zebrafish fin growth and knowledge of their expression patterns during androgen exposure can provide insight into the genetic mechanisms of action of androgen-induced anal fin elongation. Adult female mosquitofish were exposed to the vehicle control or the potent androgen receptor agonist 17 $\beta$ -trenbolone (TB) at a dose that was able to induce anal fin elongation after 2 weeks of exposure (1  $\mu$ g TB/L). Spatial gene expression in the anal fin was determined qualitatively using whole mount *in situ* hybridization. Shh was strongly expressed at the distal tip of the anal fin rays of the gonopodium at 7, 14, and 21 days of TB exposure. MsxC and fgfr1 had a wider range of expression along the same anal fin rays but with stronger expression at day 10 and weaker expression at day 5. Because of its consistent expression during androgen exposure, the full coding sequence of shh was obtained to gain insight into this gene's function, its relationship to other species' shh proteins, and how it can be used in connection with anal fin elongation as a way to evaluate androgen exposure. The putative protein sequence was 76% homologous to zebrafish ShhA and over 80% similar to fugu fish and flatfish shh. Higher homology was seen in the N-terminal region where the active protein product is located (< 90% for zebrafish, fugu fish, and flatfish). This work provides insight into the mechanisms of action of androgen-induced anal fin elongation and can serve as a foundation for future work into developing a bioindicator of androgen exposure.

#### 417 Potential Role of the Gastric Sodium Iodide Symporter in Determining the Sensitivity of African Clawed Frog (*Xenopus laevis*) Tadpoles to Perchlorate

**J. Carr**, Texas Tech University / Biological Sciences Department; S. Murali, M. Wages, Texas Tech University; D.L. Carr, Texas Tech University / Biological Sciences; B. Butler, E. Smith, Texas Tech University. Perchlorate is a potent blocker of iodide transport by the sodium iodide symporter. Data from our laboratory suggest that there is a dramatic decrease in the sensitivity of African clawed frog tadpoles (*Xenopus laevis*) tadpoles to perchlorate inhibition of thyroid function and metamorphosis between Nieuwkoop-Faber stages 49-55. Presently, nothing is known about the physiological mechanisms underlying changes in the developmental sensitivity to perchlorate. We hypothesize that the availability of iodide from non-thyroid iodide transporting tissues increases between stages 49-55 and that increased iodide delivery to the thyroid mitigates the adverse effect of perchlorate. To test this hypothesis, we re-evaluated which epithelial and non-epithelial tissues express the NIS gene and protein based upon RT-PCR

and perchlorate-sensitive 24 h [ $^{125}\text{I}$ ] whole animal uptake studies in stage 58-60 *X. laevis* tadpoles. RT-PCR analysis revealed that NIS was expressed in stomach and small intestine in addition to the thyroid gland. NIS mRNA was not detected in lung, kidney, skin, gill, muscle, heart or liver. Perchlorate sensitive [ $^{125}\text{I}$ ] uptake was found in stomach, lung, kidney, and small intestine but not gill, muscle, liver, or heart. Perchlorate-sensitive [ $^{125}\text{I}$ ] uptake by stomach was 6-10 times greater than in any other non-thyroidal tissue. While NF stage 49 tadpoles exhibited perchlorate-sensitive uptake in stomach it was roughly 4-fold less than that observed in NF stage 55 tadpoles. Although expression of the NIS gene was greater in NF stage 55 compared to NF stage 49 tadpoles this difference was not statistically significant. We conclude that gastric iodide uptake increases between NF stages 49 and 55, possibly due to post-translational changes in NIS glycosylation or trafficking within gastric mucosal cells. These developmental changes in gastric NIS gene expression may affect iodide availability to the thyroid gland. (Supported in part by the U.S. Department of Defense, through SERDP under a Cooperative Agreement with the USAF, Inst. for Environ. Safety, and Occup. Health, Brooks AFB, TX).

#### **418 Physiological and reproductive effects of Se in rainbow trout, brook trout, and cutthroat trout – a comparative multigenerational study** N. Pilgrim, J. Rasmussen, University of Lethbridge; V.P. Palace, Department of Fisheries & Oceans Canada, Stantec Consultants; L. Ripley, Alberta Sustainable Resource Development; A. Hontela, University of Lethbridge / Dept. of Biological Sciences.

Selenium (Se), an essential element, toxic at concentrations only slightly higher than those required for homeostasis, can be a concern in the aquatic environment. Selenium can cause oxidative stress and malformations in salmonids, and the toxicity is species-specific. This study investigated the effects of chronic diet exposure to Se methionine (SeMet) at 15 µg/g and high 40 µg/g, on Se accumulation in eggs, liver and muscle, and physiological and reproductive endpoints in adult female rainbow trout, brook trout, and cutthroat trout. Adults were fed the experimental diets for 5 months prior to spawning, eggs were collected and fertilized, and adult tissues sampled. Larvae were raised in a vertical incubator until yolk absorption. Brook trout had a higher ratio of liver and muscle Se to egg Se than rainbow trout or cutthroat trout, and a higher ratio of plasma T3:T4 with increasing Se in liver and muscle. Species-specific differences were also detected in relationship between tissue Se and gonadal somatic index (GSI) and oxidative stress endpoints. Lipid peroxidation (LPO) and glutathione (GSH) increased with increasing liver Se in rainbow trout, GSH increased in cutthroat trout, but there was no significant relationship between liver Se and LPO or GSH in brook trout. Egg Se burdens were correlated with a decrease in survival in rainbow trout and cutthroat larvae at all developmental stages, while brook trout only had decreased survival in the first developmental stage (spawned eggs to eyed eggs). This study provides new information about species differences in sensitivity to Se and reproductive effects. (Funded by NSERC MITHE-SN and Alberta Conservation Association).

#### **419 Effects of dietary selenium exposure on swimming performance and energy homeostasis in juvenile fathead minnow** L. McPhee, University of Saskatchewan / Toxicology Centre; D. Janz, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / Veterinary Biomedical Sciences.

Selenium (Se) is known to cause chronic toxicity in aquatic species. In particular, dietary exposure of fish to selenomethionine (SeMet), the primary form of Se in the diet, is of concern. Recent studies suggest that chronic dietary exposure to SeMet alters energy and endocrine homeostasis in adult fish. However, little is known about the direct effects of dietary SeMet exposure in juvenile fish. The objective of the present study was to investigate sublethal physiological effects of dietary SeMet exposure in juvenile fathead minnow (*Pimephales promelas*). Twenty days-post-hatch fathead minnow were exposed for 60 days to different measured concentrations (2.8, 5.4, 9.9, 26.5 µg Se/g dry weight) of Se in food in the form of SeMet. After exposure, samples were collected for trace metal analysis and fish were subjected to a swimming performance challenge (critical swimming speed, Ucrit). A decrease in critical swimming speed (Ucrit) occurred at the 9.9 and 26.5 µg Se/g exposure groups compared to the control group. An increase in oxygen consumption (MO<sub>2</sub>) and cost of transport (COT) was observed in the 9.9 and 26.5 µg Se/g exposure groups compared to the control group. The active metabolic rate of the high dose group was increased relative to control, however this did not translate into a significant increase in the aerobic scope. Energy storage capacity was measured via whole-body

glycogen and triglyceride concentrations. Triglyceride concentrations in non-fatigued fish were elevated in the 5.4 µg Se/g group relative to controls. Swim motion, as well as energy storage capacity will be measured in fatigued fish and the stress biomarker cortisol will also be determined. The results will then be compared between exposure groups as well as between swam and un-swam fish to gain new insights into the sublethal effects of dietary Se exposure on a juvenile fish species.

#### **420 From Cell Lines to Fish: Ozonation as a Treatment Option for the Detoxification of Oil Sands Process Affected Water** S.B. Wiseman, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / Post-Doctoral Fellow; Y. Giesy, University of Saskatchewan / Biomedical Veterinary Sciences & Toxicology Centre, Michigan State University / Department of Animal Science, University of Saskatchewan / Toxicology Centre.

In accordance with a policy of zero discharge, oil sands process-affected water (OSPW), produced by the oil sands industry in North Eastern Alberta, Canada, is stored in on-site tailings ponds. OSPW is acutely and chronically toxic to aquatic organisms. Ozonation is one possible method for remediation of OSPW as it can reduce concentrations of dissolved organic compounds, including naphthenic acids (NAs). However, given that mechanism(s) of toxicity of OSPW are not known and considering the complex exposure scenario of OSPW, studies are required to 1) determine the mechanisms of toxicity of OSPW, 2) determine the effectiveness of ozonation in reducing the toxicity of OSPW, and 3) ensure that ozonation does not cause formation of byproducts that impart toxicity upon OSPW. To address these needs, we have been utilizing a battery of *in vitro* and *in vivo* assays. Untreated and ozone-treated OSPW was characterized for endocrine disrupting properties and acute and chronic toxicity by quantifying survival, growth, and development of the benthic invertebrate *Chironomus dilutus* and the fathead minnow (*Pimephales promelas*). High-throughput sequencing of RNA to investigate gene expression in *Chironomus dilutus* and fathead minnows exposed to untreated OSPW and ozone-treated OSPW were utilized to determine mechanisms of toxicity of OSPW and to characterize the effectiveness of ozonation in attenuating toxicity. Using the H295R, T47D, and MDA cell assays we demonstrated that untreated OSPW altered synthesis of the sex steroids estradiol and testosterone as well as signaling by the estrogen receptor and androgen receptor. Endocrine disrupting effects of untreated OSPW were either attenuated or unaffected by ozonation of the OSPW. Exposure to untreated OSPW or ozone-treated OSPW did not significantly affect survival of *Chironomus dilutus*. However, growth, emergence, and pupation were significantly less in animals exposed to OSPW compared to controls, and ozonation attenuated these effects. Fish exposed to untreated OSPW up regulate several pathways related to the detoxification of xenobiotics as determined by RNA sequencing analysis. Oxidative stress and apoptosis were prominent in minnows exposed to untreated OSPW and might contribute to toxicity. These effects were not evident in fish exposed to ozone-treated OSPW. Results to date suggest that organic compounds in OSPW mediate the toxic effects of OSPW and that ozonation attenuates most of the toxicity of OSPW.

#### **421 Fundamental Studies on the Decontamination and Detoxification of Oil Sands Process-Affected Water Using Advanced Oxidation Processes** A. Afzal, N. Wang, M. Islam, L. Perez-Estrada, P. Drzewicz, P. Chelme-Ayala, University of Alberta / Department of Civil and Environmental Engineering; J.W. Martin, University of Alberta / Department of Laboratory Medicine and Pathology; M. Gamal El-Din, University of Alberta / Department of Civil and Environmental Engineering.

The oil sands industry produces large volumes of oil sands process-affected water (OSPW) as a result of bitumen extraction and upgrading processes. OSPW refers to the water that has been in contact with oil sands or released (dewatered) from tailings deposits and retained in settling basins. OSPW is a very complex mixture of suspended solids, salts, inorganic compounds, dissolved organic compounds, and trace metals. Currently, OSPW is retained on site and there is no active return to the regional watershed. To

address the environmental issues associated with the recycling and/or safe release of the OSPW into the receiving environment, engineered water treatment technologies are required. Although efforts have been made to assess individual technologies to remove or degrade specific constituent(s) of OSPW, a strategy to treat and manage the various streams of OSPW has not been proposed so far. There is an urgent need for research to find different approaches and strategies for OSPW treatment and management. Advanced Oxidation Processes (AOPs) are the chemical treatment methods designed to degrade organic and inorganic compounds by generating powerful oxidants such as hydroxyl radicals. AOPs, including ozonation, ultraviolet light (UV) combined with hydrogen peroxide ( $H_2O_2$ ), and vacuum UV, among others, are being used as treatment alternatives to accelerate the detoxification of OSPW. Moreover, AOPs are being used as pre-treatment steps in order to convert initially persistent organic compounds such as naphthenic acids (NAs) into more biodegradable intermediates, which can be treated using biological processes or other technologies. Our results show that ozone preferentially reacts with NAs with higher cyclicity. In addition, NAs with more rings and more carbon atoms are degraded more rapidly during the ozonation process. By using UV/ $H_2O_2$ , it has been found that NAs with more carbon atoms are favoured for degradation. However, increasing the number of rings (or double bond equivalents) in NAs does not show any clear structure reactivity. By using a model NA compounds (i.e., cycloheptanoic acid; CHA), it has been found that the principal byproducts formed during hydroxyl radical induced decomposition of CHA are hydroxy-CHA, dihydroxy-CHA, and oxo-CHA. This presentation is designed to bring forward the recent advances of AOPs in terms of process fundamentals, oxidation mechanism, and byproduct formation when applied to the remediation of OSPW.

**422 Gas production and gas induced transport of contaminants in tailing ponds** A. Wijdeveld, W.v. Kesteren, DELTARES; J. Foght, University of Alberta / Biological Sciences. Gas production plays an important role in the consolidation behavior of fine sediments in tailing ponds. Gas induced transport in the upper meters of the pond can enhance consolidation due to increased dewatering caused by the release of produced gas. At the same time, gas production can inhibit further strengthening of the sediment at greater depths (>10 meter) due the lack of release mechanisms and therefore the increase in gas volume in the sediment. We will present results of the large scale testing of gas induced transport and the resulting consolidation in fine sediment in a column of 15 meter in height. We also established the gas production rate in the sediment under different conditions. Combining gas induced transport measurements and gas production measurements we developed and calibrated a numeric model to predict the development of the sediment gas accumulation over a period of 1.000 years. Gas induced transport also impacts the leaching of contaminants of the pond sediment. Not only by the enhanced consolidation water flux (increased flux of dissolved contaminants), but also by the release of the gas itself. We measured the flux and composition of the gas coming from the sediment to establish the role of gas production and emission on the leaching of volatile organic compounds (VOC's) to the surface water of the pond. Most of the gas production is the result of microbiological degradation of organic compounds present in the tailing. But the gas phase itself can be an energy source for bacteria. Results based on the gas composition, SEM, confocal microscopy and selective extraction and RNA sequencing of bacteria in or around a gas bubble will be presented.

**423 Using the SPEAR approach to identify oil sands related effects on aquatic invertebrate communities** N. Gerner, UFZ Leipzig; M. Kone, University of Alberta / Civil & Environmental Engineering; A. Ulrich, University of Alberta; M. Liess, Helmholtz centre for environmental research – UFZ / Department of System Ecotoxicology, UFZ Center for Environmental Research / Department of Chemical Ecotoxicology, Helmholtz centre for environmental research – UFZ / Department of System Ecotoxicology. The Athabasca River and its tributaries are running through the Cretaceous McMurray Oil Sands Formation and are directly exposed to potential contamination via natural erosion. As a result of constantly growing mining operations along the Athabasca River, an increased input of toxic oil constituents is expected, which has the possibility to affect water quality and the environment. Current monitoring practices have been criticised for not allowing a reliable assessment of oil sands related impact. This implies the urgent necessity for an effective monitoring method that can discriminate between toxicants' effects and confounding factors. Our project aims

at developing a bioindicator system for the improvement of environmental monitoring methods in order to enable the detection of possible effects of oil sands on the aquatic ecosystem. For this purpose, the SPEAR index (SPeCiesAtRisk), a bioindicator based on the sensitivity of freshwater macroinvertebrate communities towards toxicants of interest, will be adapted to Canadian conditions. For this it will be specified for the substance groups of concern. Two sampling campaigns have been conducted in September of 2010 and 2011 and one will be conducted in September of 2012. Nine and nineteen sites have been investigated in 2010 and 2011 including references sites and sites located upstream and downstream of oil sands developments. Their macroinvertebrate communities were sampled, and in addition, water and sediment samples were taken and analyzed for major ions, polycyclic aromatic hydrocarbons (PAHs), and metals. Results of the 2010 sampling campaign indicated a negative relationship between PAH load and the community sensitivity. Thus, a decrease in the part of sensitive species in macroinvertebrate communities coincides with an increase in PAH load. The samples collected in 2011 had low PAH levels, which might be due to differences in hydrological conditions between the years. Data analysis will be expanded and the relationships between community sensitivity and toxicant load will be compared and discussed with regard to PAH and to metal contamination in 2010 and 2011. This study is expected to help achieve a more holistic understanding of potential effects of oil sand development on the aquatic ecosystem and can be implemented into current monitoring programs undertaken by environmental agencies and consultant companies.

**424 Trends in Atmospheric Deposition of Inorganic Contaminants to the Alberta Oil Sands Region Obtained from Snowpack and Lake Sediment Core Measurements** J.L. Kirk, Environment Canada / Research Scientist, Environment Canada / Aquatic Contaminants Research Division, Environment Canada; D. Muir, Environment Canada / Aquatic Ecosystem Protection Research Division, Environment Canada / Aquatic Contaminants Research Division; A. Gleason, X. Wang, F. Yang, J. Coty, A. Thawer, G. Lawson, A. Sett, Environment Canada. Atmospheric deposition is likely an important source of contaminants to the Alberta Oil Sands region. Kelly et al. (*PNAS vol 107, 2010*) demonstrated that the Oil Sands industry releases 13 elements (Sb, As, Be, Cd, Cr, Cu, Pb, Hg, Ni, Se, Ag, Tl, and Zn) considered priority pollutants (PPEs) under the US Environmental Protection Agency's Clean Water Act, via air and water, to the Athabasca River and its watershed. In spring 2011-2012, we collected snow and lake sediment cores from the Alberta Oil Sands Region to determine current and long-term trends in atmospheric deposition of 44 elements. In 2011, similar to Kelly et al., we collected snow from 30 sites located 0-200 km from the major bitumen upgrading facilities at maximum snowpack depth to quantify atmospheric contaminant loadings to the Athabasca River and tributaries. In spring 2012, this survey was expanded to ~90 sites and included the ~30 2011 sites, ~50 sites situated along transect lines within a 60 km radius the upgraders, and 8 sites in the Peace Athabasca Delta. Our 2011 results demonstrate that aerial loadings of all 13 PPEs were 1.5-13X higher at sites within 50 km of the upgraders than those >50 km away and were highest within 10 km of the upgraders. Loadings of As, Cr, Ni, and Zn were especially high, reaching up to 360, 1170, 1120, and 3270  $\mu g m^{-2}$ , respectively. Loadings of Co, Mn, and V, which were reported to the National Pollutant Release Inventory as being released in high quantities, were also elevated within 50 km of the upgraders, reaching up to 480, 22160, and 7150  $\mu g m^{-2}$ , respectively. Loadings of particulate-bound methyl Hg (MeHg) increased exponentially with proximity to the upgraders, which is important because MeHg is a neurotoxin that bioaccumulates through food-webs. Numerous crustal and rare earth elements, such Al, Ca, Fe, Ce, La, and Y showed a similar deposition pattern suggesting that in addition to the upgraders, land disturbances such as mining and land clearing are important sources of airborne contaminants. Our results support Kelly et al.'s findings that the bitumen upgraders and local Oil Sands development are sources of airborne emissions to the Alberta Oil Sands Region. 2012 snow survey results as well as results from analysis of highly-resolved, well dated lake sediment cores spanning the last 50-100 years from lakes within a 35-km radius of the upgraders will be presented to place modern contaminant deposition in the context of long-term trends.

**425 Larval Fish Toxicity of Snow Melt Waters from Oil Sands Areas** J.L. Parrott, Environment Canada / Environment Canada, National Water Research Institute / Environment Canada; W.P. Norwood, Environment Canada / Aquatic Ecosystems Protection Research Division; P.L. Gillis, J.V.

Headley, M. Hewitt, J. Kirk, R.A. Frank, J.R. Marentette, M.E. McMaster, Environment Canada; D. Muir, Environment Canada / Aquatic Ecosystem Protection Research Division, Environment Canada / Aquatic Contaminants Research Division; Z. Wang, Environment Canada. Embryo-larval fathead minnows were used to assess the toxicity of snow melt samples collected in the vicinity of the Canadian oil sands process facilities along the Athabasca River in the area of oil sands development and upstream. Snow samples were collected early March 2011 and 2012, and then shipped frozen back to the laboratory. Because the snow melt waters were low in essential ions, they were amended with several salts to mimic major ion levels up to those observed in the Athabasca River. Fertilized fathead minnow eggs were exposed (through hatch to 7-15 days post-hatch) to 25 %, 50 % and 100 % amended snow melt waters. Snow samples from upstream or far downstream of the oil sands were not toxic to larval fathead minnows at 100%. Three snow samples from around the oil sands mining and refining areas were toxic to larval minnows at 25-100 %. There was very little toxicity in larval mussels or *Hyalella* exposed to snow melt. Although pure melted snow caused effects in larval fish, samples of Athabasca River water collected just after snowmelt in 2010 caused no effects. Snow was analyzed for metals, naphthenic acids, and PAHs. Compared to other sites, the most toxic snow melt samples had higher concentrations of C1-C4 polycyclic aromatic hydrocarbons and metals, most likely from airborne deposition.

**426 Monitoring the aquatic environment in the Alberta Athabasca Oil Sands using reproductive responses in small forage fish species** M.E. McMaster, Environment Canada / National Water Research Institute; G.R. Tetreault, University of Waterloo / Biology; J. Bennett, M. Hewitt, Environment Canada / National Water Research Institute; T.W. Clark, Environment Canada; R.A. Frank, Environment Canada / AEPRD, Environment Canada / Dept. of Env. Biology & Toxicology, University of Guelph / Dept. of Env. Biology & Toxicology; J.L. Parrott, Environment Canada, National Water Research Institute. Fish were initially collected from the Steepbank River which runs through the Athabasca Oil Sands deposit, including sites off the oil sands deposit as well as within during the fall of 1999 and 2000. These fish were either unexposed, exposed to naturally occurring oil sands related compounds, or exposed to a combination of natural and anthropogenic inputs. The main objective of the study was to determine whether links with the oil sands deposit influenced baseline reproductive parameters associated with physiological or biochemical disruption in wild fish. Field collections for reproductive assessment included sampling of local fish for gonadal somatic index (GSI) as well as *in vitro* steroid production potential. These results were supported by hepatic (ethoxyresorufin-o-deethylase, EROD) activity as an indicator of exposure to oil sands related compounds. Follow-up studies were conducted during the fall of 2010-11 at the same locations to evaluate the earlier responses following additional industrial development on this tributary of the Athabasca River. Water and sediment chemistry and toxicity were also taken at these locations.

**427 A legacy of a half-century of oils sands development: the PAH and paleolimnological record in lake ecosystems** D. Muir, Environment Canada / Aquatic Ecosystem Protection Research Division, Environment Canada / Aquatic Contaminants Research Division; J. Kurek, Queen's University / Department of Biology; J.L. Kirk, Environment Canada / Research Scientist, Environment Canada / Aquatic Contaminants Research Division, Environment Canada; M. Evans, X. Wang, Environment Canada / Aquatic Contaminants Research Division; J.P. Smol, Queen's University / Department of Biology. Assessments of the environmental impacts of the Athabasca oil sands development in northeastern Alberta have noted the lack of long-term data and very limited information on pre-impact conditions. In this study we have used paleolimnological techniques to reconstruct long-term dynamics of PAH loadings, aquatic primary production, and zooplankton (Cladocera) assemblages over at least the last 50 years. We analysed dated sediment cores from 5 lakes within 35 km of the bitumen upgrading facilities in the center of the development area north of Ft McMurray, AB, and one reference lake, 100 km northwest of the upgraders. These lakes were undisturbed and received only atmospheric inputs. PAHs (47 analytes) increased precipitously beginning at the early 1970s, particularly C1-C4-alkylated PAHs and C1-C4-dibenzothiophenes (DBTs). In 4 of 5 near-field lakes, maximum concentrations were observed from the most recent (~2009-10) sediments. Total ( $\Sigma$ )PAH fluxes were 2.5 to 23-times greater than pre-1960 background levels. Increases were also evident in Namur Lake, and in a lake 22 km southwest of the upgraders, but were less

pronounced (2-8-fold) and had subsurface maxima in sediments dated to 2006. C1-C4 alkylated PAHs and DBTs predominated in all sediment samples, representing 55 to 89% and 1.8 to 17% of the  $\Sigma$ PAHs, respectively. The predominance of these groups in snow and precipitation in the region has been reported previously. Coincident with increased PAHs, climate-induced shifts in aquatic primary production are also likely contributing to lake-ecosystem changes. A paleo-ecotoxicological assessment of *Daphnia* relative abundances indicates that this sentinel species was not yet negatively impacted by decades of increased PAHs and other likely associated contaminants (e.g. metals). Multiple environmental stressors, namely climate warming and industrial contaminants, acting collectively since the latter half of the 20th century are influencing lake-ecosystem functions and zooplankton assemblages in the oil sands region. Stressors have forced freshwaters toward new ecological states largely distinct from those of previous centuries of lake-ecosystem history.

**428 An Assessment of Hg Contamination in Lake Chapala, Mexico: Implications for Ecosystem Health** M. Mora, Texas A&M University / Wildlife and Fisheries Sciences; Z. Torres, Texas A&M University / WFSC; R. Taylor, Texas A&M University / Veterinary Integrative Biosciences; D. Alvarez, Instituto Politecnico Nacional / CIIDIR; H. Buelna, Instituto Politecnico Nacional. The Lerma-Chapala Basin is the home to 10% of Mexico's human population. Lake Chapala is the largest tropical lake in Mexico and the ultimate receptor of a great variety of contaminants that are discharged through the basin to the Rio Lerma. In addition to being a major water source for the city of Guadalajara, Lake Chapala represents a major fishery and recreation resource for various communities surrounding the Lake, as well as for tourists from many parts of the country. Lake Chapala is one of the largest wintering areas for American white pelicans (*Pelecanus erythrorhynchos*), a species of special concern in the United States. We conducted a two year study to assess the impacts of Hg and other metals on fish and wildlife of Lake Chapala. Here we report the results of the analysis of Hg and MeHg concentrations in water, sediments, and three fish species which are part of the diet of fish-eating birds and also of many human inhabitants in the region. For the first year samples, mean Hg concentrations were  $0.015 \pm 0.002$  ng/ml in water,  $0.597 \pm 0.190$   $\mu$ g/g dw in sediments,  $0.626 \pm 0.065$   $\mu$ g/g dw in charal (*Chirostoma spp*),  $1.597 \pm 0.430$   $\mu$ g/g dw in carp (*Cyprinus carpio*), and  $0.176 \pm 0.113$   $\mu$ g/g dw in tilapia (*Oreochromis mozambique*). Carp from a nearby reservoir in San Antonio Guaracha, Michoacan had mean Hg levels of  $0.396 \pm 0.144$   $\mu$ g/g dw. The samples collected earlier this year are currently being analyzed. The results will be available for analysis and for further assessment of the potential negative effects of these Hg concentrations on fish-eating birds and humans. We will also present data on Hg in feathers from aquatic birds. This project contributes to one of the goals of the Commission for Environmental Cooperation regarding implementation of an action plan to eliminate sources of mercury pollution in North America. It also contributes to one of the seven priorities for action of the UNEP Global Mercury Partnership, which is to conduct research into mercury's atmospheric transport and fate.

**429 Ecosystem Response to Evolving Mercury Emissions** L. Levin, Electric Power Research Institute / Air Toxics Health & Risk Assessment; K. Vijayaraghavan, ENVIRON International Corp.. Both U.S. and Asian mercury emissions are rapidly evolving as economic and control steps are introduced in the two regions. A critical question is whether local and regional controls on point sources of mercury will result in significant changes in fish tissue levels of the substance as more distant sources increase their emissions. Repeated studies in a variety of lakes show that initially rapid changes in fish burdens of mercury are likely to be followed by slow adjustments to step changes in mercury depositing to waterways from the atmosphere. Aquatic fish populations act as band-pass filters for mercury deposition and methylation over time, serving as interannual transfer systems for methylmercury mass within the system. This study focuses on fish populations in a well-characterized lake in the northeastern U.S. and projects evolution in fish tissue levels of mercury following drops in U.S. utility emissions due to the Federal MATS rule, plus plausible emissions growth scenarios for Asian emissions. Both seasonal cycling of fish tissue mercury and longer term trends are dominated by one or both source categories depending on the growth projections for distant sources.

**430 Mercury in Fish on the California Coast: Indicators of Global**

**Atmospheric Contamination?** J.A. Davis, J. Ross, San Francisco Estuary Institute; G. Ichikawa, California Department of Fish and Game; W. Heim, Moss Landing Marine Laboratory; M. Stephenson, California Department of Fish and Game; K. Schiff, Southern California Coastal Water Research Project. The California State Water Resources Control Board's Surface Water Ambient Monitoring Program (SWAMP) has established a new statewide bioaccumulation monitoring program. The program began with a two-year screening survey of bioaccumulation in lakes and reservoirs in 2007 and 2008, followed by a two-year survey of the coast in 2009 and 2010, and a survey of rivers and streams in 2011. In the Coast Survey, 3,483 fish representing 46 species were collected from 68 locations. Five species were examined at each sampling location, including high trophic level species expected to accumulate relatively high concentrations of mercury. Many locations, 25 of the 68 sampled (37%), were in a high contamination category, with an average for the most contaminated species exceeding a threshold of 0.44 ppm used by the state in developing consumption advisories. Species with high concentrations were observed more frequently in the north and central coast regions than in the south, primarily due to regional differences in the suite of species sampled. The species with high concentrations were generally relatively old and at a high trophic position. The data from this survey indicate that methylmercury contamination is ubiquitous in the food webs of the California coast. Even remote location island locations were found to have a moderate degree of contamination. These data suggest that enough mercury is supplied to California coastal food webs to cause problematic bioaccumulation wherever long-lived predatory fish species are caught and consumed. The ubiquitous contamination observed in this survey, coupled with the minimal influence of local atmospheric sources in this region, suggests that atmospheric deposition of mercury from global sources may be a significant contributor to methylmercury in California coastal food webs. The contributions of other local terrestrial sources appear to be superimposed upon a background of global atmospheric deposition and other sources to coastal waters such as geological sources and the upwelling transport pathway. San Francisco Bay had relatively high concentrations and is an exceptional case where local sources, especially historic mercury mining, play a distinct role.

**431 Mercury biomagnification rate in aquatic food webs worldwide**

R.A. Lavoie, Queen's University / Biology; K. Kidd, Canadian Rivers Institute, University of New Brunswick / Biology, University of New Brunswick / Biology department; T. Jardine, University of Saskatchewan / Toxicology Center; M.M. Chumchal, Texas Christian University / Biology department; L. Campbell, Saint Mary's University / Biology. Trophic level is among the most important variables determining the overall concentration of mercury (Hg) in a given organism. The estimation of trophic level using nitrogen isotopes ( $\delta^{15}\text{N}$ ) revolutionized the study of Hg biomagnification. The overall rate of Hg biomagnification through food webs can be determined using the slope of  $\log(\text{Hg})$  versus  $\delta^{15}\text{N}$  regressions (called trophic magnification) and this parameter can be compared across systems that are chemically and biologically different. Mercury trophic magnification varies among aquatic food webs and to date there is no consensus on the main factors driving this variation. We compiled results from over 60 studies and 190 sites around the world (published and non-published) that measured Hg trophic magnification in aquatic food webs using  $\delta^{15}\text{N}$ . Studies ranged from freshwater to marine and from tropical to arctic ecosystems. Using GIS and statistical approaches, we examined whether variables of physico-chemistry (e.g., pH, percentage of wetland, DOC, productivity, Hg deposition, latitude and longitude) and community structure (species composition and food chain length) explained among-system differences in trophic magnification. Preliminary results suggest that trophic magnification was positively related to latitude and negatively related to mercury deposition. In contrast, Hg concentration at the base of the food chain was positively related to mercury deposition. Trophic magnification was lower in systems with longer food chain length. Specific spatial relationships will be presented. This study is among the first to comprehensively assess factors affecting biomagnification of mercury in diverse ecosystems worldwide.

**432 Ecogenetics – Can Epigenetic and Gene-Environment Interaction Studies Help Improve Mercury Risk Assessment?**

N. Basu, University of Michigan / Department of Environmental Health Sciences, University of Michigan / Department of Environmental Health; J. Goodrich, J. Head, University of Michigan. The risk assessment of mercury is complicated

due to innate inter-individual variation in exposure, biomarker values, and adverse outcomes. Recent findings by us and others suggest that epigenetic mechanisms and gene-environment interactions (which have seldom been included in mercury's risk assessment) may help explain some of this variation. In terms of epigenetics, studies on laboratory models (mink, chicken, perch) and wild animals (polar bears) reveals mercury-associated global DNA hypomethylation and impaired DNMT activity in some, but not all, organisms. Candidate gene studies in a cohort of dental professionals documents that methylation of SEPP is associated with significant changes in mercury biomarker levels. In terms of gene-environment interaction studies, work by us and others show that some genes that influence the absorption, distribution, metabolism and elimination (ADME) of mercury have polymorphic variants that can affect biomarker levels. For example, epidemiological research by our group has shown that polymorphisms in MT1A, MT1M, GSTP1, and SEPP1 can be associated with altered levels of urine and hair mercury. For both epigenetics and gene-environment interactions, high-throughput approaches are commercially available which we are now exploring in a range of studies. This presentation will provide a rationale by which ecogenetic approaches and information can be used to improve our ability to assess the human health and ecological health risks (both exposure and adverse outcomes) of mercury and help identify vulnerable groups.

**433 Mercury in Wetlands – A contribution to the definition of a global mercury policy**

J. Canario, IPMA IP / Aquatic Environment Department, IPMA I.P. / Aquatic Environment and Biodiversity, INRB IP/IPIMAR / Aquatic Environment and Biodiversity; C. Vale, IPMA I.P. The overall goal of the UNEP Global Mercury Partnership is to protect human health and the global environment from the release of mercury and its compounds by minimizing and, where feasible, ultimately eliminating global, anthropogenic mercury releases to air, water and land. Besides the decrease on mercury emissions in the northern hemisphere in the last decade, the amount of mercury circulating in the environment is still of great concern. This issue assumes a major problem in ecosystems, which due to their physical/chemical/biological characteristics, exchange mercury species mainly  $\text{Hg}^0$  (mercury volatile) and MeHg (methylmercury) with the atmosphere and food web, respectively. Wetlands, particularly salt-marshes, are among these key ecosystems where these Hg transformations and Hg escape occur. Mercury studies in Portuguese salt-marshes showed that salt-marsh plants and the surrounding rhizosphere environment are important areas of mercury retention and methylation. Levels of up to 30% of MeHg in salt-marsh sediments contrasting to the 0.01% of MeHg in non-vegetated ones and higher concentrations of both Hg and MeHg in root biomass poses a serious debate about whether salt-marshes are efficient for Hg phytoremediation. Additional studies in Portuguese salt-marsh plants in contaminated areas also showed that macrophytes are important sources of  $\text{Hg}^0$  to the atmosphere. Mercury vegetation-air fluxes measured in two salt-marsh plant species showed  $\text{Hg}^0$  emissions during three consecutive days, indicating that these ecosystems can act also as an important natural mercury source. The export nature of these ecosystems for mercury has been shown. These findings have serious implications on mercury pollution especially concerning mercury fate and speciation in wetland contaminated areas. Based on our work we believe that the definition of a global mercury policy must take into account wetland areas which occupied up to 9 million  $\text{km}^2$  of earth surface therefore incorporating these ecosystems in the UNEP monitoring and assessment mercury programs. Two types of measures should be envisaged. Encourage better understanding of mercury transformation and fluxes in key areas of the world, namely wetlands and areas where mercury is used in industrial processes. Improve technologies to reduce the mercury emissions and to sequester mercury in inorganic forms.

**434 Partitioning of total mercury and methylmercury between colloids and true solution in aqueous matrices**

D. Vignati, Irsa-Cnr, IRSA-CNR, UOS Brugherio, Université Paul Verlaine / LIEBE CNRS UMR 7146, Université Paul Verlaine / CNRS UMR 7146; S. Guedron, Université Grenoble 1 / ISTerre. Mercury is a priority pollutant which, upon conversion into the highly bioavailable and neurotoxic form monomethylmercury (MMHg), easily enters the food chain and can cause significant exposure in human beings; primarily via the consumption of contaminated fish and seafood. Bottom sediments and the associated interstitial waters are a privileged site for the inter-conversion of Hg into MMHg; while the partitioning of Hg and MMHg between colloids (particles smaller than 1  $\mu\text{m}$ , but larger than 1 nm) and true solution (the fraction smaller than 1 nm) can affect

their environmental fate and bioavailability. Because sediments constitute a critical environmental compartment for Hg and MMHg cycling, study of mercury partitioning at the sediment-water interface or in interstitial waters is a subject of particular scientific relevance. Some researchers already studied Hg/MMHg partitioning between colloids and true solution in marine waters and freshwaters; but, to our knowledge, analogous experiments for interstitial waters have not yet appeared in the scientific literature. Sediment cores and associated overlying waters (OW) were collected in Lake Geneva (Switzerland/France), Baihua reservoir (Guizhou Province, China) and in the Venice lagoon (Italy). OW were siphoned off the cores, filtered using Sterivex cartridges (0.45 µm nominal cut-off), subsampled for Hg and MMHg analysis and further fractionated by tangential flow ultrafiltration. Cores were sliced (under nitrogen atmosphere for anoxic waters/sediments) and the interstitial waters (IW) recovered by centrifugation. IW were then filtered and fractionated as for overlying waters. Both total Hg and MMHg concentrations were assayed by cold vapor atomic fluorescence spectrometry (CV-AFS). Concentrations of THg and MMHg were lower in Lake Geneva than in the Venice Lagoon and in the Baihua reservoir, reflecting the increasing contamination of the three studied sites. MMHg represented a very high percentage of THg (22–30 %) in the Baihua reservoir, while it never exceed 6 and 2 % in Venice lagoon and in Lake Geneva, respectively. Some significant correlations were found between total filterable and colloidal fractions for both total Hg and MMHg suggesting that some general mechanism of Hg partitioning probably exist.

**435 Albatross as Sentinels of Marine Pollution: Local and Global Factors** M.S. Bank, Harvard Medical School / Department of Environmental Health, Harvard School of Public Health / Dept of Environmental Health, Harvard Medical School / Harvard Center for Comparative Medicine, Harvard Medical School / Center for Animal Resources and Comparative Medicine; A.E. Vo, University of California, Berkeley / Museum of Vertebrate Zoology, Department of Integrative Biology; W. Sentman, Harvard University Extension School; S.V. Edwards, Harvard University / Museum of Comparative Zoology, Department of Organismic and Evolutionary Biology. Heavy metal pollution in the Pacific Ocean has garnered significant attention in recent years, especially with regard to rising mercury emissions from Asia. Uncertainty exists over the extent to which mercury in biota may have resulted from increases in anthropogenic emissions over time. Albatrosses, including those inhabiting the North Pacific, are wide-ranging, long-lived, keystone, avian predators. Consequently, they serve as ideal sentinel species for investigating the effects of historical and contemporary pollution as well as local and global factors related to heavy metal exposure, bioaccumulation, and ecotoxicological risk. To date, high levels of mercury and lead have been documented in albatross species throughout the Pacific. To address biotic exposure to these multiple stressors, here we synthesize and conduct meta-analyses of total mercury, methylmercury, and lead exposure data in Black-footed albatross (*Phoebastria nigripes*) and Laysan albatross (*Phoebastria immutabilis*). Our approach includes data from the field and literature, and for total mercury and methyl mercury, we use measurements from museum feathers spanning the past 130 years for Black-Footed albatross. We discuss the use and application of stable isotopes ( $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$ ) as a way to control for temporal changes in trophic structure and diet and we demonstrate the importance of conducting speciation analyses for mercury to account for historical, curator-mediated, inorganic mercury contamination of specimens. Our data showed higher levels of inorganic mercury in older specimens of Black-Footed albatross as well as two non-pelagic species (control samples) lacking historical sources of bioavailable mercury exposure, which suggests that studies on bioaccumulation should measure methylmercury rather than total mercury when utilizing museum collections. Albatross species face heavy metal exposure threats at both local (lead) and global scales (mercury, and potentially heavy metals in plastics). Heavy metal toxicity along with other stressors may undermine current and future reproductive outcomes in these seabird species, although unraveling effects from specific metals in the context of a complex metal mixture presents some challenges. Collectively, our findings and review of the literature suggest that albatrosses in this region may be an effective marine flagship species and raising the profile of these organisms likely would successfully support broader biodiversity conservation efforts in the North Pacific.

**436 Losing bugs and birds: Investigating the impact of neonicotinoid insecticides on agricultural wetlands of Prairie Canada** C. Morrissey, University of Saskatchewan / Biology; A. Main, University of Saskatchewan

/ School of Environment and Sustainability; C. Michelson, University of Saskatchewan / Department of Biology; B. Clark, Environment Canada; A.J. Cessna, National Water Research Institute / Environment Canada, Environmental Health National Program / Agriculture and Agri-Food Canada; J. Hedley, Environment Canada; P. Mineau, National Wildlife Research Centre / Canadian Wildlife Service. Carson was the first to address the problems associated with the agriculture industry's "war on insects" and the haphazard use of insecticides. In the last 50 years, the development and use of insecticides has continued to rapidly expand in opposition with equally rapid pest resistance. A newer class of insecticides – neonicotinoids – though designed for improved agricultural production, are controversial because of their persistence and high leaching potential, and evidence in Europe and North America show that they are highly toxic to a wide range of non-target aquatic insects and other arthropods. Applications also directly overlap with peak seasonal invertebrate production and the avian breeding season for a range of species and evidence suggests populations of farmland and wetland birds are declining rapidly throughout North America and Europe and are potentially susceptible to neonicotinoids indirectly through loss of insect prey. In the Canadian Prairie Pothole region, intensive and widespread use of neonicotinoids particularly for canola seed treatments prompted us to investigate the fate and effects of these chemicals in agricultural wetlands. We are evaluating neonicotinoid concentrations in water and sediment in approximately 140 wetlands from April to September along with rapid wetland assessments to evaluate the landscape and ecological variables that are contributing to wetland contamination. We are further assessing seasonal changes in insect abundance in a subset of wetlands in areas with high and low neonicotinoid use in order to link observed changes to shifts in diet, growth and reproduction of local insectivorous bird populations. The outcomes of the study will lead to better informed risk assessment practices of neonicotinoids in addition to addressing the biological integrity of aquatic ecosystems in one of Canada's most ecologically and commercially productive agricultural environments.

**437 Occurrence of Current-Use Pesticides in Surface Water, Sediment, and Biological Tissue Across the USA** K.M. Kuivila, K.L. Smalling, M.L. Hladik, J. Orlando, U.S. Geological Survey. During the last two decades, studies by the U.S. Geological Survey have shown that numerous current-use pesticides are present in surface waters across the United States and occur both dissolved in the water and bound to sediments. Pesticide use is constantly changing, so analytical methods are frequently updated to analyze new pesticides in water and sediments. We design field studies to sample streams in small watersheds with specific use-settings, rather than to conduct widespread monitoring. One series of field studies was designed to focus on pyrethroid insecticides because of their increasing use and high toxicity to aquatic organisms. Due to their hydrophobicity, pyrethroids ( $\log K_{oc} > 5$ ) tend to bind to sediments. Of the 14 pyrethroids analyzed in small agricultural and urban streams across the country, 10 were detected in suspended and bed sediments. The most frequent detections were found in urban stream bed sediments, with bifenthrin being detected most frequently. In contrast, a wider variety of pyrethroids were detected in agriculturally influenced streams. Other field studies have focused on fungicides, a group of pesticides that is rarely monitored and whose registration and use have changed dramatically over the last 5 years. Fungicides are moderately hydrophobic ( $\log K_{oc}$  2 to 4) and are considered to be relatively persistent in water and sediments. Stream samples were collected from different agricultural areas across the country, including leafy greens, orchards, peanuts, potatoes, rice, and strawberries. Of the 37 fungicides analyzed, 20 were detected in water or sediments or both. Azoxystrobin, boscalid, myclobutanil, and pyraclostrobin were detected the most frequently and at the highest concentrations. Recently, methods have been developed to analyze tissue. Although most current-use insecticides and fungicides are only moderately lipophilic, they were detected in a variety of aquatic organisms, including amphibians, crabs and crab embryos, fish, and osprey eggs. Pyrethroids (bifenthrin, cyfluthrin, etofenprox), other insecticides (chlorpyrifos, fipronil, malathion), and fungicides (pyraclostrobin, tebuconazole) were detected in tissue samples from across the country. These results highlight the importance of updating analytical methods as pesticide use changes and analyzing multiple environmental compartments.

**438 Screening of pesticide in surface waters of four basins of the Pampas Region of Argentina with different degrees of agriculture intensities** D. Marino, Y. Elorriaga, Centro de Investigaciones del Medio Ambiente

(CIMA-CONICET), Facultad de Ciencias Exactas, Universidad Nacional de La Plata; V. Aparicio, Instituto Nacional de Tecnología Agropecuaria (INTA), Estación Experimental Agropecuaria Balcarce; G. Natale, P. Carriquiriborde, Centro de Investigaciones del Medio Ambiente (CIMA-CONICET), Facultad de Ciencias Exactas, Universidad Nacional de La Plata. The Pampas Region is the main agricultural district of Argentina predominantly by the alternated production of soybean and corn in summer and wheat in winter. Despite the wide spread of this activity little is known of its impact on surface water quality and the aquatic ecosystems at the regional scale. In this study, 70 pesticides were determined in surface water samples from 22 sites distributed along four agriculture basins, two mainly agricultural and two mostly extensive livestock. Samples were filtered through 0.45  $\mu\text{m}$  GF/F immediately after collection and transported in glass bottles to the laboratory. SPE extraction was performed with C18 OASIS HLB, within the 48h after collection. Pesticide analysis was performed by UPLC-MS/MS ESI(+/-) (Acquity-Quattro Premier). Spiking and isotopic dilution methods were used for quality assurance. A total of 35 samples were analyzed. Among all the pesticides measured, only 30 were positively detected. Conversely to the expected, patterns in the composition of detected pesticides were similar in both classes of basins, only four pesticides were not observed in the less agricultural basins. On the other hand, clear differences were observed in the abundance. Differences in the frequency of occurrence of some pesticides were observed when comparing summer and winter samplings (i.e. atrazine was 100% detected in summer and 90% in winter and metsulfuron methyl 60% in winter and not detected in summer). In addition, during the summer triazole fungicides and agricultural pyrethroids were detected in the 80% and 70% of the samples, respectively. Finally, imidazolinone herbicides were detected in the 20% of the cases. In the present study a broad screening of pesticides at regional scale was performed in the Argentinean Pampas, revealing for the first time the occurrence of a wide number of pesticides together with characteristic spatial and temporal patterns.

**439 Pesticide residues in prairie pothole sediments as influenced by three dominant land-use types** S. McMurtry, Oklahoma State University / Department of Zoology; J. Belden, L. Smith, D. Daniel, S. Morrison, Oklahoma State University; B. Tangen, R. Gleason, N. Euliss, U. S. Geological Survey. Wetlands throughout the Great Plains represent some of the most heavily impacted habitats in North America due to extensive cultivation of surrounding uplands. Indeed, these depressional wetlands are typically the terminus of the watershed and thus receive substantial runoff and sediment input from cultivated uplands, influencing multiple ecosystem services provided by wetlands. Pesticides, from application on adjacent cropland and from overspray, also have the potential to move into wetlands. The United States Department of Agriculture (USDA) offers various conservation programs (e.g., Conservation Reserve Program, CRP) designed to reduce soil erosion and runoff and to restore/protect natural resources influenced by agricultural activities. Although not designed to protect wetlands per se, conservation programs such as the CRP have a substantial influence on wetlands embedded within the restored grasslands. Therefore, this study was designed to assess the extent of pesticide residue in the three dominant land-use types (cropland, native prairie, and restored grasslands) surrounding depressional wetlands in the Prairie Pothole Region of North and South Dakota. Sediments were collected from 151 prairie pothole wetlands in North and South Dakota embedded in the three dominant land-use types; 49 cropland sites, 49 native prairie sites, and 53 restored grassland sites. Sediment samples were analyzed for glyphosate and organic carbon, and are currently being analyzed for triazine and chloroacetanilide herbicides, pyrethroids and organophosphate insecticides, and strobilurin fungicides. Mean ( $\pm$ SE) glyphosate concentrations were about four times greater ( $133.6 \pm 30.9$   $\mu\text{g/kg}$ ) in sediments of wetlands embedded in cropland catchments than in wetlands embedded in native prairie or restored catchments, which did not differ ( $31.5 \pm 5.7$  and  $36.9 \pm 10.7$   $\mu\text{g/kg}$ , respectively). In addition, 76% of samples from cropland sites had detectable concentrations of glyphosate compared to 55% and 51% for native prairie and restored wetlands, respectively. These results indicate that despite the presence of pesticides in non-cropland wetlands, concentrations are lower, and that restoration of previously cropped uplands improves pesticide residue status of embedded wetlands.

**440 The effects of a fungicide, miticide, and insecticide and possible synergy, on honey bee health and behavior** J.D. Johnson, University of Maryland / Dept of Toxicology, University of Maryland Baltimore / Med school, Dept. of Toxicology; J. Pettis, USDA/ARS Bee Research Lab. Pesticides enter hives by being carried in resources such as water, pollen, nectar, and propolis and by application by beekeepers to control mites and pathogens. In the matrices of wax, honey, and pollen stores, pesticides may partition, store, and potentially interact. Three pesticides that have been reported in bee hives were applied separately and together to observation hives. Fluvalinate, a pyrethroid miticide, was applied to empty comb. Chlorothalonil, a fungicide, was injected into pollen cells. Imidacloprid, a neonicotinoid, was applied as a sugar water spray onto in-hive bees. Emerged brood weights, pollen consumption, in hive census, foraging activity, and in-hive location mapping of 300 marked bees were monitored for one month. The hives were located in a row, ca. 1 meter apart and position was randomized for each trial. At the end of the month, the hives were dismantled, the equipment cleaned, a new colony established, and the hive dose and position re-randomized. Data from four replicates by month were collected. Significant drift was noted in the 3 pesticide and chlorothalonil treated hives even after accounting for row position effects, which were also significant. Effects on other behaviors and parameters measured will be discussed.

**441 Currently Used Pesticides in the Atmosphere in Agricultural Regions of Western Canada** R. Raina, University of Regina / Dept. of Chemistry & Biochemistry; N. Fergus, University of Regina / Department of Chemistry & Biochemistry; E. Smith, N. Al-Zaharni, University of Regina / Chemistry & Biochemistry; L. Sun, University of Regina / Department of Chemistry & Biochemistry; P. Hall, University of Regina / Department of Chemistry & Biochemistry. Initial studies on pesticides in the atmosphere of Western Canada began in 2003 with focus on the Lower Fraser Valley (LFV) agricultural region (berry crops), and the Canadian prairies (grains and oil seed crops). These studies have been further expanded in 2011 to include the Okanagan Valley of British Columbia where orchards and vineyards are present. Further sampling sites in each agricultural region were added to obtain additional spatial and temporal resolution to aid in assessment of regional and long-range transboundary atmospheric sources. These regions were selected due to the high usage of pesticides in western Canada, and differences in crop types, climate, and expected types and quantities of pesticides. In LFV we examined trihalomethyl thiofungicides, and organophorus pesticides (OPs), OP degradation products, and other selected herbicides and insecticides. For some pesticides atmospheric levels have exceeded  $10 \text{ ng/m}^3$  and more recent monitoring was used to assess whether atmospheric loadings have declines since 2006 when atmospheric levels indicated that pesticides such as captan, diazinon, and malathion continued to be favoured in the region. We will also investigate whether folpet which was replaced with chlorothalonil is still present in the atmosphere (since 2006). In the Okanagan Valley atmospheric concentrations of carbaryl also exceeded  $10 \text{ ng/m}^3$  in 2011 and were for the first time linked to its usage in apple thinning during the June drop, as well as on other orchard and vineyard crops throughout the growing season. In the prairies we also provided the first detection of azole fungicides in the atmosphere in the gas phase in 2010 during a year where many farmers experienced flooding conditions. Propiconazole was detected at maximum levels of  $78 \text{ pg/m}^3$  and has historical usage in the prairies as well as further south in the grain belt of the United States. A more recently recommended azole fungicide, prothioconazole, was also detected in the gas phase up to  $35 \text{ pg/m}^3$ . These two azoles showed levels below or near the method detection limit when sampling occurred during precipitation events even when temperatures were higher and was attributed to the higher water solubility of these fungicides. Long term-trends for some common high-usage herbicides (trifluralin, ethalfurin) and endosulfan in the Canadian prairies show annual shifts indicating the importance of climate and other pressures on farmers.

**442 California Department of Pesticide Regulation's Air Monitoring Network Results for 2011** E. Vidrio, P. Wofford, R. Segawa, California Department of Pesticide Regulation. The Department of Pesticide Regulation (DPR) is the public agency responsible for protecting California and its residents from adverse health effects from the use of pesticides. In February 2011, DPR implemented a long-term statewide air monitoring network (AMN) for measuring a total of 40 pesticides and pesticide breakdown products in three agricultural communities. As part of the monitoring

location selection process for the AMN, DPR evaluated and prioritized 226 communities in California as candidates for inclusion in the network. Salinas (Monterey County), Shafter (Kern County), and Ripon (San Joaquin County) were selected as the sampling locations for the air network. Four different samples are collected for analysis of the 40 pesticides; two different sorbent glass tubes, hand-packed Teflon® cartridges with sorbent media, and Summa canisters. 24-hour samples were collected every week at each of the three sites. The starting day varied each week with the actual dates being randomly selected. Results for the first calendar year indicate low levels of exposure. Thirty of the pesticides were detected, eleven of which had concentrations above the quantitation limit.

**443 Legacy organochlorine insecticides: What the Integrated Atmospheric Deposition Project can tell us** M. Venier, Indiana University / School of Public and Environmental Affairs, Indiana University; R.A. Hites, Indiana University / School of Public & Environmental Affairs,. The regulation of insecticides in the United States began with the banning of DDT in 1970 (as part of the Environmental Protection Act that also created the U. S. EPA) and has continued to the present with the restriction of lindane in 2009. More recently, another widely used insecticide, endosulfan (which has structural similarities to the now banned hexachlorocyclopentadiene family of compounds), has become suspect and is being phased out. The Integrated Atmospheric Deposition Network (IADN) has measured the atmospheric concentrations of several current use and legacy insecticides every 12 days at five locations near the North American Great Lakes since the early 1990s. Surprisingly, the DDT-related compounds are still present in the atmosphere, and their concentrations are decreasing only slowly. On the other hand, the atmospheric concentrations of the lindane-related compounds are decreasing rapidly. Despite the supposition that insecticides had been used only in agricultural applications, the atmospheric concentrations of most of these compounds track human population density. For example, the atmospheric concentrations of the chlordane-related compounds are higher in urban areas than in more remote agricultural areas. This presentation will focus on the spatial and temporal trends of the concentrations of these pesticides. Results will be put in the context of suggestions for the development of multi-national monitoring networks.

**444 Life cycle assessment for emerging technologies: The challenges of defining and applying impact metrics** T. McKone, University of California, Berkeley, University of California and Lawrence Berkeley National Laboratory, University of California, University of California and Lawrence Berkeley National Laboratory, University of California; C. Scown, Lawrence Berkeley National Laboratory / Environmental Energy Technologies Division; A. Horvath, University of California / Civil and Environmental Engineering. Emerging technologies--which we define as technologies in the research, development, or early commercialization stages--can pose a particular challenge to life-cycle assessment (LCA). In contrast to extant technologies, emerging technologies lack data on the materials, supply chains, processes, and performance of the technology in its intended application. With large-scale deployment of energy from biomass as a case study, we will identify and evaluate the challenges of defining and applying informative impact metrics for LCA. For many bioenergy LCAs overall impact is expressed in terms of carbon emissions or energy use. But an LCA must also address resource constraints, human and ecosystems health, water resources, technology options, and economic constraints. Confronting this broader set of metrics increases the challenges of making LCAs for emerging biofuels useful and relevant. We consider six challenges: (1) addressing multiple categories of impact (carbon, energy, health, water, social welfare, etc); (2) making comparisons and aggregating among different impact categories; (3) addressing spatial heterogeneity; (4) accounting for time in allocating impacts; (5) assessing transition paths as well as end states; and (6) confronting uncertainty and variability. Recognizing LCA as a process and not a product is key to meeting these challenges. Barriers to LCA arise because many stakeholders expect LCA to provide a clear and final answer. This serves only to highlight the flaws and uncertainties of LCA and fails to take advantage of the true power of LCA as an ongoing process that organizes both information and the process of prioritizing information needs. Addressing the world's need for near-term, cost-effective, and reliable production systems for bioenergy requires that the technological, social, economic, and environmental challenges be addressed in parallel.

**445 A spatially and temporally explicit life cycle inventory of air pollutants from liquid transportation fuels** C. Tessum; J. Marshall, University of Minnesota / Civil Engineering; J. Hill, University of Minnesota / Bio-products and Biosystems Engineering. The accuracy of life cycle assessment (LCA) in estimating environmental impacts is commonly limited by a lack of detail about when and where pollutants are released to the environment. We will present a spatially and temporally explicit life cycle inventory (LCI) for liquid transportation fuels built upon the existing GREET (Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation) model from Argonne National Laboratory. GREET shows that ethanol fuel produced in the United States, as derived from either corn grain or corn stover, has higher life cycle emissions of most air pollutants than gasoline. Our results show that for ethanol these emissions are concentrated in the Midwestern "Corn Belt" of the United States and in rural areas. We find that increasing grid resolution improves the accuracy with which emissions are allocated to urban and rural areas. Temporal variations in life cycle emissions are most prominent in the agricultural stages of ethanol production. Our analysis also provides detailed chemical speciation of pollutants. For example, although cellulosic stover ethanol emits less fine particulate matter overall than corn grain ethanol, it emits a larger amount of black carbon. Altogether, the additional fuel LCI detail provided here will allow for air quality modeling in support of life cycle impact assessment (LCIA).

**446 Challenges of Life-cycle Assessment for Emerging Technologies** A. Horvath, University of California, Berkeley / Civil and Environmental Engineering, University of California, Berkeley / Civil & Environmental Eng.. Life-cycle assessment (LCA) is much practiced globally any more, but it faces significant challenges when analyzing products and services employing substantial components from emerging technologies. There is not much help available for LCA practitioners to overcome such problems, and this is a global problem. This presentation will summarize current thinking on these challenges, the reasons for their existence, and discuss a few product or service examples where LCA is struggling to assess emerging technologies. While this may have been a structural problem of LCA, I will discuss ways in which this could be minimized, if not eliminated, by concerted efforts made by the LCA community.

**447 Strategies for the LCA of emerging biomaterials** E. Bernier, National Research Council of Canada / Aquatic and Crop Resource Development Portfolio, National Research Council of Canada / Biotechnology Research Institute – Applied Ecotoxicology; C. Lavigne, National Research Council Canada / Aquatic and Crop Resource Development Portfolio; P. Robidoux, National Research Council Canada / Aquatic and Crop Resource Development Portfolio, National Research Council Canada / Project Leader. Bio-products and biomaterials are an important development axis at National Research Council Canada. LCA is a useful tool to confirm and promote their 'green' character, but also to raise potential issues and provide research guidance in order to avoid costly re-designs later. Three years of experience have allowed the development of strategies for assessing biomaterials-in-development, including: keeping the LCA study in-house for a better interaction with development scientists, thus improving research guidance opportunities; grasping the vocabulary of each industry/discipline (e.g. varying terminologies to describe bast fiber by-products and related processes); making reasonable assumptions on functional equivalence and insisting that the LCA results are conditional on their experimental verification later in project; making a careful analysis of scale-up issues when modeling lab-scale and pilot-scale processes; making an extensive use of the sensitivity analysis and using a color coding to display user-friendly results for a large number of scenarios; and putting some emphasis on ecotoxicological assessment and/or ecotoxicity screening in order to address potential emerging contaminants. In this presentation, these strategies are illustrated using sample results from three comparative LCA studies on biomaterials: polyisocyanurate insulating foams with and without kraft lignin, a by-product of wood pulping; phenol-formaldehyde resins with and without kraft lignin and carbon nanotubes; and polypropylene composites with glass, flax and hemp fibers. In general, these results show that using high-tech processes and additives in low-tech products in order to 'compatibilize' biomaterials is often unfavorable to the energy balance and overall footprint. For stationary biomaterial applications, the impacts in several categories are highly correlated to the transformation chain efficiency, while for automotive and aerospace applications, weight is the key parameter. Also, the end-of-life of biomaterials can be problematic in terms of carbon de-sequestration, methane from

anaerobic digestion, biological oxygen demand, and releasing mildly toxic but slowly degrading compounds in the aquatic environment (e.g. phenolic acids). Finally, allocation remains an issue depending on the extent to which raw biomaterials such as kraft black liquor or flax straw constitute 'waste'. Burden shifting to the 'land use' and 'aquatic eutrophication' categories may be unavoidable.

**448 Assessing sensitivity in consequential LCA using a long-term energy model: application to GHG emissions in the French energy sector** E. Bouvart, IFP Energies nouvelles / Economics and environmental evaluation department; S. Tchung-Ming, L. Patouillard, D. Lorne, F. Menten, IFP Energies nouvelles. LCA methodological principles such as defined in ISO standards are now widely applied to existing and future energy technologies. Many adaptations of these principles are possible and developed, paving the way for significantly different LCA approaches. When assessing new technologies, time horizon does not seem to be a distinctive factor to choose a given approach. However, the type of questions addressed is the right key to guide LCA practitioners in the definition of relevant methodology. This work especially pays attention to the definition of the goal and scope of the analysis, the appropriate functional unit and the results presentation in order to help for the clarification of the consequential LCA (CLCA) approach. This paper presents a case study aiming to tackle questions that could be raised by French Public Authorities (or industrials willing to comply with Public Authorities expectations) on GHG emissions impacts associated to the implementation of renewable fuel policies between 2020 and 2030. These policies intend to promote specific emerging technologies (2<sup>nd</sup> generation biofuels, transport electrification, etc.). For this purpose, a methodological framework is developed, based on CLCA, to include all processes of the French energy and transport sector that could be directly or indirectly affected by the considered decision. Calculations are performed using a long-term energy model based on cost minimization to both identify all "affected processes" based on market mechanisms and quantify corresponding GHG emissions trade-offs. This paper focuses on sensitivity analyses which are even more essential in the present prospective analysis (compared to ALCA applied on existing technology) due to additional uncertainties. Here, sensitivity analyses concentrate on energy policies that will apply in the mid-long run (renewable energy incorporation targets, GHG emissions reduction objective, fuel quality constraints etc.) and macroeconomic data such as energy resource prices. Scenario analyses are conducted to cover these issues. Results show that GHG emissions of the considered sectors can significantly vary according to energy policies that Public Authorities can set leading to different technological choices. In addition, a sectoral analysis allows to identify the substitution effects induced by relative price variations and their consequences on GHG emissions.

**449 Prospective LCA of next-generation manufacturing systems in the United States** E. Masaner, Northwestern University / Mechanical Engineering. Next-generation materials and manufacturing processes hold great promise for reducing societal energy use and environmental impacts. Examples include synthetic biology for scalable and low-impact manufacture of chemicals and fuels, advanced composites for lightweight vehicles, high-strength materials for more durable goods and structures, and nanomaterials for energy applications. Rigorous, prospective assessment of the potential environmental and economic implications of such technologies is critical for informing decisions on RD&D investments, policy incentives, and initial target markets, all of which can help usher advanced manufacturing technologies through the "valley of death." This presentation will discuss methodological issues and new structured analysis approaches for systems assessment of advanced manufacturing technologies in the United States from both life-cycle environmental and economic perspectives. LCA of manufacturing technologies is particularly challenging given that environmental and economic benefits are often accrued in other economic sectors (e.g., advanced composites will save energy in transportation, but not necessarily in manufacturing); thus, a consequential approach is crucial. Moreover, technology investments are such that major costs (and possibly environmental impacts) are often borne by the manufacturing sector while benefits are accrued in the end use sectors. This can create misalignment of environmental and economic incentives, which can stall technology development and deployment. The research presented here is designed to address these challenges. As background, we'll discuss a new mass-based input-output model that is being developed by the project team (Northwestern, NREL, and ORNL) to quantify the systems effects of materials and

process substitutions at the U.S. national level. Next, we'll discuss major modeling challenges for substituting traditional processes and materials with advanced processes and materials while also accounting for environmental and economic impacts in a consequential manner. We'll then discuss a new structured method for modeling technology change in the industrial sector and its affected end use sectors, which will provide the LCA community with a foundational approach for assessing advanced manufacturing systems at different time scales. We'll illustrate the research contributions with a U.S. case study.

**450 Anticipatory Life Cycle Assessment of Photovoltaics** B.A. Wender, Arizona State University / School of Sustainable Engineering and The Built Environment; T.P. Seager, Arizona State University / School of Sustainable Engineering & Built Environm. There is a critical need for life cycle assessment (LCA) during the formative stages of technology development, so that the systemic environmental consequences of new technologies may be identified and mitigated early in product development cycles. For example, several studies have called for the application of LCA to nanotechnology. However, LCA typically relies on detailed inventory and performance data collected from *existing* industries at commercial scales. In the case of nanotechnology, collecting manufacturing and use-phase LCA inventory data is problematic, both because nanotechnologies are proprietary and because the energy and material flows studied at the laboratory-scale will likely change as the technology matures. This necessitates the development of *anticipatory* LCA methods that can be used to explore potential environmental impacts of technologies and industries before they exist at scale, or as they evolve. Anticipatory LCA can be viewed as a quantitative scenario development tool used in situations of high uncertainty (e.g., nano-enabled energy technologies) to inform research, investment, and policy decisions. This requires a combination of laboratory-scale inventory measurements and technological performance modeling. This presentation demonstrates the value of, and challenges impeding, anticipatory LCA through a case study of photovoltaics (PV). While the economic experience curves in PV are well understood, and optimistically project the cost of PV to continuously come down as efficiency improves, it is not obvious that *environmental* experience curves are also monotonically declining, especially as PV increasingly incorporates nano-scaled materials. The results suggest that anticipatory LCA may uncover new research directions that will reduce life-cycle burdens, such as improving synthesis reactions yields, recovering catalysts from waste streams, recycling inert gases, and finding substitutes for scarce or critical materials. Thus, anticipatory LCA can result in reorientation of the research agenda within the laboratory towards pathways that reduce environmental impacts.

**451 Prospective Life-cycle Modeling of a CCS System Using Metal-Organic Frameworks for CO<sub>2</sub> Capture** R. Sathre, E. Masaner, Lawrence Berkeley National Laboratory. Metal-organic frameworks (MOFs) are promising new material media for carbon dioxide (CO<sub>2</sub>) capture. Their tunable adsorption patterns may allow efficient separation of gases, e.g. from power plant exhaust. Here we conduct scenario-based prospective life-cycle system modeling to estimate potentials and implications of large-scale MOF application for post-combustion CO<sub>2</sub> capture and storage (CCS). The methodological approach includes parametric system modeling to quantify relations between system components; scenario projections of plausible pathways for system scale-up; proxy data on analogous materials and processes; and uncertainty analysis of parameter significance. We estimate the system-wide primary energy use, greenhouse gas (GHG) emissions, metal resource use, and economic costs associated with projected large-scale MOF production and CCS deployment. We compare the performance of a MOF-based system to a currently more mature amine-based capture technology. We discuss balancing two critical factors: thermodynamic efficiency of the capture/regeneration cycle; and life-cycle embodied energy and cost of the material and its ancillary systems. We identify uncertain and/or variable parameters that strongly influence the performance of the MOF capture system, including solvent use, media lifespan, capture cycle time, capital cost, and regeneration energy. Optimization of one or more of these parameters may significantly reduce the GHG mitigation cost of MOF technology. This early-stage life-cycle modeling is intended to generate knowledge to inform decisions made by material scientists (e.g. performance targets for laboratory research), process engineers (e.g. critical design parameters for system scale-up), and policy makers (e.g. GHG mitigation potentials and costs of CCS).

**452 Consequences of our Plastic Age** C.M. Rochman, San Diego State University and University of California, Davis / Marine Ecology/Environmental Health. 8% of the world's fossilized fuels are consumed for the production of plastic products. Many of these items benefit society; however, increasing production, consumption and poor management of waste has led to large quantities of plastic debris in the environment. This has fueled concern among environmentalists, scientists, industry-workers and policy-makers about the safety of this material to our economy, health, wildlife and habitats. This presentation will introduce the session and will review our understanding of the costs and benefits of plastic to our economy and the well being of organisms. Using recent insights from field and laboratory experiments, I will discuss plastics as a multiple stressor in habitats taking into account the plastic material in addition to priority pollutants that sorb to them. To better understand hazards associated with plastics in aquatic habitats we examined (i) the fate of priority pollutants to the most abundant types of plastic debris in marine habitats and (ii) the toxicological consequences for fish that ingest this material. These findings will be discussed in relation to the need to integrate policies for managing waste, debris and other contaminants at international levels so that they reduce the problems caused by plastic debris that frequently crosses international boundaries.

**453 Comparing Polycyclic Aromatic Hydrocarbon (PAH) Profiles in Polystyrene Foam Before and After Deployment in San Diego Bay, CA** E. Hoh, San Diego State University / Graduate School of Public Health; T.N. Davis, San Diego State University; C.M. Rochman, San Diego State University and University of California, Davis / Marine Ecology/Environmental Health. In a previous study, we found that polystyrene (PS) foam recovered from San Diego County beaches contained greater concentrations of PAHs than other recovered plastic debris. This finding led us to further examine unexposed PS foam and PS virgin pre-production pellets. Both contained greater concentrations of PAHs than virgin polyethylene (PE), polypropylene (PP) and polyvinyl chloride (PVC). Furthermore PS foam contained much greater concentrations than the non-expanded virgin PS, suggesting that PAHs may be a byproduct of PS foam manufacturing. These results led us to examine PAH profiles in detail across different types of PS foam both exposed and unexposed to an urban bay. For three months, three replicates of each of three types of plastic foam (PS hard and soft white foam, and polyurethane foam) were deployed in San Diego Bay, CA. Another three replicates of each type were not exposed to the bay and were immediately stored at -20°C. We characterized and compared the chemical profiles among types of plastic foam and between those exposed to the bay using a non-targeted analysis using comprehensive two-dimensional gas chromatography with time-of-flight mass spectrometry (GCxGC/ToF-MS). This non-targeted analysis provides unbiased chemical analysis. Therefore, we were able to detect a broad array of chemicals including PAHs present in the plastic foams and determine changes of the chemical profiles of each type before and after deployment in the bay. Comparing the total ion chromatograms and 3D contour maps of the samples, a greater number of peaks were found in all three plastic foam types before deployment (PS foam hard: 1319, PS foam soft: 2105, and polyurethane foam: 4375) than those after deployment (PS foam hard: 930, PS foam soft: 1220, and polyurethane foam: 3091). Regardless of PS foam types, we observed a greater number of PAHs before deployment compared to after. Furthermore, our results suggest an increase of higher molecular weight PAHs from the bay but a loss of lower molecular weight PAHs. These results suggest that both PS foam and polyurethane foam leach chemicals into the marine environment as well as sorb contaminants from the environment. Further detailed data analysis including identification of individual peak is in process. Future results will be discussed with a goal of better risk assessment of plastic foam marine debris because our results suggest PS foam may be a source of PAHs to the marine environment.

**454 Detection of polybrominated diphenyl ethers (PBDEs) in tissue of seabirds and the ingested plastics** K. Tanaka, H. Takada, R. Yamashita, Tokyo University of Agriculture & Technology / Laboratory of Organic Geochemistry (LOG); Y. Watanuki, Hokkaido University / Faculty of Fisheries. Plastic debris has been frequently observed on sea surface even in open ocean. Ingestion of the plastics by marine organisms such as seabird has been often observed. It has been also revealed that marine plastics contain toxic chemicals derived from additives and sorption from ambient sea water. Transfer of the chemicals from the ingested plastics to internal system of marine organisms has been a question to be addressed. Several studies

focused on PCBs (polychlorinated biphenyls) to examine their transfer from ingested plastics to seabirds. So far only weak evidences of the transfer of chemicals from ingested plastics to seabird tissue have been obtained, thought they were significant. The reason behind the weak evidence was that PCBs are exposed to seabirds both through food web and the ingested plastics. The present study focused on polybrominated diphenyl ethers (PBDEs). PBDEs were measured in the abdominal adipose of 12 individuals of short-tailed shearwaters, *Puffinus tenuirostris*, that were accidentally caught during experimental fishing in the North Pacific Ocean. All the examined seabirds contained plastics in their digestive tract with 0.04 g to 0.62 g per individual. PBDEs were detected in all the seabird samples with concentration range of total PBDEs from 0.5 to 151 ng/g-wet tissue. In most of the individuals (8 of 12), lower brominated congeners (e.g., BDE#47, BDE#99, and BDE#100) were dominant. These congener profiles are similar to those commonly observed in pelagic fishes. In 3 individuals, however, BDE#209 was dominant over lower brominated congeners. Also in one individual, BDE#183 was dominant. BDE#209 and BDE#183 were major components of Deca-BDE and Octa-BDE technical products, respectively, and both are normally not detected in pelagic fish and, therefore, exposure of BDE#209 and BDE#183 to seabird through food web is unlikely. On the other hand, BDE#209 and BDE#183 were detected in the plastics in the digestive tracts of the seabirds examined in the present study. Furthermore, detection pattern of these congeners in the ingested plastics matched with that in the abdominal adipose, i.e., three individuals showed dominance of these higher brominated congeners both in ingested plastics and the adipose. These data suggest plastic-mediated transfer of chemicals to the internal tissue of marine organisms.

**455 Drawing Linkages from Presence of Marine Plastic Debris to Potential Pelagic Food Web Impacts** A. Cook, U.S. EPA. Plastic debris in the marine environment, including fragments and microplastics (pieces ranging in size from 0.3mm to 5 mm), contain organic contaminants that have either been added during the plastics manufacturing, or adsorbed from surrounding seawater. The pelagic food web (including food consumed by humans) is potentially contaminated as a result of these chemicals contained within or adsorbed to marine plastic debris. Research has shown that ambient persistent organic pollutants including polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethane and metabolites (DDTs) adsorb to plastic debris. Exposure to persistent organic pollutants (POPs) contained within the plastics or adsorbed onto them is likely to occur because marine organisms ingest the contaminated marine plastic debris. Few studies, however, have examined the effects of introduction of marine debris-borne contaminants on fish tissue. The prevalence of plastic debris in the marine environment poses the threat of transfer of POPs associated with this debris into the food web. Because POPs bioaccumulate in aquatic organisms that serve as prey for marine predators that are ultimately human food sources, humans may potentially be ingesting these bioaccumulated POPs. US EPA Region 9 and California EPA's Office of Environmental Health Hazard Assessment (OEHHHA) have partnered to complete a fish tissue study using fish from the family Myctophidae, which have a circumglobal distribution and perform key roles in ecological communities and the pelagic food web. These fish, taken from an area in the North Pacific referred to as the "Eastern Garbage Patch", have been sampled for the presence of POPs in fish tissue. Plasticizers and/or surfactants detected in fish tissue samples along with POPs can demonstrate likely plastic debris exposures that have the potential to bioaccumulate, thus potentially impacting the human food chain. Presence of POPs in fish tissue samples with no detections of plasticizers and/or surfactants does not allow the conclusion that plastic debris exposure is, at least partially, responsible for the presence of POPs. In either case, the potential for the POPs to bioaccumulate through the food chain still exists. Results of such studies will help resolve this potential problem and possible threat, and allow public policy and practices to evolve to address this issue.

**456 Ingestion and effects of microplastics on zooplankton** M. Cole, Plymouth Marine Laboratory; P. Lindeque, Plymouth Marine Laboratory / Zooplankton Group; E. Fileman, Plymouth Marine Laboratory; T.S. Galloway, University of Exeter / Biosciences Department. Small plastic detritus, or microplastics, are a widespread and ubiquitous contaminant of marine ecosystems. The ingestion of microplastics by a wide range of marine biota, including mussels, worms, fish and seabirds, has now been documented. However, despite the vital ecological role of zooplankton in the marine food web, the impact of microplastics on zooplankton has remained

under-researched. This work explores the uptake and biological effects of microplastics on a range of zooplankton species. We have used an integrated approach, combining feeding rate studies and novel bio-imaging techniques to document ingestion and egestion for a range of plankton displaying different feeding behaviours. Our initial experiments, using fluorescence microscopy and Coherent Anti-stokes Raman Spectroscopy (CARS), have established that many zooplankton species, including copepods and decapod larvae, can ingest a range of polystyrene microplastics (0.4 – 30 µm diameter). Using the copepod *Centropages typicus*, we have conducted exposures to natural assemblages of algae with and without 7 µm and 20 µm diameter microplastics. Our preliminary results indicate that the presence of 7 µm microplastics significantly decreases algal feeding. Suppressed feeding may have repercussions on zooplankton health (e.g. reduced egg production and growth), an area that will be the focus of our on-going research. We will present our latest progress with these studies with a view to understanding the impact that microplastics can have on zooplankton function and health.

**457 Exploring the physical effects of microscopic plastic particles in a sediment-dwelling marine polychaete** S. Wright, / Biosciences; T.S. Gallo-way, University of Exeter / Biosciences Department; A. Bakir, University of Plymouth, University of Plymouth Enterprise Ltd / Finance; R. Thompson, S. Rowland, University of Plymouth. Microplastics form a ubiquitous component of marine debris, accumulating in oceans and sediments worldwide from low densities to localized 'hotspots'. Since they occupy the same size fraction as sediment grains, microplastics may be ingested by low trophic infauna adopting indiscriminate feeding strategies, the ecotoxicological costs of which remains unknown. The current work aims to determine the potential effects of microplastics on the behaviour and health of an ecologically important benthic model invertebrate species. The sediment-dwelling marine polychaete *Arenicola marina* is a widely distributed, OSPAR-approved species and forms an important component of marine food webs. *A. marina* has already shown the capacity to ingest microplastics. We are using an integrated approach combining sublethal toxicological measurements at the individual level with population level parameters and bio-imaging techniques to determine the uptake and fate of microplastics in vivo. Preliminary 21 day exposures to 3% unplasticised polyvinylchloride (uPVC, 212-250 µm) by weight have indicated sublethal effects, with inhibited casting and therefore feeding rates. Consequently, growth rates may be suppressed. We now hope to assess the potential population-level effects which may arise from inhibited casting rates using Darwinian fitness parameters. Future work will include *A. marina* exposures to uPVC and polyethylene (PE) of different shapes and sizes at concentrations based on reported environmental levels to determine the effective concentration (EC10) and associated integrated health impacts. The results will offer insight into the potential impacts of marine litter on fundamental physiological processes in this important component of the marine benthos.

**458 The NOAA Marine Debris Monitoring and Assessment Project: Current Efforts and Future Applications** S.M. Lippiatt, National Oceanic & Atmospheric Administration / Marine Debris Program, NOAA / IMSG; C. ARTHUR, NOAA / IMSG; N. WALLACE, NOAA. Scientific monitoring of marine debris (solid, persistent, man-made material) is necessary in order to understand the source, distribution, abundance, movement, and impact of debris on local, regional, and global scales. Furthermore, establishing baseline information on the abundance and types of marine debris is necessary for evaluating the effectiveness of measures to prevent marine debris and its impacts. As a result of the potential for Japan tsunami debris to reach U.S. shorelines, the NOAA Marine Debris Program (MDP) has worked with various partners at sites along the West Coast, Hawaii, and Alaska to coordinate shoreline monitoring on a monthly basis. At all sites, surveys follow the established NOAA MDP shoreline survey protocols. Preliminary results will be shared and the applicability of monitoring information to mitigation and prevention efforts will be discussed.

**459 Being SMART about plastic debris: you can't manage what you don't measure** M. Browne, National Center for Ecological Analysis and Synthesis / University of California. In 2011, 47 companies that produce plastic signed a joint declaration to develop solutions to prevent plastic debris from contaminating habitats. This strategy calls for "(i) public-private partnerships aimed at preventing debris, (ii) working with the scientific community to better understand the scope, origins and impact of marine litter and the range of solutions to the problem, (iii) promoting comprehensive

science-based policies and enforcement of existing laws to prevent marine litter, (iv) promoting best practices in waste management particularly in coastal regions, (v) enhancing opportunities to recover plastic products for recycling and energy recovery, (vi) stewarding the transport and distribution of plastic resin pellets and products to its consumers and promote this practice along the supply chain". This talk will critically evaluate this strategy and some of the obstacles it may face. I will assess whether or not policy is up-to-date with current scientific understanding and whether "energy-recovery" is helpful. I will appraise the methods scientists and managers use to understand the problems of plastic debris and whether or not they are finding solutions. A key component of my talk will be discussing the cost-effectiveness of collecting data with and without hypotheses and adequate sampling designs. I will propose a new model for managing plastic debris that treats actions by regulators, managers and industry as large-scale field experiments. Through this ecoLOGICAL approach, the problem (hypothesis) is clearly articulated and the relevant sampling design and statistical framework chosen to determine whether the problem was fixed by the action. The advantage of this approach, over existing models, is that it provides a specific, measurable, achievable, realistic and time-scaled approach to measure the progress of industry (as well as scientists, government and public) is making toward fulfilling its aim in reducing plastic debris.

**460 Alternatives to the Fish Early Life-Stage Test: A Research Strategy for Discovering and Annotating Adverse Outcome Pathways During Fish Development** D.C. Volz, University of South Carolina, University of South Carolina / Department of Environmental Health Sciences; D. Villeneuve, U.S. Environmental Protection Agency; H. Aladjov, International QSAR Foundation; G. Ankley, U.S. Environmental Protection Agency; S. Belanger, The Procter & Gamble Company; K. Crofton, U.S. Environmental Protection Agency; M. Embry, ILSI Health and Environmental Sciences Institute; D. Hinton, Duke University; M. Hornung, U.S. Environmental Protection Agency; T. Hutchinson, Centre for Environment, Fisheries, and Aquaculture Science; T. Iguchi, National Institute for Basic Biology; R. Johnson, U.S. Environmental Protection Agency; M. Leonard, L'Oréal; D. Mount, T. Norberg-King, U.S. Environmental Protection Agency; L. Ortego, Bayer CropScience; S. Padilla, U.S. Environmental Protection Agency; R. Tanguay, Oregon State University; J. Tietge, U.S. Environmental Protection Agency; L. Truong, Oregon State University; G. Veith, International QSAR Foundation; L. Wehmas, Oregon State University; G. Whale, Shell Health. The OECD 210 fish early life-stage (FELS) test is the primary guideline test used to estimate chronic fish toxicity, as well as support ecological risk assessments and chemical management programs around the world. As a step toward developing alternatives to the FELS test, a HESI-sponsored expert workshop was convened in May 2012 to continue discussing approaches for screening and prioritizing chemicals for FELS testing. These discussions were built on the tiered testing strategy initially proposed by Volz et al. (2011). While this strategy was first illustrated using three Adverse Outcome Pathways (AOPs) relevant to early fish development, we recognized that the initial screening tier must be expanded to a broad range, or battery, of toxicologically relevant AOPs to account for multiple mechanisms of toxicity within and across chemical classes. Therefore, the primary objective of the May 2012 workshop was to begin identifying and discussing the scope and breadth of potential AOPs during early fish development. Based on discussions prior to and during the workshop, we concluded that, while providing a strong foundation to begin defining AOPs during early fish development, the existing peer-reviewed literature is likely not sufficient for establishing quantitative linkages across multiple levels of biological organization. Therefore, we outlined a comprehensive research strategy to (1) systematically discover, characterize, and annotate AOPs during early fish development and (2) prioritize development of these AOPs based on current restrictions and demands to reduce animal use for toxicity testing, particularly in the European Union. The overall goal of this research strategy is to provide the conceptual and scientific foundation for identification and development of resource-efficient predictive assays that address the toxicological domain of the OECD 210 test. This presentation will provide an overview of key findings from the workshop, as well as a summary of our proposed approach for discovering and annotating AOPs during early fish development. The contents of this abstract neither constitute nor reflect official US EPA policy.

**461 Discovering and Annotating Fish Early Life-Stage (FELS) Adverse Outcome Pathways: Putting the Research Strategy into Practice** D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory; D.C. Volz, University of South Carolina / Department of Environmental Health Sciences; H.T. Aladjov, Bulgarian Academy of Sciences / IBPhBME; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship Organization, The Procter & Gamble Company / Central Product Safety Department; K.M. Crofton, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL; M.R. Embry, ILSI Health & Environmental Sciences Institute / Senior Scientific Program Manager; D.E. Hinton, Duke University / Nicholas School of the Environment; M.W. Horning, U.S. EPA / National Health and Environmental Effects Research Laboratory / Mid-Continent Ecology Division; T. Hutchinson, Centre for Environment, Fisheries, and Aquaculture Sciences (CEFAS); T. Iguchi, National Institute for Basic Biology; R. Johnson, U.S. Environmental Protection Agency / ORD/NHEERL/MED; M. Leonard, LOreal; D.R. Mount, US Environmental Protection Agency / ORD; T.J. Norberg-King, U.S. EPA / ORD, NHEERL, Mid-Continent Ecology Division; L.S. Ortego, Bayer CropScience / Ecotoxicology; S. Padilla, U.S. Environmental Protection Agency / Neurotox; T. Robert, Oregon State University; J.E. Tietge, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; L. Truong, Oregon State University / Department of Environmental and Molecular Toxicology, Environmental Health Sciences Center, The Oregon Nanoscience and Microtechnologies Institute and the Safer Nanomaterials and Nanomanufacturing Initiative; G. Veith, International QSAR Foundation; L.C. Wehmas, Oregon St. University / Mid-Continent Ecology Division; G. Whale, Shell Health, Research and Technology Centre. In May 2012, a HESI-sponsored expert workshop yielded a proposed research strategy for systematically discovering, characterizing, and annotating fish early life-stage (FELS) adverse outcome pathways (AOPs) as well as prioritizing AOP development in light of current restrictions and calls for reduction in the use of animals in testing, particularly in the European Union. This presentation illustrates that strategy using specific examples. The scope of AOP development was defined by the desire to develop alternatives to the OECD 210 FELS toxicity test which could increase efficiency and reduce cost. Key anatomical and physiological events occurring during the developmental period covered by the FELS test were identified. Review of the extant peer-reviewed literature identified existing knowledge concerning the normal regulation of those developmental events and associated physiological functions. Using the key event of swim bladder development and inflation as an example, we illustrate how basic biological knowledge was mined to develop a series of putative AOPs applicable to FELS development. One set of putative AOPs focused on disruptions to swim bladder development while another focused on disruptions to swim bladder function. These putative swim bladder-specific AOPs can be used to identify potential molecular screening assays that may be predictive of impaired swim bladder development or inflation or additional endpoints for inclusion in an extended fish embryo test, as well as to identify critical research gaps. Finally, we discuss the relative priority of conducting research to develop and fill gaps in swim bladder-related AOPs in the context of the overall strategy. The contents of this abstract neither constitute nor reflect official US EPA policy.

**462 Development and validation of OECD test guidelines on mollusc reproductive toxicity tests** V. Ducrot, INRA / Ecotox & Quality of Aquatic Ecosyst, INRA / Ecotoxicology and Quality of Aquatic Ecosystems; A. Sieratowicz, Johann Wolfgang Goethe University; L. Lagadic, INRA / Ecotox & Quality of Aquatic Ecosyst; J. Oehlmann, Johann Wolfgang Goethe University; D. Azam, INRA; R. Brown, AstraZeneca; M. Coke, M. Collinet, INRA; J. Dobrick, P. Egeler, ECT Oekotoxikologie GmbH; H. Holbech, University of Southern Denmark; T. Hutchinson, Cefas; A. Jach, BASF AG; K. Kinnberg, University of Southern Denmark; G. Le Page, AstraZeneca; P. Lorenz, ECT Oekotoxikologie GmbH; I. Planojevic, Universiteit Antwerpen; K. Ruppert, Johann Wolfgang Goethe University; C. Schmitt, Universiteit Antwerpen; U. Schulte-Oehlmann, Johann Wolfgang Goethe University; C. Veauvy, C. Askem, A. Smith, Cefas; L. Weltje, BASF AG / Agricultural Centre, BASF SE / Crop Protection; P. Matthiesen, Centre for Ecology and Hydrology / Far Sawrey. To date validated guidelines in line with the OECD Conceptual Framework for the Testing and Assessment of Endocrine Disrupting Chemicals have been developed

for rodents, amphibians, fish, insects and crustaceans. Tests for vertebrates are well represented in the battery but, except for arthropods, no further invertebrate group has been considered. The comparison of endpoints relevant for reproduction in invertebrates shows in many cases a much higher sensitivity in molluscs versus daphnids. Based on this result, the OECD test guideline programme has been extended in 2011 to cover reproduction effects of chemicals. Existing mollusc toxicity test protocols have already been critically reviewed and compared in the literature and in a OECD Detailed Review Paper on Mollusc Life-Cycle Toxicity Testing that identifies two relevant candidate species for developing such freshwater tests: *Potamopyrgus antipodarum* and *Lymnaea stagnalis*. However, this review did not clarify which toxicity test design and test conditions are the most appropriate for chemicals assessment with the selected species. Therefore, a guideline will be developed describing partial- and two generation full-life cycle test procedures in these species, so as to propose a balanced suite of apical mollusc toxicity tests applicable for the assessment of any type of chemical, including endocrine disruptors, as level 5 assays as described in the OECD Conceptual Framework. The guideline project is led by a consortium of European experts on mollusc toxicity tests (Germany/United-Kingdom/France/Denmark) from academia, industry and stakeholders. To date, expert knowledge has been gathered and formed the basis of draft standard operating procedures (SOPs) for the culture and test implementation in both species. Pre-validation tests have been performed involving 10 partner labs. They consisted in a 28-d study with Cadmium (Cd) and Bisphenol A (BPA) in *P. antipodarum* and in a 56-d study with Cd and tributyltin (TBT) in *L. stagnalis*, cumulative individual fecundity being used as the main endpoint. Pre-validation with Cd and TBT were successful in both species but results of the BPA tests showed higher variability due to exposure issues. Current work is focusing on the optimization of culture and reproduction test methods for e.g. the assessment of reproduction enhancing compounds. Obtained results and draft SOPs will be submitted to VMG-Eco in November 2012 for validation, before a ring test is conducted.

**463 Results of the OECD validation study of the Zebrafish Embryo Toxicity Test and Relationships to Acute Fish Toxicity Tests** S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship Organization, The Procter & Gamble Company / Central Product Safety Department; T. Braunbeck, University of Heidelberg / Department of Zoology; F. Busquet, ALTERTOX; G. Carr, The Procter & Gamble Company / Quantitative Sciences; A. Gourmelon, OECD / Environment, Health and Safety Division; M. Halder, European Commission / DG Joint Research Centre, IHCP, EURL ECVAM; A. Lillicrap, Norwegian Institute for Water Research; J. Rawlings, The Procter & Gamble Company / Environmental Stewardship Organization; R. Strecker, University of Heidelberg / Department of Zoology; S. Walter-Rohde, UBA, German Federal Environment Agency. The OECD Acute Fish Toxicity Test Guideline (TG 203) is an integral component in the environmental safety assessment of chemicals globally. A promising alternative approach to the acute fish toxicity test is based on the use of zebrafish embryos. In 2005, the German Federal Environment Agency submitted a draft TG on "Fish embryo toxicity (FET) test" to the OECD TG Program and a supportive Background Paper. OECD established an *ad hoc Expert Group on the FET* that concluded a validation study should be performed. The validation study evaluated the transferability, and the intra/interlaboratory reproducibility of the Zebrafish FET (ZFET). Newly fertilized zebrafish eggs were exposed for up to 96h to chemicals. Four apical endpoints are recorded daily as indicators of acute lethality in fish: coagulation of the egg, lack of somite formation, non-detachment of the tail bud from the yolk sac and lack of heart-beat from which LC50 values were determined. Twenty chemicals of various modes of action and physical-chemistry profiles were tested at 5 different concentrations in 3 independent runs in at least 3 laboratories with appropriate controls. Stock solutions and test concentrations were analytically confirmed for 11 chemicals. The 96-h LC50s for the suite of compounds ranged from 0.028-54,800 mg/L. Intralaboratory variability was less than interlaboratory variability for most chemicals. Interlaboratory variability was highest for the most toxic compounds or for chemicals that possessed challenging physical-chemical profiles. The *ad hoc Expert Group* concluded results were acceptable and consistent with expectations for ecotoxicity testing. A comparison of FET toxicity data and corresponding fish acute toxicity data (229 chemicals, 20 modes of action) was compiled to assess the overall relationships between the two. Regressions of FET versus fish acute toxicity were generated that resulted in a slope of 0.99, intercept of -0.19 and correlation

coefficient of 0.95 supporting a conclusion that the FET is a robust test method that predicts acute fish toxicity well. "Disclaimer: Opinions expressed and arguments employed herein are those of the authors and do not necessarily reflect the official views of the OECD or of the governments of its member countries, or the European Commission"

**464 Effectopedia: the collaborative science approach to adverse outcome pathways** H.T. Aladjov, Bulgarian Academy of Sciences / IBPhBME; G. Veith, International QSAR Foundation. The 21<sup>st</sup>-Century shift to a more prospective hazard identification and hypothesis generation requires strategic use of systems biology, QSAR and toxicological information. Adverse Outcome Pathways (AOPs) offer a unifying concept that can integrate the specialized knowledge from various disciplines and describe the causal linkages among biological responses over time. Effectopedia is an open-knowledge aggregation and collaboration tool for delineating AOPs in an encyclopedic manner with greater predictive power. It is designed to populate "AOP space" both with discrete cause-effect studies and with critical reviews in biology that are relevant to toxicology. To achieve both human and machine interpretability, Effectopedia uses an ontology-enhanced, natural language interface that offers clarifying questions and special tags to define the semantic knowledge while preserving the natural language description of the AOP's elements. The use of ontologies allows Effectopedia users the added advantage of publishing their contributions as nanopublications. Effectopedia serves as a visual editor to delineate of causal linkages at any level of biological organization and test species. It creates a common organizational space that (1) helps experts identify exactly where their specialized knowledge is needed in order to extend the causal linkages of biological responses and (2) creates a web-based conference room for dialogue and synthesis by experts with interest in a specific AOPs. Effectopedia creates live scientific documents that are instantly open for focused discussions and feedback, whilst giving credit to original authors and reviewers. Uncoupling the review and contribution processes allows different organizations to define their own set of criteria for quality assurance and associate them with the existing pathways while not slowing down the open (Wiki inspired) stream of contributions. New evidence of case studies, AOPs or discrete AOP segments can be distributed to interested contributors immediately, keeping Effectopedia's information current and providing historical documentation of its evolution.

**465 Adverse Outcome Pathways During Zebrafish Embryogenesis: A Case Study Using Paraoxon** K.L. Yozzo, University of South Carolina / Environmental Health Sciences; D.C. Volz, University of South Carolina, University of South Carolina / Department of Environmental Health Sciences. Using paraoxon as a reference acetylcholinesterase (AChE) inhibitor, the objective of this study was to develop an Adverse Outcome Pathway (AOP) that provided quantitative linkages across multiple levels of biological organization during zebrafish embryogenesis. Our hypothesis was that, similar to chlorpyrifos, developmental exposure to paraoxon (the neurotoxic metabolite of parathion) from 5 to 96 hours post-fertilization (hpf) results in concentration-dependent inhibition of AChE activity, leading to secondary motoneuron abnormalities and altered locomotion at 96 hpf. Within normal embryos, we first demonstrated that *ache* transcripts and AChE activity increased in a stage-dependent manner following segmentation. We then showed that static exposure of embryos to paraoxon (31.2-500 nM) from 5 to 96 hpf resulted in significant stage- and concentration-dependent inhibition of AChE activity, albeit these effects were fully reversible within 48 h following transfer to clean embryo media. Surprisingly, even in the presence of significant AChE inhibition, exposure to non-teratogenic paraoxon concentrations ( $\leq 250$  nM) did not adversely impact secondary motoneuron morphology nor larval locomotion based on confocal microscopy and preliminary behavioral evaluations at 96 hpf, respectively. Therefore, we investigated the potential effects of paraoxon exposure on spontaneous tail contractions at 26 hpf – an early locomotor behavior that (1) results from innervation of primary (not secondary) motoneuron axons to target axial muscles and (2) occurs in the absence of visual cues and detectable AChE activity. Interestingly, we found that, compared to vehicle controls, the frequency of spontaneous tail contractions was significantly higher following exposure to paraoxon concentrations as low as 31.2 nM (the lowest concentration tested), an effect that was not blocked by co-exposure with a non-selective muscarinic nor nicotinic acetylcholine receptor (AChR) antagonist. Overall, our data suggest that (1) normal AChE activity is not required for embryonic development and (2) AChE-independent tail

contractions at 26 hpf are sensitive to paraoxon exposure, an effect that is likely not due to direct paraoxon binding to AChRs. Using a well-studied reference chemical, this study highlights the potential challenges in developing AOPs that provide quantitative linkages from molecular initiating events to endpoints relevant for ecological risk assessments.

**466 Alternative strategies for assessing effluent toxicity in fish: A comparison of the fish embryo test and the larval growth and survival test** M.K. Sellin Jeffries, Miami University / Department of Zoology, Miami University; A.E. Stultz, Miami University / Department of Zoology; J. Rawlings, S. Belanger, Procter & Gamble; J.T. Oris, Miami University / Department of Zoology. In the United States (US), any facility discharging effluent directly to surface waters must conduct routine evaluations of whole effluent toxicity (WET). One method commonly used to obtain WET data is the 7 day larval growth and survival test (LGS) in which newly hatched fathead minnows (FHM), *Pimephales promelas* are exposed to effluents for 7 days with mortality as an endpoint. Given the increasing emphasis on animal welfare in toxicity testing, the goal of the current study was to identify an alternative test method capable of fulfilling the regulatory requirements for WET data, while minimizing the use of protected organisms or life stages. One such alternative to the LGS is the fish embryo toxicity test (FET), which has been sanctioned for WET testing in the European Union using embryonic zebrafish (ZF, *Danio rerio*). In order for the FET to be adopted in the United States, it would ideally be applicable to species commonly used in contract laboratories (i.e., FHMs) and demonstrate comparable sensitivity to the LGS. Thus, the main objectives of this study were 1) to develop test methods that harmonize the FHM-FET with the ZF-FET and the ZF-LGS with the FHM-LGS and 2) to compare the sensitivity of the FET and the LGS using both FHMs and ZF. To accomplish the first objective, tests using existing protocols for the FET and LGS were carried out with both species under different temperature and feeding regimes in order to determine optimal test conditions. The existing protocols were then modified and applied to the remaining experiments. To address the second objective, lethal and sublethal (e.g., length, weight, otolith size, deformity frequency) endpoints were evaluated following FET and LGS testing of each species using the reference toxicant 3,4-dichloroaniline and two types of effluents. These results provide evidence indicating the ability of the FHM-FET to serve as an alternative to the FHM-LGS for WET testing carried out in the US.

**467 Yet another analysis of sample size effects on the estimation of LC50 in common toxicity experiments, and free software to analyze your data!** G. Carr, The Procter & Gamble Company / Quantitative Sciences GCO; J. Rawlings, J. Brill, The Procter & Gamble Company / Environmental Stewardship Organization; S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship Organization, The Procter & Gamble Company / Central Product Safety Department. Statistical methods for concentration-response models of quantal responses such as the probit model, are widely known and applied. Recent work on the design of these experiments has focused on substantial reductions of animal usage. A clear understanding of the tradeoffs to implementing these reductions is not readily available, however. To close this gap, extensive computer simulations were performed to quantify the effects of sample size on the quality of statistical results. The placement of exposures relative to the true, but unknown, LC<sub>50</sub>; the slope of the response; and the group sizes, must all affect the properties of the estimator. The results obtained in these simulations reflect, and quantify, the intuition that reducing study size must negatively impact the quality of results. The likelihood of a successful study, when group sizes are pushed to minimum levels, is shown to be highly dependent on the true, but unknown, LC<sub>50</sub> being well centered in the range of concentrations tested. When test concentrations are not well centered on the true LC<sub>50</sub>, the performance of the method is greatly degraded. In the course of our work on the development and validation of the fish embryo test for acute toxicity, a program was developed to fit probit-type models with a special class of confidence interval for the LC<sub>50</sub> (profile likelihood) that is more computationally difficult, but far superior to the standard interval method in problematic cases. Such cases are more likely to occur in smaller sized studies. A freely available program to fit this class of models in the R language for statistics is also presented, which includes the more robust confidence interval calculations and high-quality graphical summaries.

**468 Contaminants of Emerging Concern Early Warning Network: Regional Expansion of National Centers for Coastal Ocean Science Mussel Watch Program** K. Kimbrough, G. Lauenstein, NOAA/National Centers for Coastal Ocean Science / NCCOS Mussel Watch Program; J.D. Christensen, National Oceanic and Atmospheric Administration / Coral Reef Conservation Program, NOAA Ocean Service; N. Dodder, SCCWRP; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP; S. Weisberg, Southern California Coastal Water Research Project; D.A. Alvarez, USGS Columbia Environmental Research Center; E.T. Furlong, U.S. Geological Survey / National Water Quality Laboratory; S. Klosterhaus, San Francisco Estuary Institute; D. Gregorio, California Water Resources Control Board. A California pilot project was launched in 2009 to determine which, if any, contaminants of emerging concern (CECs) should be added to future Mussel Watch (MW) Program monitoring activities. The objectives of this study were to: 1) maintain connection to long-term MW by sampling a subset of historical sites for legacy and metal constituents; 2) expand spatial coverage to provide stratification by land use (urban, low development and agricultural) and proximity to regulated discharges; 3) focus analytical resources on high priority CECs (e.g. PPCPs, household chemicals and current use pesticides); 4) examine the efficacy of passive sampling devices (PSDs) as surrogates for contaminant exposure and bioaccumulation; and 5) create a regional-state-federal partnership to more efficiently and comprehensively utilize monitoring resources. Mussels (native and caged) were collected from 68 stations (25 historic) during 2009-10 and analyzed for more than 200 individual CECs; a subset of these samples were also analyzed for alternative flame retardants, perfluorinated chemicals and carbon nanomaterials. PSD arrays including Polar Organic Chemical Integrative Samplers (POCIS), solid phase microextraction (SPME) and polyethylene devices (PEDs) were deployed and retrieved at 11 sites for comparison with tissue CEC residues. The resulting data was analyzed to characterize the extent and severity of tissue CECs; assess for differences by land use and discharge categories; and investigate for concordance between tissue and PSD concentrations. This pioneering study will help guide future CEC monitoring efforts at the regional, state and federal levels.

**469 Occurrence of CECs in Bivalve Tissues from the California Mussel Watch Pilot Study** N. Dodder, SCCWRP; S. Klosterhaus, San Francisco Estuary Institute; R. Grace, Axyx Analytical Services; J. Ramirez, B&B Laboratories; M.J. La Guardia, Virginia Institute of Marine Science / Environmental & Aquatic Animal Health, Virginia Institute of Marine Science / Environmental Science; L. Ferguson, Duke University / Department of Civil and Environmental Engineering, Duke University / Nicholas School of the Environment, Duke University / Department of Civil & Environmental Engineering, Pratt School of Engineering / Department of Civil & Environmental Engineering; K. Kimbrough, G. Lauenstein, NOAA/National Centers for Coastal Ocean Science / NCCOS Mussel Watch Program; D. Gregorio, State Water Resources Control Board – CA; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP. In 2009, a pilot project was initiated within NOAA's Mussel Watch Program to monitor for contaminants of emerging concern (CECs) in California coastal waters. Native bivalves were collected from 68 stations extending the length of California's coastline. Stations were categorized by land use and proximity to regulated discharges. Approximately 150 CECs were measured by multiple laboratories, using primarily GC-MS and LC-MS/MS based methods. The CECs detected were (number measured/number detected): pharmaceuticals and personal care products (PPCP) (89/31), polybrominated diphenyl ethers (PBDE) (26/16), current use pesticides (CUP) (26/7), perfluorinated compounds (PFC) (12/5), hexabromocyclododecane (HBCD) and alternate flame retardants (9/4), and alkylphenols (AP) (4/4). The classes had sum concentrations per station of PPCP = AP > PBDE > CUP = HBCD = PFC. Single walled carbon nanotubes were not detected. CECs were highest for stations classified as urban, with the exception of CUPs which had higher concentrations for agriculturally-influenced stations. The CEC profiles (types and abundance) for urban stations were consistent across northern and southern population centers within California, indicating a generic rather than regional management approach is warranted. The influence of storm water and wastewater treatment plant discharges was also investigated. These results will help suggest CECs for inclusion in future Mussel Watch surveys and California-specific monitoring projects.

**470 Polyethylene-Water Partition Coefficients for In Situ Passive Sampling of Contaminants of Emerging Concern in Santa Monica Bay and Los Angeles Harbor** A.S. Joyce, University of Southern California / Chemistry, Univ. of Southern California; M.S. Pirogovsky, University of Southern California / Chemistry; W. Lao, Southern California Coastal Water Research Project; J.F. Haw, University of Southern California / Department of Chemistry; R.G. Adams, Loyola Marymount University; K.A. Maruya, Southern California Coastal Water Research Project. Low-density polyethylene (PE) used for in-situ sampling of organic chemicals in water requires pre-calibration and knowledge of the degree of attainment of equilibrium between the sorbing and aqueous phases. PE-water partition coefficients ( $K_{PEW}$ ) for brominated diphenyl ether (BDE) 47, tetrabromophthalate (TBPH), the DDT metabolites p,p'-DDMU and p,p'-DDNU, methoprene, and PCB congeners 8, 101 and 209 were determined in spiked seawater laboratory experiments. Measured  $K_{PEW}$  values for p,p'-DDMU, PCB 101, and BDE 47 were similar to previously reported values. Log  $K_{PEW}$  was correlated with log  $K_{OW}$  for targeted analytes (log  $K_{OW} < 8$ ). Aqueous concentrations of these chemicals were estimated after correction for non-equilibrium conditions using pre-calibrated PE samplers (containing performance reference compounds) that were co-deployed with caged mussels near large wastewater treatment plant outfalls in Santa Monica Bay and Los Angeles Harbor. PE estimated aqueous concentrations of target analytes in the ng/L range were correlated with mussel soft tissue concentrations, suggesting that PE samplers represent a viable sampling alternative to bivalve sentinels for water quality monitoring of hydrophobic organic compounds.

**471 Occurrence of contaminants of emerging concern in coastal California waters using passive sampling devices** D.A. Alvarez, USGS Columbia Environmental Research Center; K. Maruya, N. Dodder, Southern California Coastal Water Research Project; E. Furlong, USGS NWQL; K. Smalling, USGS; W. Lao, Southern California Coastal Water Research Project. Marine life is constantly exposed to a myriad of organic contaminants originating from urban and agricultural centers along the coast. These chemicals may include legacy organics and contaminants of emerging concern (CECs) which can enter the ocean via surface runoff, rivers and streams, and direct discharge of wastes. Many of the CECs do not accumulate in the tissues of common monitoring species (i.e., bivalves and fish) but may be present at levels in the water to be potentially harmful to sensitive species. Passive sampling devices were deployed at established NOAA Mussel Watch sites along the California coast to provide data on the presence and concentrations of these contaminants. The polar organic chemical integrative sampler (POCIS) was used to sample CECs with a wide range of water solubilities such as pharmaceuticals, fragrances, flame retardants, and current-use pesticides. Solid-phase microextraction (SPME) and polyethylene devices (PEDs) were used to sample hydrophobic contaminants such as PAHs, PCBs, PBDEs, and chlorinated pesticides. The predominant CECs identified were the phosphate-based alternative flame retardants and fragrances. Chemical residues in the passive samplers were positively correlated to the chemical concentrations in mussel tissue, for most of the PCBs, PBDEs, and pesticides sampled by the SPME and PEDs. Out of 34 common chemicals analyzed in both the POCIS and mussel tissue, there were no common detections indicating a low bioaccumulation potential for many of these chemicals. This study indicates that passive sampling techniques can be used as a surrogate for determining the potential exposure of aquatic organisms to a variety of organic contaminants and multiple types of samplers are often needed to be used in concert in order to achieve a holistic assessment of exposure.

**472 The occurrence and fate of chemicals of emerging concern (CECs) in effluent dominated river systems in southern California** A. Sengupta, Southern California Coastal Water Research Project / Biogeochemistry; M. Lyon, D. Smith, Los Angeles Regional Water Quality Control Board; A. Heil, Los Angeles County Sanitation Districts; D. Heil, J. Drewes, Colorado School of Mines; S. Snyder, University of Arizona; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP. Chemicals of emerging concern (CECs) are a diverse group of relatively unmonitored and unregulated chemicals that are known to occur at trace levels in treated wastewater, yet little is known about their occurrence and fate once discharged into ambient receiving waters. To investigate the concentration and fate of CECs in two effluent-dominated coastal rivers, receiving water samples were collected at sites downstream of municipal wastewater treatment plant (WWTP) discharge points during two dry-weather sampling

events. A reference sample in each watershed was also collected upstream of known WWTP discharge locations to serve as background input of CECs (e.g. via dry weather runoff and atmospheric contributions). All samples were extracted and analyzed for more than 50 pharmaceuticals and personal care products, current use pesticides and flame retarding chemicals using research grade LC-tandem MS and low and high resolution GC-MS. For most CECs, aqueous concentrations in the stream were higher compared to the reference sites, and also decreased with increasing distance from WWTP discharge locations. With the field-collected data, we used a one-dimensional transport – equilibrium chemistry model to parse out the chemical (e.g. photolysis, sorption) and physical (e.g. transport, dilution, water-sediment partitioning) processes that the CECs undergo in these systems.

#### 473 Determination of pharmaceuticals in nearshore marine sediment samples from the Southern California Bight

E.T. Furlong, S.L. Werner, U.S. Geological Survey / National Water Quality Laboratory; A.S. Pait, NOAA/NOS/NCCOS / Center for Coastal Monitoring and Assessment; M. Choi, National Fisheries Research and Development Institute, Korea / Marine Environment Research Division, National Fisheries Development and Research Institute / Research Scientist; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP; H. Choi, National Fisheries Development and Research Institute. Many coastal urban marine ecosystems receive liquid and solid discharge from wastewater treatment, which was not designed to efficiently remove trace concentrations of the pharmaceuticals and other contaminants of emerging concern that are typically present in discharge. Coastal marine sediments are a likely sink for pharmaceuticals that adsorb to solids by hydrophobic or other interactions, and are a potential means of exposing benthic organisms to these compounds. Consequently, the presence and concentrations of pharmaceuticals were the subject of study at five sites adjacent to wastewater discharges and at 20 sites more widely distributed within the Southern California Bight (SCB), a biologically diverse and productive region that is comprised of the 700 km of recessed coastline from Point Conception, in Santa Barbara County, California to Cabo Colnett, just south of Ensenada, Mexico. Grab samples of surficial sediment were collected, chilled immediately after collection and then frozen prior to analysis. Thawed wet sediment aliquots were extracted by using pressurized liquid extraction with a water/acetonitrile mixture. Following extraction, an aliquot of the sample extract was solvent exchanged into water modified with ammonium formate, filtered, and analyzed for 85 pharmaceuticals by HPLC/MS/MS, using positive electrospray ionization and selected reaction monitoring. Twenty-three pharmaceuticals were each detected in 3 or more samples, with median concentrations ranging between 0.12 and 7.6 nanograms per gram (ng/g). Thirteen pharmaceuticals were detected in one or two samples, and 49 pharmaceuticals were not detected at all. Diphenhydramine, an over-the-counter antihistamine, was detected at the highest concentration, 130 ng/g. The four most frequently detected pharmaceuticals, present in fourteen or more samples, were azithromycin, caffeine, verapamil, and thiabendazole, detected at frequencies of 80, 68, 68, and 56 percent, respectively, with maximum concentrations of 19, 14, 4.5, and 1.7 ng/g, respectively. Overall, pharmaceuticals were detected at higher concentrations and at greater frequency in the five sediment samples collected adjacent to discharges than in the 20 samples collected more widely within the SCB. However, a quantitative relationship between proximity to discharge points and the composition or concentrations of pharmaceuticals detected in sediments could not be discerned.

#### 474 Use of Bioassays to Identify Contaminants of Emerging Concern in Aquatic Ecosystems

D. Schlenk, University of California-Riverside / Department of Environmental Sciences; R. Lavado, University of California-Riverside / Department of Environmental Sciences; J.E. Loyo-Rosales, University of California Berkeley / Department of Civil and Environmental Engineering; W. Jones, University of California Riverside / Department of Environmental Sciences; L.A. Maryoung, University of California Riverside / Department of Environmental Sciences; N. Riar, University of California-Riverside / Department of Environmental Sciences; I. Werner, Swiss Centre for Applied Ecotoxicology, Eawag/EPFL / Department of Anatomy, Physiology and Cell Biology; D.L. Sedlak, University of California Berkeley / Department of Civil and Environmental Engineering. Contaminants of Emerging Concern (CECs) represent a “universe” of known and unknown compounds including pharmaceutical and personal care products, nanomaterials, and human metabolites. Aquatic organisms tend to have the greatest exposure to human-derived CECs due to point source discharge

of domestic wastewater effluents and to non-point source runoff to surface water. Significant uncertainty exists in determining the ecotoxicological risk of these compounds. Some studies have shown that exposure to relatively low concentrations of synthetic hormones have abolished populations of fish. Populations of threatened and endangered species of fish in the San Francisco Bay Delta have shown significant declines leading to changes in water allocations to the Central Valley and Southern California. Using an easily measured endocrine response (estrogenic activity), evaluations of surface waters that drain into the estuary were carried out. Site-specific patterns of activity were observed with causal compounds varying between the Napa River and the Delta of the Sacramento River. Further analyses of the Sacramento River Delta have indicated the potential for pyrethroid insecticides and surfactant mixtures as contributing factors to this response. Whether estrogenic activity is causally linked to population decline is uncertain. However, the temporal association between urban pyrethroid use and population declines in Delta fish species indicates further research is necessary.

#### 475 From ‘omics to otoliths: using *Menidia* species to assess endocrine disruption

S.M. Brander, Bodega Marine Lab, University of California, Davis / Environmental Toxicology, / Department of Biology & Marine Biology; R.E. Connon, University of California – Davis / School of Veterinary Medicine, Aquatic Toxicology Laboratory, University of California, Davis / Anatomy, Physiology and Cell biology; G. He, University of California, Davis / Dept. Environmental Toxicology; J.A. Hobbs, University of California, Davis / Dept. Wildlife, Conservation, Fisheries; K.L. Smalling, U.S. Geological Survey; J.W. White, University of North Carolina, Wilmington / Dept. Biology and Marine Biology; S. Teh, University of California, Davis / School of Veterinary Medicine, Dept. Anatomy, Physiology and Cell Biology; I. Werner, Swiss Centre for Applied Ecotoxicology, Eawag/EPFL / Department of Anatomy, Physiology and Cell Biology; M.S. Denison, University of California, Davis / Dept. Environmental Toxicology; G.N. Cherr, University of California, Davis / Bodega Marine Lab, Departments of Environmental Toxicology and Nutrition. Endocrine disrupting chemicals (EDCs) are known to interfere with endogenous hormones and cause physiological abnormalities in fishes. Both theory and empirical data confirm that EDCs can also cause declines in fish populations. However, few studies have attempted to link complex environmental EDC mixtures with responses at multiple tiers of the biological hierarchy, including population-level effects. Additionally, the use of environmentally relevant fishes as surrogate species from regions with demonstrated fish population decline, such as the San Francisco Bay and Sacramento San Joaquin Delta, is lacking. This is of particular importance to endangered or threatened fish species that cannot be sampled in sufficient numbers from the wild to determine whether endocrine disruption is playing a role in their decline. To this end, we undertook a four-tiered investigation into estrogenic and androgenic EDC effects in *Menidia audens* (Mississippi silverside), an Atherinid distributed throughout the impacted San Francisco Bay (SFB) estuary. Correlations were observed between biological scales that indicated *Menidia* are impacted by the complex EDC mixtures present in Suisun Marsh, SFB at the molecular, organism and population levels. Results from laboratory exposures to pyrethroid pesticides commonly detected in the SFB using *Menidia beryllina* (inland silverside), which indicate that the pyrethroids bifenthrin and permethrin can act as estrogens or anti-estrogens, lend support to field observations. We used the data collected from these and other ongoing research efforts to parameterize a population dynamic model. This model includes the functional relationship between EDC effects, sex ratio, and mating success and provides a general, analytical understanding of the potential effects of EDCs on population persistence in *Menidia* and other impacted group-spawning species, such as the Delta smelt.

#### 476 The Role of Contaminants, in the Context of Multiple Stressors, on the Collapse of the Striped Bass Population in the San Francisco Estuary

D.J. Ostrach, University of California at Davis / Pathobiology, Conservation & Population Biology Laboratory, Ostrach Consulting / Pathobiology, University of California at Davis / Center For Watershed Sciences. This investigation into the collapse of the striped bass population in the San Francisco Estuary (SFE) began in the late 1980s by addressing the starvation hypothesis. Our findings ruled out the starvation hypothesis but uncovered significant sublethal contaminant effects. It was thought that the decline was due to hydrodynamic changes relating to Delta outflows, effects of the State and Federal water projects and an invasive clam potentially limiting food supply for pelagic larvae. However, the combined effects of these

factors did not explain the collapse of striped bass or other pelagic fish in the SFE. Most agency research efforts continued to focus on uncovering a major cause of the collapse to determine management action. As investigations continued over the next 15 years, management and researchers began to accept that multiple stressors and associated interactions contributing to the decline of pelagic fish in the SFE ecosystem were complicated, multifaceted and research efforts were redirected accordingly. In 2005 as part of the Interagency Ecological Program Pelagic Organism Decline investigations, I assembled a research team with expertise in histopathology, analytical chemistry, geochemistry, toxicology, protein profiling, ecological modeling, spatial mapping, microbiology and parasitology. The goal of this research program was to assess the significance of contaminants relative to other stressors on the decline of the striped bass population. Significant progress was made over a three year investigation and identified contaminants as an important stressor on striped bass throughout the first 6-8 months of life. Maternal transfer of xenobiotics and adverse effects was documented over an extended period of time likely causing population level effects. Findings of abnormal disease and parasitism were found in juvenile striped bass in all three years studied and are considered to have a significant impact on the health status of the fish and subsequently the population. In addition, data indicated adult striped bass are also adversely affected by the bioaccumulation of contaminants such as PBDEs and heavy metals. This interdisciplinary multiple stressor approach yielded significant findings on the role of contaminants in the decline of striped bass in the SFE in a relatively short period of time. This study illustrates the utility and importance of using this type of approach to investigate contaminant effects in complex ecosystems.

**477 Habitat Use of Striped Bass in the San Francisco Estuary, and Their Relation to Total Mercury and Heavy Metal Body Burden Upon Capture** J.H. Walsh, Moss Landing Marine Laboratories; J. Hunt, J. Davis, San Francisco Estuary Institute; G.M. Cailliet, Moss Landing Marine Laboratories; D. Ostrach, Ostrach Consulting. Striped bass (*Morone saxatilis*) is a resident anadromous fish in the San Francisco Estuary (SFE) encountering anthropogenic contaminants due to habitat proximity to pollution sources. Habitat use has been shown to be an important factor in the bioaccumulation of contaminants in striped bass. Several studies have shown that contaminants are likely in part responsible for the decline of this striped bass population and pose potential health risks to consumers. In this study we performed an integrated assessment of concentrations of metals in striped bass fillets, and used strontium isotope ratios from otoliths to distinguish freshwater, estuary, and marine habitat use. This approach, using recently developed methods integrate habitat use and contaminant data, provides a new and more accurate approach to diagnosing and analyzing contaminant effects in striped bass. Results indicate that mercury and selenium are at or approaching levels of concern in striped bass tissue, and mercury tissue concentration increased over time. Findings also indicated that cadmium levels in fillets, normally bioaccumulated in visceral organs, were detected in a third of the samples. Furthermore, we document further evidence of a freshwater resident subpopulation and determined that distinct subpopulations exist based on habitat use. When results from these methods are integrated, there was also indirect evidence that striped bass females are passing significant amounts of mercury into their eggs. The data indicate that several contaminant stressors continue to pose a serious threat to recovery of striped bass in the SFE. Habitat use of individual striped bass also needs to be addressed in future surveys estimating population size and to identify if certain striped bass subpopulations are more at risk from contaminants. The results and approach used in this study will aid ecosystem managers in better understanding and addressing contaminant effects in San Francisco Estuary pelagic fish species.

**478 Transcription Profiling in Delta Smelt (*Hypomesus transpacificus*): Up- and Downstream Exposures from a Wastewater Effluent** R.E. Connon, University of California – Davis / School of Veterinary Medicine, Aquatic Toxicology Laboratory, University of California, Davis / Anatomy, Physiology and Cell biology; M. Hasenbein, Technische Universität München / Aquatic Systems Biology Unit, Department of Ecology and Ecosystem Management; I. Werner, Swiss Centre for Applied Ecotoxicology, Eawag/EPFL; E. Fritsch, University of California, Davis / Molecular Biosciences; A. Javidmehr, L. Deanovic, University of California, Davis / Anatomy, Physiology and Cell biology; S. Beggel, Technische Universität München / Aquatic Systems Biology Unit, Department of Ecology and Ecosystem Management; E.R. Hudson-Davies, University of California, Davis / Anatomy, Physiology and Cell biology; J. Geist, Technische Universität

München / Aquatic Systems Biology Unit, Department of Ecology and Ecosystem Management. The delta smelt (*Hypomesus transpacificus*) is an endangered fish species endemic to the Sacramento-San Joaquin Estuary, California; populations of which have significantly declined over the past three decades. Contaminant exposure is one of many likely contributors to the decline. We investigate transcriptional responses in larval delta smelt resulting from exposure to water samples collected at the Department of Water Resources Field Station at Hood, a site of concern situated upstream of known delta smelt spawning habitats, and downstream of the Sacramento Regional Wastewater Treatment Plant (SRWTP). Microarray assessments indicate impacts on the energy metabolism, DNA and RNA processing, the immune system, development and upon activity. Transcription responses of fish exposed to water samples from Hood were compared with exposures to 9% effluent samples from SRWTP, water from the Sacramento River at Garcia Bend (SRGB); upstream of the effluent discharge, and SRGB water spiked with 2 mg/L total ammonium; 9% effluent equivalent. Results indicate that transcriptomic profiles from Hood are similar to SRWTP effluent and ammonium spiked SRGB water, but significantly different from SRGB, however, SRGB samples were also significantly different to laboratory controls, suggesting that SRWTP effluent is not solely responsible for the responses determined at Hood, that ammonium exposure likely enhances the effect of multiple-contaminant exposures, and the observed mortality at Hood is due to the combination of effluent discharge including contaminants arising from upstream of the tested sites. This study shows that transcriptomic responses of fishes can be valuable endpoints for identification of sources of toxic compounds in surface waters that occur at sublethal concentrations.

**479 The effects of a commonly used pyrethroid pesticide, bifenthrin, on the reproduction of steelhead (*Oncorhynchus mykiss*)** K.L. Forsgren, University of California, Riverside / Department of Environmental Sciences, University of California / Dept of Environmental Sciences; N. Riar, D. Schlenk, University of California-Riverside / Department of Environmental Sciences. The San Francisco Bay Estuary and Sacramento-San Joaquin Delta (Bay-Delta) is an important breeding and nursery ground for many species. Habitat quality and contamination of surface waters are limiting factors for ESA-listed fish stocks in watersheds with significant land use. Bifenthrin has received little attention regarding its effects on salmonid populations despite being detected in northern California runoff. While the potential for aquatic toxicity is evident, it is unknown what effect bifenthrin exposure has on the reproductive health of fishes. Plasma sex steroids and gonadosomatic index (GSI) were determined in juvenile steelhead exposed to bifenthrin (low:  $0.028 \pm 0.006$  ug/L; high:  $0.719 \pm 0.073$  ug/L) for 14 days and gonadal tissue was examined histologically. In male steelhead, sex steroids were not significantly altered (E2  $p = 0.0634$ , T  $p = 0.0833$ , 11-KT  $p = 0.3057$ ) after treatment. GSI was reduced ( $p = 0.0231$ ), but the testis did not show measurable histological damage. Female steelhead exposed to bifenthrin (high dose) had significantly ( $p = 0.0251$ ) elevated estradiol-17b (E2) levels. There was no difference in testosterone (T;  $p = 0.1430$ ), 11-ketotestosterone (11-KT;  $p = 0.0760$ ) or GSI ( $p = 0.1937$ ). Although ovarian follicle diameter significantly ( $p < 0.0001$ ) increased in bifenthrin-treated fish, widespread atresia was observed throughout the ovary (low dose  $91.24 \pm 8.89\%$ ; high dose  $82.76 \pm 10.84\%$ ). These data indicate that exposure to bifenthrin results in reproductive dysfunction in female steelhead while males appear to be relatively unaffected. The ecological implications are uncertain, but further study is warranted. Additionally, given the increased urban use of bifenthrin and relatively high levels in the aquatic environment, a more comprehensive understanding of the impact of bifenthrin on wildlife will be imperative for improving risk assessment of pyrethroid use in the Bay-Delta in coming years.

**480 Current-Use Pesticides in the San Francisco Bay-Delta Estuary: Exposure to Complex Mixtures and Multiple Environmental Compartment** M.L. Hladik, K.L. Smalling, J.L. Orlando, K.M. Kuivila, U.S. Geological Survey. Current-use pesticides pose a potential threat to aquatic organisms in the San Francisco Bay-Delta Estuary, an ecologically important habitat and a location for large-scale ecosystem restoration. It is critical to understand the effects of pesticides on this ecosystem, which requires a detailed knowledge of pesticide exposure throughout the watershed. Pesticides are transported into the estuary dissolved in the water or bound to the sediments. Recent studies have shown that aquatic organisms of concern can accumulate current-use pesticides; these organisms are exposed to pesticides

via water, sediments, and food. Hundreds of pesticides are applied annually within the San Francisco Estuary watershed on a variety of crops and in urban areas. As a result of these diverse inputs, aquatic organisms are exposed to complex mixtures of pesticides that vary spatially and temporally. Pesticide use changes over time as older pesticides are withdrawn, new pesticides or new uses for pesticides are registered, and new pests become a problem. Monitoring programs need to adapt to these changing use patterns to be effective. The U.S. Geological Survey's analytical methods are routinely updated and currently include over 100 pesticides and pesticide degradates in all relevant environmental compartments (water, sediment and tissue) using GC/MS and LC/MS/MS. Case studies from our current and past research efforts will be highlighted. Pyrethroid insecticides are usually bound to sediments and their high aquatic toxicity requires low detection limits; therefore, special methods were developed for these compounds. The number of fungicides used is increasing with the registration of new active ingredients, and 34 are included in our current methods. Rice, an important crop in this watershed, has seen a change in herbicide applications after molinate was phased out in 2009; this is reflected by increased detections of propanil (and its degradate) and clomazone. Increasing both our knowledge of pesticide occurrence and our collaborations with toxicologists, ecologists, and fisheries biologists will aid in linking pesticide exposure to effects on aquatic organisms within multi-stress environments such as San Francisco Bay-Delta Estuary.

**481 A comprehensive study of the occurrence of pyrethroids in water and sediment from the lower American River** S. Clark, S. Ogle, Pacific EcoRisk; T. Albertson, Caltest Analytical Laboratories; C. Harbourt, G. Hancock, Waterborne Environmental; G. Mitchell, FMC Corporation; A. Barefoot, D. Tessier, DuPont Crop Protection; M.G. Dobbs, Bayer Crop Science, Bayer CropScience / Ecotoxicology Group; P. Hendley, Syngenta Crop Protection, LLC. / Senior Syngenta Fellow, Syngenta Crop Protection, LLC. / Product Safety; K.S. Henry, Syngenta Crop Protection, Inc. / Ecological Sciences. The American River is a high quality water source used for the Sacramento metropolitan area. In a previous study in which grab samples of water were collected from the river bank during 4 rain events and one dry weather event, pyrethroid insecticides were detected in water samples collected over a 30-km reach of the lower American River at concentrations that were reported to be toxic to the amphipod *Hyaella azteca*. In October 2011, a follow-up monitoring study was initiated by the Pyrethroid Working Group with the goal of providing a more robust assessment of pyrethroid concentrations in water and sediment of the lower American River. Water samples were collected during 3 rain events and 2 dry events along cross-river transects at 7 locations, with 5 stations per location and 3 depths per station, resulting in a maximum of 105 samples per event. Sediment samples were collected at each station during a dry weather event. All water and sediment samples were analyzed for bifenthrin, cyfluthrin, lambda-cyhalothrin, cypermethrin, deltamethrin, esfenvalerate, fenpropathrin, and permethrin. All pyrethroids were less than the reporting limit (

**482 Pyrethroid concentrations in the American River: historical assessment and impact of proposed regulatory controls** T.M. Young, University of California-Davis / Dept. of Civil & Environ. Engineering; B. Jorgenson, University of California, Davis / Agricultural and Environmental Chemistry. A watershed pyrethroid insecticide exposure model was developed for the lower American River watershed located in California, USA. The model incorporated empirically derived washoff functions based on previously run small scale rainfall simulations, along with actual pyrethroid insecticide use and watershed properties for Sacramento County, California. The model was calibrated to in-stream monitoring data and utilized to predict daily river pyrethroid concentration for a period spanning 1995 through 2010. Based on model predictions, a marked increase in pyrethroid toxic units is observed starting in the calendar year 2000, coincident with a watershed-wide increase in pyrethroid use. Approximately 80% of the predicted toxic unit exposure in the watershed was associated with the pyrethroids bifenthrin, cyfluthrin, and cypermethrin. Pyrethroid applications for above-ground structural pest control purposes utilizing suspension concentrate categorized product formulations accounted for greater than 93% of the total toxic unit exposure for all modeled years except 1995. Application of mitigation strategies, such as curtailment of structural perimeter band and barrier treatments as proposed by the California Department of Pesticide Regulation, yielded an approximate 80% reduction in predicted total toxic unit exposure in all modeled years. The model also predicted that similar

mitigation gains could be achieved through a switch from suspension concentrate categorized products to emulsifiable concentrate categorized products. Even with these mitigation gains, the predicted concentration of some pyrethroids would continue to exceed chronic aquatic life criteria for pyrethroids on a frequent basis, illustrating the recalcitrant nature of the pyrethroid problem.

**483 Predicting the effectiveness of label changes in reducing pyrethroid loads to the American River** W.W. Williams, G. Hoogeweg, Waterborne Environmental, Inc; D. Denton, U.S. EPA Region 9 / c/o SWRCB; P.L. TenBrook, U.S. Environmental Protection Agency, Region IX; R. Breuer, California Department of Water Resources / Environmental Water Quality and Estuarine Studies; K.D. Moran, TDC Environmental, LLC. Attention has been drawn to pyrethroid detections in the American River and other waterways draining urban land uses in California. In response, the California Department of Pesticide Regulation has required changes in pyrethroid labels limiting structural uses to spot and crack treatments. The potential washoff of pyrethroid residues were estimated for urban areas draining to the American River from 10 years of historical pesticide use records under pre- and post- label changes. The results indicate that significant reductions in pyrethroid loads to the American River are likely to occur under the modified application practices.

**484 Assessing Stormwater Impacts on Coastal Preserves: An Integrated Approach in the La Jolla Area of Special Biological Significance, San Diego, CA** S. Gruber, Weston Solutions, Inc., Weston Solutions; D. McCoy, Weston Solutions, Inc.; C. Stransky, AMEC Earth and Environmental, AMEC Earth & Environmental / Aquatic Sciences, AMEC Environment & Infrastructure / Senior Aquatic Scientist; R. Schottle, AMEC Environment & Infrastructure; S. Jarrell, Scripps Institution of Oceanography. The variable nature of stormwater runoff presents unique challenges with regard to accurately characterizing water quality and potential receiving water impacts. A multiple lines of evidence (MLE) approach is needed to accurately characterize potential biological impacts and stressors of concern to cost-effectively identify future Best Management Practices (BMPs). This is particularly true when assessing stormwater impacts on coastal marine preserves such as Areas of Special Biological Significance (ASBS), where reliance on water quality monitoring alone may be unprotective of the unique beneficial uses found in these areas. State regulators in California have recently adopted Special Protections for these areas that rely on a MLE approach for assessment. Results of an integrated, MLE approach currently being conducted in two adjacent ASBS (ASBS 29 and 31, collectively referred to as the La Jolla ASBS) will be showcased in this presentation. The goal of the program is to assess the potential impacts of stormwater runoff on different coastal habitats to better understand the extent to which the ASBS Special Protections are truly protective of beneficial uses. The assessment used an integrated approach, which focused on four lines of evidence: 1. water chemistry (stormwater and receiving water constituents monitored over the course of a storm); 2. toxicity to native marine species (*in situ* toxicity, laboratory toxicity, and Toxicity Investigation Evaluations (TIEs)); 3. bioaccumulation with several native marine species; and 4. biological community measures of potential impairment associated with stormwater impacts. Initial results of the multi-year study have shown that potential impacts to the ASBS from stormwater is highly dependent upon the inter-related dynamics of tidal stage, receiving water habitat, proximity to storm drain outfalls, and cross-contamination from discharges well outside of the ASBS. These site specific variables are important considerations when assessing potential stormwater impacts on the ASBS and need to be considered when implementing and interpreting results of more general monitoring required by the Special Protections. The results from this study have important implications for managing stormwater discharges to ASBS with respect to new the new regulations designed to protect the beneficial uses of these important coastal resources.

**485 Comparison of Modeled Biological Condition of California Streams at Statewide and Regional Geographic Scales** J.T. May, US Geological Survey / California Water Science Center; L.R. Brown, US Geological Survey; R.D. Mazor, Southern California Coastal Water Research Project; A.C. Rehn, P.R. Ode, California Department of Fish and Game; I.R. Waite, US Geological Survey. The ability to predict changes in biological condition of California streams in response to stressors such as climatic variation and human development is becoming increasingly essential for establishing resource management objectives and strategies. We used boosted regression

trees (BRT) to model stream biological condition, as measured by predicted benthic macroinvertebrate taxonomic completeness, (the ratio of observed to expected, O/E models). BRT models are robust, requiring few assumptions compared with traditional modeling techniques such as multiple linear regression. The BRT models were constructed to provide baseline support for the development of numerical biological objectives for California's Wadeable Streams by identifying important environmental and stressor variables statewide and for eight regions within the state. Regions were defined on the basis of ecological, hydrologic, and political factors and roughly corresponded with ecoregions. Environmental and stressor variables were derived from geographic information system coverages. The statewide model explained 55% of the variance and identified the composite measure of anthropogenic disturbance (the sum of urban, agricultural, and managed vegetation land cover) as the most important variable. The individual regional models explained from 57 to 87% of the variance. Measures of human disturbance were important in the three coastal regions. Along the south and central coast, near-site measures of urbanization were most important. In the north coast region, the composite measure of disturbance at the watershed scale was most important. In the two mountainous regions, natural gradients were most important, including slope, precipitation, and temperature. The remaining three regions had relatively small sample sizes ( $n \leq 75$  sites) giving mixed results. The statewide model could be used to predict biological conditions at unsampled sites using a consistent set of predictor variables, which may be useful for planning and management purposes. The regional models provide a more specific understanding of regionally important environmental and stressor gradients.

**486 Developing sediment contaminant objectives protective of all beneficial uses: Examples from San Diego Bay, CA** J. Diamond, Tetra Tech, Inc.; M. Bowersox, Tetra Tech, Inc. / Laboratory Department; J. Flippin, Tetra Tech, Inc. / Center for Ecological Sciences; C. Boschen, Tetra Tech, Inc.. Biological and chemical sediment data indicated impairments in areas of San Diego Bay, CA, prompting the need for a total maximum daily load (TMDL) for certain contaminants including PAHs, PCBs, and chlordane. These contaminants have the potential to bioaccumulate and thereby have detrimental effects on wildlife and humans. San Diego Bay provides many beneficial uses including aquatic life propagation, wildlife habitat and propagation, and fish and shellfish harvesting for human consumption (both recreational and subsistence). While a variety of sediment quality objectives (SQOs) are available for the contaminants of interest based on aquatic life protection (including some that are region-specific), it was not clear whether these SQOs are protective of wildlife and humans. Also, these contaminants lack or have uncertain sediment screening levels for indirect exposures to wildlife and humans. To address these challenges, an ecological and human health risk assessment process was used to identify appropriate sediment targets for wildlife and humans, respectively. For human exposure, a set of sediment targets were identified for each contaminant based on different risk factors. Depending on the exposure assumptions, the cancer risk level, and the biota-sediment accumulation factor (BSAF) used, SQOs based on aquatic life may or may not be protective of human consumption of fish and shellfish in the bay. Certain SQOs based on aquatic life toxicity were protective of all uses for chlordane but for PCBs and PAHs, ecologically based SQOs could be an order of magnitude higher than targets based on cancer risk. Having accurate, defensible data regarding BSAFs and exposure is critical to developing appropriate sediment targets for these contaminants in waterbodies having significant fish and shellfish consumption uses.

**487 Effects of Southern California Wildfires on Storm Water Contaminant Runoff** E.D. Stein, Southern California Coastal Water Research Project / Biology department; J. Brown, Southern California Coastal Water Research Project; T. Hogue, M. Burke, University of California, Los Angeles. Periodic wildfires are a natural component of southern California's forest and scrubland and are essential to maintaining overall ecological health of these systems. However, relatively little attention has been paid to the effects of post-fire runoff on downstream loading of pollutants, such as metals and organic compounds. These compounds may be of particular interest if burned areas drain to impaired waterbodies. In addition to the direct effects of runoff from burned landscapes, the materials left behind in ash at the burn location can be carried away from the fire in smoke and ash. Subsequent atmospheric deposition can markedly increase the quantity of various constituents available to storm flows downwind of fires. The goal of this study is to assess regional patterns of runoff and contaminant loading

from wildfires in urban fringe areas of southern California. Post-fire stormwater runoff was sampled from five wildfires that each burned between 115 and 658 km<sup>2</sup> of natural open space between 2003 and 2009. Between two and five storm events were sampled per site over the first one to two years following the fires for basic constituents, metals, nutrients, TSS, PAHs and various halogens. Results were compared to data from 16 unburned natural areas and 6 developed sites. Mean copper, lead and zinc flux (kg/km<sup>2</sup>) were between 112 and 736 fold higher from burned catchments and total phosphorous was up to 921 fold higher compared to unburned natural areas. PAH flux was four times greater from burned areas than from adjacent urban areas. Ash fallout on nearby unburned watersheds also resulted in a three-fold increase in metals and PAHs. Attenuation appears to be driven mainly by rainfall magnitude.

**488 Incorporating nonperennial and ephemeral streams in bioassessment programs** R.D. Mazor, C. Solek, Southern California Coastal Water Research Project; E.D. Stein, Southern California Coastal Water Research Project / Biology department; P. Ode, CA Department of Fish and Game / OSPR; A.C. Rehn, California Department of Fish and Game. Nonperennial streams comprise the majority of stream length in coastal southern California, but most stream assessment tools were developed for perennial streams. Consequently, many bioassessment programs in California exclude nonperennial streams from their purview, and leave much of the region unassessed. To address this gap, we conducted a two-part pilot study in the San Diego region. First, we compared extent estimates the National Hydrography Dataset Plus (NHD Plus) with those derived from ambient surveys to see if maps could correctly identify the extent and location of nonperennial streams. Surveys found that nonperennial streams were less extensive than estimated by the NHD Plus, but still comprise large portions of the region (73% vs. 90% for NHD Plus). The discrepancies may be caused by data limitations within the NHD Plus, as well as by changing conditions, as site visits suggest that nonperennial streams in urban areas have been converted to perennial flows. Second, the validity of the Southern California Index of Biotic Integrity (IBI) was evaluated by repeated sampling at 12 nonperennial and 3 perennial sites representing a gradient of stress. Flow status does not preclude high IBI scores, and low stress nonperennial sites had scores similar to those observed at low stress perennial sites. Furthermore, the IBI declined as stress increased. The IBI was stable at most sites both within and between years, but sharp declines were observed at high stress sites. These declines were associated with declines in discharge, fast water habitat, and (to a lesser extent) increases in sands and fines and macroalgae cover. These findings suggest that the IBI can accurately assess nonperennial streams represented in the study, and that it responds to stress in a predicted manner. These findings support the use of the IBI to assess nonperennial streams, although additional sampling at a large number of reference streams will determine if any refinements to the IBI are necessary. Future research will focus on streams with highly ephemeral flow, where new assessment tools based on other biological indicators will need to be developed.

**489 Regional Assessment of Trash in Southern California Streams** T. Von Bitner, Orange County Public Works. Stormwater agencies have recognized trash as a key stressor to water quality conditions in southern California, but there was no coordinated effort to develop a consistent method of estimating trash loadings, understand its pathways into the environment and to identify and prioritize remediation efforts at the watershed scale. To address this issue, in 2011 the Southern California Stormwater Monitoring Coalition Regional Monitoring Program (SMCRMP) included trash to its list of indicators used to identify key stressors to stream health throughout the region. The SMCRMP stream assessment program is a probability based sampling program designed to assess the ambient condition of the regions 15 major watersheds through a collaborative effort among stormwater agencies who annually sample for benthic macroinvertebrates, attached algae, water chemistry and toxicity, physical habitat conditions. The goal of the Trash Assessment Pilot Project (TAPP) was to improve our understanding of the spatial distribution and magnitude of the trash problem at both the regional and local scales and to examine the sources of trash and its pathways into streams. During the 2011 survey 77 sites were assessed for trash with a total of 2087 pieces of trash counted. Urban streams contained more trash than open space streams and the top three categories of trash included 60% plastic items, 11% glass items, and 7% metal items. The most abundant item counted were plastic bags followed by Styrofoam, and plastic food wrappers. In all, the top five items constituted 60% of all items

collected across southern California streams. These results are being used by state and local agencies to determine the best management approaches for dealing with this wide ranging problem. The 2011 TAPP was made possible by a multi-partner collaboration involving the SMC member agencies, the three southern California Regional Water Quality Control Boards, the State of California Surface Water Ambient Monitoring Program (SWAMP), the Department of Fish and Game, and the Los Angeles and San Gabriel Rivers Council for Watershed Health.

**490 Sources and Effects of Endocrine Active Compounds in Urbanized Aquatic Environments** H. Schoenfuss, St. Cloud State University / Aquatic Toxicology Laboratory, St. Cloud State University / Department of Biological Sciences WSB-273, St. Cloud State University / Department of Biological Sciences MS-273; T. Minarik, Metropolitan Water Reclamation District of Greater Chicago; D. Martinovic, University of St. Thomas; M. Schultz, The College of Wooster. Urban aquatic ecosystems often lack the upstream/downstream dichotomy of undisturbed watersheds. Furthermore, sources of aquatic pollution can be multifold complicating efforts to link sources and biological effects. Over four years we assessed endocrine active compound (EAC) presence and biological effects across a large urban aquatic ecosystem. Specifically, we measured EACs in the effluent and receiving waters, conducted quarterly total estrogenicity assays, and analyzed in excess of 5,000 fish tissues from wild-caught and laboratory reared animals for the presence of the egg-yolk protein vitellogenin (vtg) and for histopathological changes. Steroidal estrogens (E1, E2, E3) were frequently detected at very low ng/L concentrations across sampling sites while nonylphenol (NP) was more variable and often found at high ng/L concentrations especially in treated wastewater effluent. Our study documented estrogenic activity throughout the system (0.4-7.8ng/L estradiol equivalency), that wastewater treatment plant effluent contributes significant EAC loads to the aquatic ecosystem, and that these contributions are less temporally variable than non-point sources of EACs. Male sunfish caged downstream of major water reclamation plant effluents exhibited a slight, but significant increase in plasma vtg concentrations, however, the presence of vtg in upstream caged fish suggests additional sources of EACs. Plasma vtg in male sunfish caged for 14 days was usually 25-50% lower than in wild caught sunfish at the same site, indicating that no exposure plateau had been reached. Interestingly, while exposed male fish responded with the to-be-expected induction of the egg-yolk protein vitellogenin (a common biomarker in male fish exposed to estrogenic EACs), they did not develop histopathological changes to their reproductive organs (i.e., intersex) that have been reported in more pristine aquatic ecosystems that are subject to sudden influx of wastewater discharge. The absence of widespread histopathological changes suggesting organismal adaptation in historically effluent dominated aquatic ecosystems. The comprehensive assessment used in this study is well suited to understand how EACs enter the urban environment and may affect resident fish populations. Funding by the Metropolitan Water Reclamation District of Greater Chicago.

**491 Toward an assessment of anthropogenic impacts in two sectors of the Salado Estuary (Ecuador) subjected to different levels of environmental stressors** P. Calle Delgado, Escuela Superior Politecnica del Litoral / Facultad de Ingeniería Marítima y Ciencias del Mar (FIMCM), Escuela Superior Politecnica del Litoral / Department of Marine Engineering Biological, Ocean Sciences and Natural Resources; L. Monserrate, Escuela Superior Politecnica del Litoral / Department of Marine Engineering Biological, Ocean Sciences and Natural Resources; F. Medina, Escuela Superior Politecnica del Litoral; J. Landivar, Escuela Superior Politecnica del Litoral / Department of Marine Engineering Biological, Ocean Sciences and Natural Resources. The Salado Estuary is part of the Gulf of Guayaquil, which is the largest and more productive estuarine system of the South America western coast. The present study, evaluated the physical, chemical and biological conditions of two sectors of this Estuary differing in anthropogenic influences during the dry and wet seasons of 2008 and 2009 respectively. The first sector is the section of the estuary within an industrial-urbanized zone, the city of Guayaquil (SAC), and the second sector is within a protected area, the Reserve of Faunal Production El Salado Mangroves (RPFMS). Measurements of temperature, salinity, dissolved oxygen (DO), pH, hydrogen sulfide, and total dissolved solids (TDS) were measured *in situ*. Samples for ammonia, macrobenthos, and sediment (composition and heavy metals, including lead and mercury) analysis were also collected. Severe hypoxia, anoxia and high fluctuation of salinity occurred in SAC. The two sectors

differed significantly for DO, salinity, TDS, % silts and clays, and species diversity. These differences occurred primarily in the dry season, with only pH and % of silts sediment composition differing in the wet season. Species richness for SAC (8 species) and RPFMS (21 species) was greater in the dry season and declined in the wet season (4 and 11 species, respectively). The most abundant organisms during the dry season for both sectors were benthic annelids. Tubificid oligochaetes were the dominant species making up 98.6% of total macrobenthic community for SAC during the dry season and accounting for 79.4% during the wet season. Individuals from the phylum Nematoda were the most abundant species for RPFMS during the wet season. The Sediment analysis revealed concentrations of lead were significantly higher in SAC. High sediment concentrations of mercury exceeded Ecuadorian sediment thresholds, and the Effects Range Low (ERL) and Effects Range Median (ERM) sediment quality guidelines in both sectors. The degree of contamination and disturbance of benthos is greater in SAC than in RPFMS; however, the RPFMS showed mERMq (Effects Range-Median Quotient) values above 0.144, indicating negative impacts to the benthos. Environmental management strategies and precautionary approaches are required to be enforced by the local authorities to lessen the magnitude and severity of anthropogenic impacts to the Salado Estuary.

**492 Increasing the global relevance of Ni Biotic Ligand Models in aquatic effects assessments of nickel** C.E. Schlekut, E. Rogevich Garman, NiPERA; G. Merrington, WCA Environmental Ltd.; K. De Schampheleere, Laboratory of Environmental Toxicology and Aquatic Ecology, Gent University. Nickel is a priority substance under the European Union's Water Framework Directive (WFD). A bioavailability-based Environmental Quality Standard (EQS) has been proposed for Ni under the WFD. Compliance with the bioavailability-based EQS will be determined by using a user-friendly tool based on Ni Biotic Ligand Models (BLMs). The user-friendly tool, known as Bio-Met ([www.bio-met.net](http://www.bio-met.net)), simplifies the complex speciation, ecotoxicity normalization, and Species Sensitivity Distribution calculations that are necessary when using the full BLMs. The user-friendly version requires a limited number of water quality parameters (pH, Ca<sup>2+</sup>, and dissolved organic carbon (DOC)), thereby allowing for high throughput of samples to facilitate regulatory compliance checking. While the Bio-Met tool is scientifically robust, both the tool and the underlying BLMs have limitations that constrain their application domains. For example, the Ni BLMs have been validated to a pH of 8.2, whereas many European waters have higher pH ranges. A set of comparative toxicity tests was performed on five aquatic species to extend the pH boundary to 8.7. Results indicated that the increase in Ni toxicity with increasing pH was greater than would have been predicted from previous tests at pH ranges below 8.2, illustrating the need to perform such studies. Incorporating these results into Bio-Met will extend the pH boundary and cover most surface waters in Europe. Ni BLMs have only been validated in Europe and in the United States, raising concerns about the relevance of the models to waters and ecological communities in other geographic regions. To this end, the broad geographic validity of the Ni BLMs will be evaluated by determining if the BLMs can predict Ni toxicity to Australian aquatic species in natural Australian waters that exhibit broad ranges of pH, Ca<sup>2+</sup>, and DOC. Given the relative evolutionary isolation of Australian ecological communities, and the unique geochemical characteristics of Australian surface waters, validating the current Ni BLMs to Australian species in Australian waters will be a powerful step in terms of harmonizing bioavailability-based approaches for assessing aquatic risks of Ni.

**493 Integrating algal physiological interactions within the Biotic Ligand Model** M. Lavoie, University of Quebec / INRS-ETE; C. Fortin, INRS – Eau, Terre et Environnement / Université du Québec, University of Quebec / INRS-ETE; P.G. Campbell, University of Quebec / INRS-ETE. The current version of the Biotic Ligand Model (BLM) ignores the effects of essential and non-essential metals on the physiology of organisms and their repercussions on long-term metal uptake and toxicity. This study aimed to evaluate the effects of essential trace metals (Co, Cu, Fe, Mn, Zn), Ca and one non-essential metal (Cd) on the kinetics of membrane-bound transport systems, in order to predict chronic cadmium toxicity in the freshwater alga, *Chlamydomonas reinhardtii*. To do so, short-term Cd and Zn accumulation kinetics were measured for algae acclimated and exposed to different concentrations of free essential metals and to the presence/absence of Cd<sup>2+</sup>. Cadmium accumulation and toxicity was also measured after long-term exposures (60 h). Short-term experiments have shown that Cd

uses three different transport systems (Cd-1, Cd-2 and Cd-3) and that an increase in free  $\text{Zn}^{2+}$  and  $\text{Ca}^{2+}$  concentrations non-competitively inhibited Cd accumulation by approximately 30 to 60%. Moreover, an increase in the concentrations of all five trace metals combined within the acclimation medium led to a significant decrease (by around 3.8-fold) of the Cd binding affinity to the Cd-2 transport systems. We also found that pre-acclimation to  $\text{Cd}^{2+}$  in the presence of low free  $\text{Zn}^{2+}$  and  $\text{Co}^{2+}$  concentrations increased by as much as six-fold the capacities ( $V_{\text{max}}$ ) of the Cd-2 and Zn-2 uptake systems. However, the  $V_{\text{max}}$  of the Cd-2 and Zn-2 transport systems only increased slightly when the cells were acclimated to both high  $[\text{Cd}^{2+}]$  and  $[\text{Zn}^{2+}]$ . These observations are coherent with a Zn nutritional requirement. In the presence of high Zn, transporters are down-regulated due to the relative abundance of Zn leading to a decrease in Cd uptake; in the presence of Cd, transporters are up-regulated to compensate for the relative scarcity of Zn, leading to an increase in Cd uptake. Our biotic ligand model incorporating the physiological effects of Ca, Cd and essential trace metals on Cd transport systems properties predicts steady-state Cd accumulation in the presence of varying concentrations of essential elements reasonably well. Cadmium toxicity can also be accurately predicted as a function of internalized Cd across varying trace metal concentration regimes since algal sensitivity to intracellular Cd was unaffected by the different essential element combinations.

**494 Integration of Biotic Ligand Models (BLM) and Bioaccumulation Kinetics into a Mechanistic Framework for Acute Toxicity Prediction of Metals** K. Veltman, M. Huijbregts, J. Hendriks, Radboud University of Nijmegen / Department of Environmental Sciences. Acute metal toxicity in freshwater organisms is a function of three key factors: geochemical conditions (e.g. DOC), metal-specific properties (e.g. ligand affinity), and species characteristics (e.g. size). The Biotic Ligand Model (BLM) adequately addresses the influence of geochemical conditions and ligand affinity on acute toxicity, but does not yet consider the large influence of species characteristics on toxic response. Also, metal uptake rates are thought to be of key importance in the onset of toxicity and it is a current topic of debate whether the BLM equilibrium framework needs to be refined by a more kinetic approach. In a previous study, we showed that BLM and bioaccumulation kinetics can be integrated into a common, mechanistic framework for metal uptake in aquatic organisms. Metal uptake rate constants were shown to be a function of the metal-specific covalent index, the species-specific ventilation rate and the maximum uptake rate. Metal-specific affinity constants are similar across various aquatic organisms and significantly correlated to the covalent index ( $X^2_{\text{mT}}$ ), which expresses metal affinity for proteins. Furthermore, species-specific ventilation rates scale to body mass to the power  $-1/4$  according to well-established allometric relationships. This implies that if metal uptake rate is an accurate predictor of acute toxicity, than acute toxicity metrics ( $\text{LC}_{50}$ ) should also be quantitatively related to the covalent index and species weight. Here, we provide a quantitative comparison of the mechanistic description for metal uptake with acute toxicity values for organisms belonging to different size classes and with acute toxicity values for different metals. Acute toxicity data ( $\text{LC}_{50}$ ) were empirically collected based on strict selection criteria. The results show that the model accurately predicts acute silver toxicity across organisms belonging to different size classes. Furthermore, it is found that acute toxicity is significantly related to the metal-specific covalent index and that this relationship is similar across various aquatic organisms. However, the relationships, i.e.  $\text{LC}_{50}$  vs  $X^2_{\text{mT}}$ , and uptake rate vs  $X^2_{\text{mT}}$ , are not directly compatible. It is concluded that uptake rate is an important variable in explaining observed differences in toxicity across metals and across species, yet it is not the only explanatory variable. Current efforts focus on model refinement by a more thorough consideration of toxicodynamics.

**495 Mitigation of acute and chronic Ni toxicity to *Hyalella azteca* by Ca and natural organic matter in very soft waters** K. Chan, Wilfrid Laurier U; J. McGeer, Wilfrid Laurier University / Department of Biology. This study is directed on understanding the role of base cations and natural organic matter (NOM) on the recovery of aquatic invertebrates in ecosystems damaged by long term smelter emissions. The goals of the research are to test the validity of biotic ligand principles (competition and complexation) to Ni toxicity in *Hyalella azteca* in very soft waters typical of boreal shield conditions and to understand the role of NOM source on its capacity mitigate against the impacts of Ni. Amphipods (source: Hannah Lake, Sudbury ON) were cultured and tested in soft water (Ca 0.1, Mg 0.05, Na

0.1 and Cl 0.1 (all mM), pH 7.0 and 21°C) following standard methods (Environment Canada EPS1/RM/33). In acute exposures the effects of Ca were tested across a range of concentrations: 0.1, 0.3, 0.75 and 2.0 mM. The  $\text{LC}_{50}$  varied from 0.56 mg/L to 3.2 mg/L demonstrating protective effects of Ca against Ni toxicity. Protective effects were not observed when Mg increased to 0.5 mM and it appeared to act as a stressor as survival of controls was reduced. Dissolved organic carbon concentrations of 6 mg C/L and higher offered significant protection against Ni toxicity. Modelling with the biotic ligand model (BLM) showed that predictions closely matched measured toxicity. Tests with NOM sources collected from boreal waters across Ontario (tested at 6 mg DOC/L) showed that some sources offered more protection than others but there was no clear relationship between NOM optical characteristics (absorbance and excitation emission matrix spectroscopy) and protective capacity. Short term accumulation (6 h) was used to establish linkages between toxicity mitigation and uptake, which followed saturable kinetics. Targeted chronic testing demonstrated that the protective effect of Ca in acute exposures extended to the long term however the degree of protection was proportionally less. In the very soft waters the acute to chronic ratio was approx 50. Chronic effects of Ni were assessed on the basis of both growth (dry weight) and survival. Survival was generally a more sensitive indicator of Ni impacts. Results are considered in the context of the biotic ligand model and understanding the importance of NOM source. This project is supported by the TALER (Terrestrial Aquatic Linkages for Ecosystem Recovery) Research Program, NSERC, Vale and Xstrata.

**496 Modeling uptake of trivalent trace metals by phytoplankton: a case deviating from BLM predictions** A. Cremazy, P.G. Campbell, C. Fortin, INRS-ETE. Major progress has been achieved in recent years in our ability to predict metal bioavailability to aquatic biota. This is due in large measure to the development and improvement of models such as the Biotic Ligand Model (BLM). According to the BLM, provided pH and water hardness are constant, metal bioavailability should be proportional to the free ion activity. The applicability of the BLM to divalent trace metals has been thoroughly investigated since the pioneering work of Sunda and Morel and their co-workers in the 1970s. However, its relevance to trivalent trace metals such as aluminum is still largely unknown. Although the toxic effects of aluminum are relatively well documented, the uptake mechanisms are still speculative and the links between speciation and accumulation remain elusive. This situation is mainly caused by the analytical difficulties encountered when working with trivalent metals, such as the lack of affordable and suitable radio-isotopes and the dearth of sensitive analytical techniques. Scandium (Sc) was used in the present study as a substitute for aluminum, to investigate the applicability of the BLM to trivalent metals. Scandium shares chemical similarities with aluminum and it has a suitable radio-isotope ( $\text{Sc-46}$ , half life of 83.8 days). Sc internalization fluxes in a unicellular alga (*Chlamydomonas reinhardtii*) were determined by kinetic uptake experiments between pH 4.50 and 7.90 and at constant ionic strength. If proton competition is taken into account, Sc internalization fluxes measured between from pH 4.50 to 6.00 are well modeled by the BLM. However, this model underestimates the fluxes at pH  $\geq 6.50$  where Sc speciation is largely dominated by the hydroxo-complexes  $\text{Sc}(\text{OH})_n^{3-n}$  ( $n = 1, 2$  and  $3$ ). Various reasons for this deviation were investigated, including a pH dependency of the potential at the surface of the biological membrane and the contribution of labile Sc hydroxo-complexes through their dissociation in the unstirred layer next to the alga surface. These hypotheses were discarded based on experimental evidence and theoretical considerations. The remaining hypothesis is that the observed deviation from the BLM could be the result of the uptake of one or more undissociated Sc hydroxo-complexes.

**497 Site-specific issues with applying the BLM to evaluate Cu toxicity: overestimation of Cu-DOC complexation and model anomalies in low hardness waters** J.M. Morris, Stratus Consulting; A. Maest, Stratus Consulting Inc.; A. Craven, University of Colorado-Boulder / Chemistry and Biochemistry; J. Lipton, Stratus Consulting Inc.. The Biotic Ligand Model (BLM) was used to estimate concentrations of  $\text{Cu}^{2+}$  in site waters in Alaska and to predict the toxicity of copper to rainbow trout. Visual MINTEQ was also used to predict  $\text{Cu}^{2+}$  concentrations using conditional log K values for  $\text{Cu}^{2+}$ -dissolved organic matter (DOM) binding derived from the same site waters over a range of total copper concentrations. The BLM predicted considerably lower  $\text{Cu}^{2+}$  concentrations than our empirical data when the total copper concentrations were greater than  $1 \mu\text{g L}^{-1}$  ( $2 \times 10^{-8} \text{ M}$ ) under modeled site conditions. The discrepancy could be reconciled by decreasing

the dissolved organic carbon (DOC) input values to the BLM by ~7 times (actual stream value was 2.17 mg C L<sup>-1</sup>). Other researchers have suggested that inputting one-half the measured DOC concentrations to the BLM yields a better fit with fish toxicity data in some cases. These findings suggest that the BLM appears to apply stronger net Cu<sup>2+</sup>-DOM binding across a range of Cu:DOM ratios and water qualities found in many site waters, which could result in an under-prediction of copper toxicity. Additionally, the BLM applies a log K value of 7.4 for the strength of copper binding to the gill (biotic ligand) for rainbow trout. Plots of total copper LC<sub>50</sub> and gill log K values show that a gill log K of 7.4 is close to the inflection point for predicted toxicity, and even small changes in gill log K can produce large changes in predicted copper toxicity. Finally, at hardness values < 20 mg L<sup>-1</sup> as CaCO<sub>3</sub>, the BLM predicts lower Cu toxicity to rainbow trout than at somewhat higher hardness values. The lower predicted toxicity appears to be related to differences in modeled metal binding affinities between the gill and DOC. At very low hardness values (~5 mg L<sup>-1</sup> as CaCO<sub>3</sub>), the BLM predicts that copper will preferentially bind with DOC, and modeled LC<sub>50</sub> values decrease with increasing hardness (e.g., 5-20 mg L<sup>-1</sup> as CaCO<sub>3</sub>). At higher hardness values (e.g., >25 mg L<sup>-1</sup> as CaCO<sub>3</sub>), the LC<sub>50</sub> is predicted to rise by ~4 or 5 mg Cu L<sup>-1</sup> for each ~20-mg L<sup>-1</sup> increase in hardness. There is no empirical evidence to suggest that aquatic biota are more tolerant of metal concentrations at low hardness values, and the hardness-based water quality criteria equations do not produce this peculiarity. A number of headwater streams around the country have low-hardness waters and use of the BLM at those sites should proceed with caution.

#### 498 Use of Multiple Linear Regression to Model the Influence of Water Chemistry on Chronic Iron Toxicity to Freshwater Organisms

B.J. Adams, Rio Tinto / Product Stewardship; P.H. Rodriquez, Centro de Investigación Minera y Metalúrgica (CIMM); A. Cardwell, Oregon State University; L.M. Tear, Windward Environmental LLC; W.A. Stubblefield, Oregon State University; K.V. Brix, McMaster University; D.K. DeForest, Windward Environmental LLC. Chronic iron toxicity tests were conducted with an alga (*Pseudokirchneriella subcapitata*), a cladoceran (*Ceriodaphnia dubia*), and the fathead minnow (*Pimephales promelas*) over varying dissolved organic carbon (DOC), hardness, and pH levels. The ability of DOC, hardness, and pH to explain variability in iron toxicity (EC10s) was evaluated using multiple linear regression (MLR) analysis. DOC and hardness were found to have an important influence on iron EC10s for *C. dubia*, while DOC, hardness, and pH all have an important influence on iron EC10s for *P. subcapitata* and *P. promelas*. Differences in the MLR models for each species demonstrate that the most sensitive of these three species varies depending on the water chemistry. For example, *P. promelas* is the most sensitive species in waters with very low pH (5.5-6), low hardness (10-20 mg/L), and low DOC (1 mg/L), but quickly becomes the least sensitive species as these parameters increase. *C. dubia* is the most sensitive species over the broadest range of DOC, hardness, and pH levels, but *P. subcapitata* becomes the most sensitive species in waters with a combination of low DOC and high hardness. This study clearly shows that water chemistry has an important influence on chronic iron toxicity and that the influence of water chemistry on iron toxicity is variable between the three species tested. From a regulatory perspective, the MLR models can be used to derive freshwater quality guidelines or criteria that account for site-specific chemistry.

#### 499 Water effect ratio model to support site-specific copper criteria across multiple drainages in an arid landscape

B. Fulton, ARCADIS / Risk Assessment and Ecological Sciences; D. Edge, A. Thatcher, J. Meyer, ARCADIS. Aquatic life criteria for copper are usually based exclusively on site-specific water hardness. However, previous studies have demonstrated other water quality parameters have equal or greater effects on copper toxicity than hardness alone. These water chemistry parameters should therefore be incorporated in the development of site-specific copper criteria to reflect mechanisms of copper toxicity and to provide an appropriate level of protectiveness. The water effect ratio (WER) procedure can be used to derive site-specific metal criteria that explicitly account for water chemistry. However, the available WER guidance is largely designed for point-source copper discharges to perennial systems. We present a case study that describes challenges associated with applying the WER procedure to a complex network of ephemeral drainages influenced by diffuse copper contamination in an arid landscape. To expand the application of the WER procedure to these ephemeral systems, we describe a WER model based on multiple regression analyses between empirical toxicity tests and water chemistries.

Hardness, alkalinity, organic carbon and total dissolved solids significantly correlated with site-specific copper toxicity. These relationships were used to develop a WER model that can be applied to a network of ephemeral waters at a mine site in the southwestern United States to derive adjusted copper criteria. The relationships between mechanisms of copper toxicity and model parameters are discussed, and a comparison to biotic ligand model predictions is included.

#### 500 Are Current Bioaccumulation Criteria and Approaches Relevant for Ionizing Substances such as Pharmaceuticals?

M.A. Bonnell, Environment Canada / New Substances Division, Environment Canada / Science and Risk Assessment Directorate. PB(T) properties of substances are most often used to "rank" or prioritize chemicals for further evaluation (e.g., Canadian categorization of the DSL), but can also be used to determine the "risk" an individual substance may pose to the environment without having extensive information on distribution or exposure (cf., listing in Annex XIII of REACH guidance). The basis for each of these properties can be linked to the assessment of legacy neutral organic chemicals that are often, but not always, of global concern (e.g., UNEP POPs). Current bioaccumulation criteria, assessment approaches and models have relied on the passive diffusion hydrophobicity-lipophilicity paradigm for the purpose of determining the potential for adverse effects from exposure to contaminants. We will examine the purpose of current bioaccumulation criteria and the extent to which these criteria and approaches should be applied to pharmaceuticals as example ionizing bio-active substances. We will also examine additional bioaccumulation metrics that could be used in place of or in addition to current criteria or approaches to bioaccumulation assessment.

#### 501 Prospects and limitations for applying mechanistic bioaccumulation models for ionogenic organic chemicals in aquatic ecosystems

J. Armitage, University of Toronto Scarborough; J.A. Arnot, ARC Arnot Research & Consulting Inc., University of Toronto Scarborough / Department of Physical and Environmental Sciences; T.N. Brown, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Environmental Chemistry; F. Wania, University of Toronto at Scarborough / Dept. of Physical & Enviro. Science; D. Mackay, Trent University / Environmental Studies. Relatively few measured bioconcentration factors (BCFs) for ionogenic organic chemicals (IOCs) in fish are available and generalized mechanistic BCF models have recently been developed. While BCFs may be considered for categorization purposes (i.e. 'B' or 'Not B'), BCFs are generally not recommended for exposure and risk assessment because i) dietary exposure and food web dynamics are not considered and ii) pertinent environmental conditions in the field (e.g. pH, temperature, concentration of suspended solids) may differ substantially from those in the laboratory. Mechanistic bioaccumulation models that address differences in exposure and environmental conditions have been developed for neutral organic chemicals, providing a conceptual framework to follow when developing food web models for IOCs. The main questions with respect to modeling bioaccumulation of IOCs are i) how does ionization influence bioavailability of IOCs in the physical environment, ii) what is the influence of degree of ionization on chemical uptake efficiency (e.g. across the gills, in the gut) and iii) how does ionization influence the sorption capacity (i.e. distribution coefficients) of the organism. Here we further develop and apply a mechanistic BCF model for IOCs in fish to quantitatively examine these issues for sets of hypothetical IOCs. For example, we compare modeled BCFs and bioaccumulation factors (BAFs) in aqueous environments with different pH and suspended solid loads. We also explore the propagation of uncertainty in estimated biotransformation rate constants on the modelled BCFs and BAFs. Key strengths and uncertainties in the modeling approaches are identified and discussed in order to prioritize research needs.

#### 502 The role of membrane-water partitioning and membrane permeability of charged species for bioaccumulation of ionizable organic chemicals

B.I. Escher, Entox, The University of Queensland / National Research Centre for Environmental Toxicology. Predictive models for bioaccumulation are largely based on correlations with hydrophobicity parameters like the octanol-water partition coefficient. They fail for compounds with ionizable groups, metabolic capacity and those compounds whose uptake is driven by other processes than passive diffusion. A mechanistic understanding of the processes underlying bioaccumulation will improve the predictive power of bioaccumulation models. In this presentation we will give an overview on the relevant processes with a focus on ionizable compounds,

namely organic acids and bases, and how these can be described, experimentally determined and/or modelled. Membrane-water partitioning provides an appropriate surrogate for understanding the steady-state BCF of ionizable organic chemicals. Membrane permeation investigated with simplified test systems such as those that are used in the screening of pharmaceuticals will provide kinetic parameters for uptake of ionizable chemicals, including ion-trapping models, where it is assumed that only the neutral species can readily permeate a biological membrane. Apparently higher prediction of uptake than predicted from the pH-partition rule is then possible if ionic species will reconstitute inside the cell according to intracellular pH.

**503 Immobilised artificial membrane (IAM) chromatography: An investigation of the effect of pH on ionisable species** S. O'Connor, S. Latvala, M. Ledbetter, G. Hodges, S. Gutsell, Unilever; T. Gouin, Unilever / Safety and Environmental Assurance Centre. The octanol/ water partition coefficient is used in many areas of ecotoxicology and modelling as a measure of hydrophobicity or lipophilicity. It is well known that for ionisable chemicals or surfactants the measurement of  $K_{ow}$  is difficult due to the tendency of these types of materials to sit on the octanol/water barrier. Similarly, the accuracy of the prediction of  $K_{ow}$  for these types of materials is variable depending on the model used to calculate it. In part this is due to differences between  $K_{ow}$  and partitioning across biological membranes. It is possible that improved understanding of the intermolecular forces involved in membrane partitioning may be gained if more biologically relevant parameters are considered. Phosphatidylcholine (PC) is a ubiquitous phospholipid which is a major component of biological membranes. Immobilised Artificial Membrane (IAM) Chromatography utilises a phospholipid membrane made of PC. Using PC as a stationary phase and aqueous or organically modified buffers as a mobile phase, a partition coefficient ( $k_{IAM}$ ) for chemicals can be determined as a measure of the ability of a chemical to partition into the liposome layer (phospholipophilicity). As in biological systems and in buffers, ionisable compounds exist in different states which means that they interact to a different extent with biological membranes. This study was designed to determine the effect of the pH of the system on the retention of the chemicals in their ionic and neutral forms using IAM chromatography. As expected, the data indicated that the retention of ionisable chemicals is affected by the pH. Chemicals had a value for the neutral form ( $\log k_{IAM}$ ) and the ionised form, ( $\log k_{IAM (ion)}$ ) under relevant extreme pH conditions. However, at pH between these extremes, retention of the chemicals were based on an aggregate of both neutral and ionised species. It was also recorded that this aggregate retention indicated that the extent of ionisation of the system was not directly linked to the pKa of the compound under aqueous conditions but was shifted positively along the pH scale for acids and negatively for bases. The data also indicated that functional groups attached to the chemical also had an effect on both the difference between  $\log k_{IAM}$  and  $\log -k_{IAM(ion)}$  ( $\Delta k_{IAM}$ ) and the change in pKa ( $\Delta pKa$ ).

**504 Regulatory approaches to assessing Bioaccumulation of Pharmaceuticals: A Salty Tale** G. Rattray, Health Canada / Environmental Impact Initiative Division. Traditional regulatory approaches to determining whether a compound is bioaccumulative involve assessing partitioning between water and a lipid substitute, either through modelling or measuring ( $\log K_{ow}$ ), and subsequent evaluation against established criteria. While this approach may work well for neutral organics, in the case of pharmaceuticals where the active ingredient is often ionisable, the appropriateness of both the models and test methods are called into question. Furthermore, unlike neutral compounds where uptake is generally by passive diffusion, pharmaceuticals have a variety of routes into cells. This talk will explore the challenges of accurately assessing the bioaccumulation of pharmaceuticals in the context of an environment risk assessment conducted with a standardised regulatory set of data elements. The question of whether there is an opportunity to leverage some of the human health data (i.e. ADME) in a weight of evidence approach to get a more global view of the potential concern of the substance rather than simply assessing against arbitrary pass-fail criteria will be addressed.

**505 Development of An Initial Predictive Understanding of Bioconcentration of the Weakly Basic Pharmaceutical Diphenhydramine in Fish** B. Du, Baylor University / The Institute of Ecological, Earth, Environmental Sciences, Baylor University / Department of Chemistry and Biochemistry; Department of Environmental Science, Baylor, Baylor University / The Institute of Ecological, Earth, Environmental Sciences, Baylor; B.W. Brooks,

Baylor University / Environmental Science and Biomedical Studies, Baylor University / Department of Environmental Science; J. Berninger, Baylor University / Department of Environmental Science; K.A. Connors, Baylor University / Institute of Biomedical Studies, Baylor University / Department of Environmental Science; C.K. Chambliss, Baylor University; R.J. Erickson, U.S. EPA / Mid-Continent Ecology Division; J.W. Nichols, U.S. Environmental Protection Agency / ORD, NHEERL, Mid-Continent Ecology Division. Increasing evidence demonstrates that introduction of pharmaceuticals to aquatic ecosystems can result in the accumulation of parent compounds and/or their pharmacologically active metabolites in aquatic organisms. Unlike many historical contaminants, such as polychlorinated biphenyls and organochlorine pesticides, most therapeutics are ionizable compounds (~70% are weak bases), which suggests bioaccumulation and toxicity of these chemicals are influenced by site-specific pH. Unfortunately, the bioavailability and bioaccumulation of ionizable chemicals in general and pharmaceuticals in particular are poorly understood in fish and other aquatic organisms. The objective of present study was to develop an initial understanding of pH influences on the uptake of a weakly basic pharmaceutical, diphenhydramine (DPH), in the fathead minnow model. DPH, a first generation antihistamine drug found in many common over-the-counter formulations, was selected as a model compound because it is moderately lipophilic and ionized at environmentally relevant pH ( $pK_a$  -9.0,  $\log P$  -3.3). DPH has further been reported by our group to bioaccumulate in fish in the field, and to elicit pH dependent toxicity in laboratory studies with model aquatic organisms. We performed laboratory studies to characterize DPH uptake by adult male fathead minnows across an environmentally relevant pH gradient based on a slightly modified OECD guideline (TG305) for bioconcentration. Based on observations from these studies, we tested several models for predicting bioconcentration of ionizable compounds by fish. Finally, we examined the utility of these approaches for predicting bioaccumulation of DPH in an effluent-dominated stream, the North Bosque River, Texas, USA, during one of the most severe droughts in US history. Our findings indicate that accurate prediction of DPH uptake by fathead minnows requires a modeling approach that accounts for pH of the exposure water. Additionally, uptake of DPH by fish in the field was underestimated, suggesting that future studies are necessary to understand trophic transfer of ionizable pharmaceuticals in surface waters.

**506 Predicting the oral uptake efficiency of chemicals in mammals: Combining the hydrophilic and lipophilic range** I.A. O'Connor, M.A. Huijbregts, A.M. Ragas, J. Hendriks, Radboud University, Nijmegen / Environmental Science. Environmental risk assessment requires models for estimating the bioaccumulation of untested compounds. So far, bioaccumulation models have focused on hydrophobic compounds, and only a few have included hydrophilic compounds. Our aim was to develop a model to estimate the oral uptake efficiency of pollutants in mammals for compounds over a wide  $K_{ow}$  range with an emphasis on hydrophilic compounds. An existing model was extended by dividing the diffusion resistance through the membrane into a polar outer and apolar inner membrane resistance, which were related to the water phase using  $K_{ow}$  and the heptane water partition coefficient  $K_{hw}$ , respectively. The model was calibrated on two sets of data, i.e., the uptake efficiencies of environmental pollutants measured in different mammals during feeding studies and the human oral absorption efficiencies of pharmaceuticals. The new model estimated the uptake efficiency of neutral ( $RMSE=14.6$ ) and dissociating ( $RMSE=19.5$ ) compounds with  $\log K_{ow}$  ranging from -10 to +8. The inclusion of the  $K_{hw}$  improved uptake estimation for 33% of the hydrophilic compounds ( $r^2=0.60$ ,  $RMSE=21.2$ ) compared to the model version based on  $K_{ow}$  only ( $r^2=0.07$ ,  $RMSE=33.9$ ), while all hydrophobic compounds were estimated equally well by both model versions. Therefore, the new model provides a tool to estimate the uptake efficiency for new compounds such as pharmaceuticals and is based on mechanistic processes.

**507 Bioaccumulation of ionizing mono-phthalate esters in a marine aquatic food-web** EA Gobas, Simon Fraser University / School of Resource and Environmental Management (Faculty of Environment), Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment, Simon Fraser University; M. McConnell, V. Otton, Simon Fraser University; M. Ikononou, Institute for Ocean Sciences. Dialkyl phthalate esters (DPEs) are a family of widely used industrial chemicals, which upon biotransformation and biodegradation, produce monoalkyl phthalate esters (MPEs), which due to their low  $pK_a$  of approximately 3.2

occur predominantly in the ionic phase at normal environmental pH levels. Due to their presence in aquatic environments, the bioaccumulation behavior of MPEs was studied in a range of aquatic species of a marine aquatic ecosystem in Vancouver. The results of the study indicate that the high solubility of MPEs in sea water causes a high bioavailability and a resulting high degree of biodegradation. The results further indicate that the high aqueous solubility and low lipophilicity of the ionic forms of MPE produces high respiratory elimination rates in aquatic biota and a lack of biomagnification or biodilution in the food-chain. Trophic Magnification Factors (TMFs) were approximately 1.0. Bioaccumulation Factors (BAFs) of MPEs were higher than expected from log D. This is likely due to the formation of MPEs resulting from the biotransformation of the DPEs. The bioaccumulation field study of MPEs reveals some key aspects of the bioaccumulation behavior of the anionic weak acids, which will be summarized and discussed in a modeling context.

**508 Ethinylestradiol disrupts fathead minnow (*Pimephales promelas*) population dynamics over three generations** A. Schwindt, Colorado State University / Fish, Wildlife, and Conservation Biology; D. Winkelman, Colorado Cooperative Fish and Wildlife Research Unit – USGS. Environmental estrogens are found worldwide in aquatic ecosystems and can lead to developmental and reproductive disruption in fishes. However, little is known about the population level consequences of exposure. Understanding population level responses to estrogen exposure is critical to the conservation and management of a wide variety of fishes. We evaluated the effects of 17 $\alpha$ -ethinylestradiol (EE2), the synthetic estrogen in human birth control, on three generations of fathead minnows (*Pimephales promelas*) in outdoor aquatic mesocosms and laboratory aquaria. We introduced five male and five female fish to each of 28, 1100L mesocosms and exposed the fish to 0, 5 (3.7), 10 (6.9), or 20 (15.2) ng/L of EE2 (measured concentrations) for 3.5 months (N=7). Fish were allowed to behave naturally and reproductive output was recorded. Following exposures in the mesocosms, the F1 offspring were counted, moved into the laboratory, and split into two groups. One group continued exposure to EE2 at nominal 5 or 10ng/L (N=4) while the other group recovered for 4 months (N=4). Breeding trials were conducted on the F1 for 1.5 months and reproductive output was recorded. Results from the mesocosms indicate that EE2 reduced both F0 reproductive output and F0 male survival. Results from the laboratory experiment indicate that early life EE2 exposure caused permanent reduction in F1 reproductive output evidenced by reduced numbers of F2 fish. In the F1 fish that were continuously exposed to EE2 no F2 offspring were produced and EE2 induced testis-ova in the gonad of F1 males. Our results suggest that exposure to trace concentrations of EE2 significantly impacts fathead minnow population dynamics and early life exposure causes irreversible damage to their reproductive system.

**509 G-Protein-Coupled Estrogen Receptor-1 (GPER): A Potential Target for Xenoestrogens During Vertebrate Embryogenesis** S. Jayasinghe, University of South Carolina / Department of Environmental Health Sciences; D.C. Volz, University of South Carolina, University of South Carolina / Department of Environmental Health Sciences. G-protein-coupled estrogen receptor 1 (GPER) is a G-protein-coupled receptor that induces non-genomic signaling in response to some nuclear estrogen receptor ligands. To date, the distribution and functional characterization of GPER within vertebrate organs have been restricted to juvenile and adult animals. However, the role of GPER during vertebrate embryogenesis is currently unknown. The overall objectives of this project were to (1) characterize the spatiotemporal expression patterns of *gper* during vertebrate embryogenesis and (2) identify the potential impacts of ligand-induced GPER activation during vertebrate embryogenesis. Using wildtype zebrafish, we first demonstrated that (1) *gper* exhibited strong stage-dependent expression patterns during embryogenesis; (2) aberrant GPER activation by a selective GPER agonist (G-1) – but not inhibition by a selective GPER antagonist (G-15) – resulted in developmental malformations; and (3) co-exposure with G-15 blocked G-1-induced teratogenesis, suggesting that G-1 toxicity is mediated via aberrant GPER activation. Based on these data, we hypothesized that the developing cardiovascular system was the primary target organ for G-1-induced toxicity. Using quantitative *in vivo* imaging assays and transgenic zebrafish (*flil:egfp*), we then demonstrated that G-1 exposure resulted in impaired cardiac morphology and performance as well as, at higher concentrations, early circulatory arrest. Similarly, embryonic exposure to reference xenoestrogens – genistein and bisphenol-A (BPA) – with known affinity

to human GPER resulted in concentration-dependent effects (albeit with lower potency than G-1) on the developing cardiovascular system. To begin revealing mechanisms of G-1-, genistein-, and BPA-induced cardiovascular malformations, we then relied on a battery of inhibitors and antagonists that target signaling events downstream of GPER. While genistein and BPA appeared to involve distinct signaling mechanisms compared to G-1, our data suggest that cardiovascular malformations resulting from G-1, genistein, or BPA exposure likely involved EGFR transactivation, MAPK activation, and reduced levels of vascular endothelial growth factor- $\alpha$  (Vegf- $\alpha$ ) and Notch ligand delta like 4 (Dll-4) mRNA. Overall, our findings suggest that GPER activation represents a potentially novel and understudied mechanism of cardiovascular toxicity for environmentally relevant chemicals that affect vertebrate embryogenesis.

**510 Towards better understanding of the mechanisms of action of the ureic based herbicide linuron** C.J. Martyniuk, University of New Brunswick / Dept. of Biology/Canadian Rivers Institute, University of New Brunswick / Biology; A. Ornostay, University of New Brunswick Saint John / Department of Biology and Canadian Rivers Institute, University of New Brunswick Saint John / Biology; S. Alvarez, Donald Dansforth Plant Sciences Center; A. Cowie, M. Hindle, C. Baker, University of New Brunswick; N. Hogan, University of Saskatchewan; B. Lo, Nautilus Environmental; C. Kennedy, Simon Fraser University; J. Elphick, V.L. Marlatt, Nautilus Environmental. Linuron (LIN), a ureic-based herbicide, is an endocrine disruptor with a suspected anti-androgenic mode of action (MOA). However, the effects of this herbicide on the teleostean reproductive axis are not completely understood. We have measured responses in both male and female fathead minnows (FHM) to LIN using reproductive endpoints that encompass a range of biological organization (gene expression, proteomics, sex steroids, vitellogenin, gonadal histopathology, secondary sex characteristics, fecundity, and survival). Using an *in vitro* steroid production bioassay, we show that LIN does not significantly affect  $E_2$  production in a 12 hr incubation period, however LIN did affect molecular signaling pathways that included the biosynthesis of cholesterol, T-cell receptor signaling, and increased the gene expression networks of follistatin and steroid hormone receptors. Comparisons of expression patterns and support vector machine classification demonstrated that the gene expression responses to LIN are more similar to that activated by anti-androgens such as flutamide when compared to androgens. A 21d reproductive bioassay using 1, 10, and 100  $\mu$ g LIN/L showed that secondary sex characteristics, fecundity, and survival of fry were not affected by LIN. There were also no significant changes in ovary histology or mRNA abundance for steroid-related genes (e.g. *aromatase*, *estrogen receptors*). However, plasma vitellogenin (Vtg) production was significantly decreased in females after exposure to 1 and 100  $\mu$ g LIN/L, suggesting reproductive impairment may be occurring at the liver and Vtg synthesis. There was no Vtg induction in males. Using iTRAQ quantitative proteomics, LIN altered many proteins involved in stress and cell signaling (e.g. prostaglandin E synthase 3, cell death proteins, glutathione S transferases). Sub-network enrichment analysis identified that interferon and epidermal growth factor signaling were regulated by LIN, and these signaling pathways were associated with depressed plasma vitellogenin in females. These data suggest that LIN can have adverse effects at the site of the liver and disrupt gene pathways in the ovary that have the potential to impact steroid production.

**511 Impacts of hypersaline acclimation on the sublethal toxicity of chlorpyrifos on salmonid olfaction** L.A. Maryoung, University of California – Riverside / Environmental Science, University of California Riverside / Department of Environmental Sciences; N. Agarwal, G. Hardiman, R. Sasik, University of California, San Diego / Department of Medicine; K. Tierney, University of Alberta / Biological Sciences; D. Schlenk, University of California-Riverside / Department of Environmental Sciences. Acclimation to hypersaline environments has been shown in previous studies to enhance the acute toxicity of organophosphate pesticides to euryhaline fish species; however sublethal effects have been far less studied. The present study focuses on the sublethal toxicity of the organophosphate chlorpyrifos to salmonid olfaction during and after hypersaline acclimation. Salmonids rely on olfaction to detect chemical cues that provide crucial information about food, predators, reproductive status of mates, environmental contamination, and natal streams of imprinting. The purpose of this study was to link molecular, physiological, and behavioral alterations in salmonids undergoing exposure to chlorpyrifos while acclimating to hypersaline conditions.

To determine molecular effects of combined exposure, salmonids were acclimated to three different salinities (8ppt, 16ppt, 32ppt) for one week and mRNA was collected from the olfactory rosettes. Microarray hybridization was used to determine differences in gene expression for the different salinity treatments. Through literature searches potential target genes involved in signal transduction, which have been shown to be impacted by chlorpyrifos exposure in zebrafish, were identified and targeted in microarrays. The genes included gefitin, parvalbumin 8, calmodulin 2b, chloride intracellular channel 4, guanine nucleotide binding protein (G protein) gamma 1 subunit, and adrenergic alpha 2B receptor. To assess physiological effects, electroolfactograms and behavioural assays will be compared to molecular effects to determine appropriate and relevant adverse outcome pathways for salmonids undergoing exposure during saltwater acclimation (NIEHS P30ES07033).

**512 Dietary selenomethionine exposure alters aerobic metabolism and methionine catabolism in adult zebrafish** J. Kallarakavumkal Thomas, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / graduate student; S.B. Wiseman, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / Post-Doctoral Fellow; J.P. Giesy, University of Saskatchewan / Biomedical Veterinary Sciences & Toxicology Centre, Michigan State University / Department of Animal Science, University of Saskatchewan / Toxicology Centre; D. Janz, University of Saskatchewan / Toxicology Centre, University of Saskatchewan / Veterinary Biomedical Sciences. Our previous study reported impaired swimming and increased accumulation of stored energy in adult zebrafish (*Danio rerio*) exposed chronically to environmentally relevant concentrations of dietary selenomethionine (SeMet). The present study investigated potential mechanisms of impaired swimming and elevated stored energy accumulation in adult zebrafish exposed to similar concentrations of dietary SeMet. Fish were fed 1.3, 3.4, 9.8 and 27.5 µg Se/g, dry weight in the form of SeMet for 90 days. At the end of the exposure, fish from each treatment group were divided into three subgroups: a) no swim, b) swim, and c) repeat swim. Fish from the no swim group were euthanized immediately at 90 days and whole body triglycerides, glycogen and lactate, and gene expression of energy metabolism and methionine catabolism enzymes were determined. Individual fish from the swim group were placed in a swim tunnel respirometer and swimming performance was determined using the critical swimming speed ( $U_{crit}$ ) method. After both  $U_{crit}$  and oxygen consumption ( $MO_2$ ) analyses, fish were euthanized and whole body energy stores and lactate were determined. Similarly, individual fish from the repeat swim group were subjected to two  $U_{crit}$  tests ( $U_{crit-1}$  and  $U_{crit-2}$ ) performed with a 60 min recovery period between tests, followed by determination of energy stores and lactate. Impaired swim performance was observed in fish fed greater than 3 µg Se/g in the form of SeMet. Oxygen consumption, standard metabolic rate (SMR) and cost of transport (COT) were significantly increased, and factorial aerobic scope (F-AS) was significantly reduced in fish fed elevated dietary SeMet. Whole body triglycerides increased with increasing dietary SeMet exposure. Both dietary SeMet exposure and swimming had significant effects on whole body lactate concentration in fish. Elevated SeMet exposure significantly down-regulated mRNA abundance of protein tyrosine phosphatase 1B (PTP 1B) in muscle, and  $\beta$ -hydroxyacyl coenzyme A dehydrogenase (HOAD), sterol regulatory element binding protein 1 (SREBP 1) and methionine adenosyltransferase 1 alpha (MAT 1A) in liver of adult zebrafish. Ongoing work is investigating muscle histology of adult zebrafish fed elevated dietary SeMet. Overall, the results of this study provide new insights into mechanisms of SeMet toxicity to freshwater fish.

**513 Arsenic reveals molecular mechanism, physiological effects, population-level variation, and evolutionary basis for osmotic plasticity in killifish** J.R. Shaw, Dartmouth College / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; T.H. Hampton, Dartmouth Medical School; B.L. King, Mount Desert Island Biological Laboratory; A. Whitehead, University of California, Davis; R.N. Keith, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; E.G. Notch, D. Jung, Dartmouth Medical School; S.P. Glaholt, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; J.K. Colbourne, Indiana University / The Center for Genomics and Bioinformatics; C.Y. Chen, Dartmouth College; B.A. Stanton, Dartmouth Medical School. *Fundulus heteroclitus* is a teleost adapted to life in estuaries. Its tidal niche produces large osmotic gradients; and many populations tolerate abrupt changes in salinity along this gradient, ranging

from freshwater to marine. Killifish also reside in close proximity to humans, increasing their risk of exposure to anthropogenic stressors. Since killifish provide unique access to the biology that underlies physiological plasticity and stress tolerance, we sequenced, assembled, and annotated its transcriptome, expressed under 72 different conditions. This sequence information was used to discover how arsenic disrupts osmotic plasticity, investigate the response across populations and explore underlying evolutionary mechanisms. We observed that non-toxic arsenic concentrations disrupt chloride balance and block seawater acclimation. Microarray experiments conducted as fish are moved from freshwater to seawater demonstrate that the combined stresses of arsenic and salinity produces large, non-additive antagonistic, interactions at the mRNA level that are consistent with the phenotypic observation that arsenic constrains physiological plasticity by inhibiting seawater acclimation. These interaction genes, which functionally are enriched in biological processes such as mitochondrial function, and tight junction signaling, are more tightly regulated between individual fish than other differentially regulated genes across all treatments (i.e. canalized). In experiments of three natural populations of killifish residing along a salinity cline ranging from freshwater to marine environments, we observed salinity dependent variation in the expression and regulation of these arsenic and seawater interaction genes. These genes are locally enriched and more tightly regulated in only the freshwater population. To address evolutionary mechanisms for the tight regulation, we observed that interaction gene sets have fewer associations with upstream controlling genes. This suggests that canalization has evolved via a more loosely coupled association with regulating genes as a means to reduce expression noise in variable environments. Collectively, these studies demonstrate the power of genomics applied to the killifish system to understand environmental effects on genes in natural populations.

**514 Linking the sublethal effects of mercury on the hypothalamic-pituitary-gonadal axis of yellow perch in Lake Michigan to ecological effects** C.A. Murphy, Michigan State University / Department of Fisheries and Wildlife, Lyman Briggs College, Michigan State University / Lyman Briggs College; B. Armstrong, Michigan State University; M. Carvan, R. Goetz, University of Wisconsin, Milwaukee; N. Basu, J. Head, University of Michigan. The development of appropriate extrapolation models to link key molecular initiating events to adverse outcomes is a crucial component of the adverse outcome pathway (AOP) framework. Only recently, a few of these models, that convert sublethal responses of stressors to endpoints that can be interpreted at the ecological level, have been developed – and only in a few model species, eg fathead minnow. Very few extrapolation models exist for larger, long-lived, commercially valuable species. Here we illustrate how this can be done on a species of commercial and ecological relevance to the Great Lakes, yellow perch (*Perca flavescens*). We incorporate the sublethal effects of ecologically relevant doses of mercury contamination on the Hypothalamus-Pituitary-Gonadal (HPG) axis of yellow perch, measured at the molecular and physiological level, and link these effects to population relevant points such as fecundity. Such endpoints can then be input into population models to project population effects. In our approach, we used laboratory fish exposed to mercury in a controlled experiment that spanned the period of gonadal growth. We sampled fish at several time points during this experiment to build and calibrate a vitellogenesis model. We then linked the vitellogenesis model to perch population models – in these models, we attempt to incorporate differences that manifest as a result of differences in life history within and between species. We collected fish from various sites around Lake Michigan to determine the extent of mercury contamination and how much each population/sub population is likely impacted. We found that different populations of yellow perch are exposed to different levels of mercury contamination – such exposure manifests in measurable sublethal effects that can be incorporated into our models. Our model results suggest that some perch populations are more impacted and are more at risk than others due to mercury contamination and that this approach may be useful to determine the harmful effects of sublethal effects across a wider array of populations and species.

**515 Mechanistic Insight into the Effect of Venlafaxine on Cortisol Stress Axis Activity in Rainbow Trout** M. Vijayan, University of Waterloo / Biology; N. Melnyk-Lamont, University of Waterloo; C. Best, M. Rodriguez, University of Waterloo / Biology. Venlafaxine, a serotonin-norepinephrine reuptake inhibitor, is a commonly prescribed antidepressant. Although this drug is present in municipal waste water effluents, its impact on fish

performance is largely unknown. We carried out a series of studies to test the hypothesis that environmentally relevant levels of venlafaxine disrupt the functioning of the hypothalamus-pituitary-interrenal (HPI) axis in rainbow trout (*Oncorhynchus mykiss*). Fish were exposed to environmentally relevant venlafaxine concentrations (0.2 µg/L and 1.0 µg/L) and sampled 7 d after exposure. Fish were also subjected to a physical stressor to assess the impact of the drug on the HPI axis performance. In the brain, venlafaxine treatment impacted the levels of neurotransmitters (serotonin, norepinephrine, dopamine) and their metabolites in a region-specific manner. Also, the drug disrupted mRNA abundances of genes encoding key proteins involved in HPI axis activity, including corticotropin-releasing factor, pro-opiomelanocortin and steroidogenic acute regulatory protein in selected brain regions. At the peripheral level, the stressor-induced glucose response was attenuated by venlafaxine treatment. The drug also disrupted the transcript levels of key corticosteroidogenic genes in the head kidney post-acute stressor exposure. Altogether, environmentally relevant levels of venlafaxine perturbs the highly conserved stress axis activation in rainbow trout, and the mode of action involves the disruption of key central and peripheral targets involved in HPI axis functioning. This study was supported by an NSERC discovery grant.

**516 Studying naphthenic acid toxicity using the model green algae *Chlamydomonas reinhardtii*** K.L. Goff, University of Saskatchewan / Toxicology; J. Headley, Environment Canada; J.R. Lawrence, Water Science and Technology Directorate, Environment Canada / Water Science and Technology Directorate, Environment Canada / Research Scientist; T. Ellis, Canadian Light Source. Studies of the toxicity and biodegradation of oil sands naphthenic acid fraction components (NAFCs) have chiefly focused on bacteria, fungi, and emergent macrophytes, with a large and still-growing body of information on animal toxicity. This complex and still poorly quantified mixture is known to have toxic effects on diverse taxonomic groups, including fish, benthic invertebrates, birds, small mammals, emergent macrophytes, and has been identified as a possible primary agent of toxicity in the oil sands process water mixture. The mode of toxic action is not known, though classical naphthenic acids are anionic surfactants and in some species their surfactant properties may play a role in their ecotoxicology. One of the algal species identified in oil sands process waters is *Chlamydomonas frigida*; while there is little information in the literature regarding this species, the genus is well-understood due to *C. reinhardtii*'s frequent use as a model organism. Three lines of *C. reinhardtii* were selected for inclusion in this study; an extremely well-characterized laboratory wild-type strain, and two mutants lacking cell walls as initial trials indicated the possibility of NAFC interactions with the cell wall. All three were grown heterotrophically in nutrient media spiked with a dilution series of NA. Culture densities were measured to obtain growth curves and survival data, and examined for changes in growth form. Exposed cells were examined with infrared spectromicroscopy, confocal laser scanning microscopy, and subjected to lipid analysis. The NAFC-containing media was also analyzed using high resolution mass spectrometry for algae-mediated changes in NAFC composition. Tolerance and growth data will be presented for each line, and changes in algal physiology and NAFC composition of the media following algal growth will be reported.

**517 Evaluating the Effects of Naphthenic Acid Fractions on *Oryzias latipes*** A.E. Bauer, University of Waterloo / Department of Biology; R.A. Frank, Environment Canada / AEPRD, Environment Canada / Dept. of Env. Biology & Toxicology, University of Guelph / Dept. of Env. Biology & Toxicology; J. Headley, K. Peru, Environment Canada; M. Hewitt, Environment Canada / National Water Research Institute; A. Farwell, University of Waterloo / Department of Biology; D.G. Dixon, University of Waterloo. Naphthenic Acids (NAs) are a complex group of alkyl-substituted acyclic, monocyclic and polycyclic carboxylic acids, with surfactant properties that are released from oil sands during bitumen extraction. In fact, they have been deemed the most toxic component of oil sands process material and process water (OSPW). Studies have indicated that an increase in NA concentration within reclamation pond water increases the potential for detrimental reproductive effects, as well as increased larval mortality and pathologies in fish. High molecular weight NAs are degraded more slowly than low molecular weight NAs resulting in a higher proportion of high molecular weight NAs in aged OSPW. Furthermore, studies have identified a decrease in toxicity associated with aged OSPW and degraded NAs. This has led to the thought that not all compounds within these classes are of equal toxicity. This area is where research is lacking. Few studies have evaluated

the toxicity associated with a fractionated extract of oil sands NAs. This study assesses the difference in toxicity associated with different molecular weight fractions of an oil sands NA extract on Japanese medaka (*Oryzias latipes*). The NA extract was fractionated by distillation, allowing for the collection of fractions by molecular weight. Each fraction was then tested at multiple concentrations with an acute embryo-larval bioassay to determine 10d LC50s, deformities, and hatch endpoints. These endpoints were then compared between fractions. Results suggest that not all fractions display equal toxicity and that toxicity may be associated with molecular weight. Furthermore, this study has identified time to hatch and hatch success as relevant endpoints in relating NA molecular weight to its toxicity.

**518 Evaluation of the effects of oil sands-influenced surface waters on the health of fishes** M.R. Van den Heuvel, Canadian Rivers Institute, University of Prince Edward Island; N.S. Hogan, University of Saskatchewan / Toxicology Centre. Since 1995, efforts have been underway to determine the impacts of oil-sand related contamination on fish health. The overarching questions are, 1) do toxicological effects occur? 2) what are the causative agents? and 3) what are the thresholds of effect? Initial studies with yellow perch showed no reproductive effects, but indications of increased disease. This led to the present research program (2008-present) to identify disease and causes as well as to follow up on reproductive and multi-species responses. The experimental program used stocking studies with wild yellow perch and white sucker into experimental ponds in conjunction with in situ trout caging studies, and rainbow trout laboratory studies with oil-sands derived naphthenic acids. Field/in situ research was conducted with waters from three primary sites: Mildred Lake, a reservoir receiving only Athabasca River water, used as the reference site; South Bison Pond, a drainage basin that has received unextracted oil sands-contaminated overburden; and Demonstration Pond, a constructed pond containing oil sands mature fine tailings capped with fresh water. The primary results showed consistent disease responses in yellow perch, but limited effects in white sucker. Male yellow perch and white sucker showed lower testicular development in the most contaminated site. Trout in situ studies also showed suppressed immune function and disease. Elevated bile fluorescence and induced CYP1A enzymes were consistent in all species. Injection studies with naphthenic acids in laboratory trout were not consistent with the effects observed in the field. Evaluation of water chemistry and exposure indicators suggest that the observed effects are due to organic compounds and not salinity. Fish are exposed to both naphthenic acids and polycyclic aromatic hydrocarbons and the involvement of PAHs in the immune response is favored. While organic compounds likely contribute to effects, alkalinity/pH could also become a limiting factor in fish survival. Without specific causative agents, thresholds cannot be determined; however, based on measurement of bulk naphthenic acids, effects on disease will begin to occur at 5 mg/L, and effects on reproduction and disease are likely above 10 mg/L of naphthenic acids in yellow perch, the most sensitive species examined to date.

**519 Assessment of immunotoxicity of oil sands process water in animals** M.O. Hagen, E. Garcia-Garcia, University of Alberta / Biological Sciences; A. Oladiran, B.A. Katzenback, S. Mitchell, M. Karpman, University of Alberta; M. Gamal El-Din, University of Alberta / Civil and Environmental Engineering; J. Martin, University of Alberta; M. Belosevic, University of Alberta / Biological Sciences. In these studies, we exposed goldfish OSPW using a real-time flow-through apparatus for up to 12 weeks and mice orally to the organic fraction of OSPW (OSPW-OF). For studies using fish, we measured gene expression of pro-inflammatory cytokines in the gill, kidney, and spleen using quantitative-PCR. We observed an up-regulation of cytokine gene expression after acute exposure of fish to either high concentrations of commercial NAs or aged OSPW. Sub-chronic exposure of fish to high concentrations of NAs caused a down-regulation in immune gene expression in fish exposed. In order to determine whether goldfish host defense was affected by exposure to NAs, fish were infected with a blood parasite *Trypanosoma carassii* and their ability to control the infection was documented. Following acute exposure to NAs fish exhibited consistently lower parasitemia compared to controls. After sub-chronic exposure of fish to NAs, fish had higher parasitemia than control fish. Thus, the exposure of goldfish to NAs or aged OSPW elicited an enhancement in pro-inflammatory gene expression and increased resistance to parasitic infection after acute exposure, and down-regulation of immune gene expression and increased susceptibility to parasitic infection after sub-chronic exposure to NAs. In contrast to the results obtained in studies using fish, the immune gene

expression was significantly down-regulated in mice after acute exposure to OSPW-OF, and after sub-chronic exposure (8 weeks) the mRNA levels of various immune genes were similar to those of sham-inoculated controls. The immune gene expression differed between the organs examined (spleen, liver and mesenteric lymph nodes) during both acute and sub-chronic exposures of mice to OSPW-OF. We also developed a rapid in vitro assay for assessment of the immunotoxic effects of OSPW-OF.

**520 Assessing Deposition of Polycyclic Aromatic Compounds (PACs) in air across the Alberta Oil Sands Using Passive Air Samplers** T. Harner, Environment Canada / Atmospheric Science & Technology Directorate, Environment Canada / ASTD; K. Su, S. Genualdi, J. Karpowicz, C. Mihele, J. Charland, L. Zhang, Environment Canada. As part of the Joint Implementation Plan for Oil Sands Monitoring, polycyclic aromatic compounds (PACs) have been measured in air to track concentrations and associated deposition, with the ultimate objective of assessing cumulative environmental impacts. This study is responding to concerns regarding deposition of PACs to the Athabasca river and its watershed and potential health risks to humans and other terrestrial and aquatic life. Continuation of the air monitoring network in the short and long-term will provide a baseline against which the expansion of oil sands activities and future PAC air concentrations can be compared. The spatial component of the air monitoring study uses passive air samplers comprising polyurethane foam (PUF) disks housed in stainless steel chambers. These are deployed at 17 sites, some of them close to emission sources while others at varying distances from the active zones, over 2-month integration periods, since November 2010. Concurrently, active air samples are collected at three of the sites, every 6<sup>th</sup> day, for 24 hours, and provide a means of calibrating the passive samplers. The results of the calibration indicate that the PUF disks are able to capture both gas-phase and particle-phase PACs. Comparison of passive results against the high volume air sampler data for the three collocated sites indicates that the passive sampling rates for both gas- and particle-phase PACs is approximately 5 m<sup>3</sup>/day. These preliminary findings support the continued use of PUF disk samplers as a long-term monitoring tool in the oil sands region. The simplicity and small-size of the samplers coupled with their ability to operate electricity-free contributes to their feasibility. Air concentration results from the first year of sampling, targeting 16 PAHs and dibenzothiophene including their C1 to C4 alkylated homologues, will be presented. The use of the data in a model to assess atmospheric deposition of PACs across the entire oil sands region will also be discussed.

**521 Chemical fingerprinting of oil sands naphthenic acids from natural and industrial sources** R.A. Frank, Environment Canada / AEPRD, Environment Canada / Dept. of Env. Biology & Toxicology, University of Guelph / Dept. of Env. Biology & Toxicology; G. Bickerton, J. Headley, Environment Canada; S.J. Rowland, University of Plymouth / School of Geography, Earth and Environmental Sciences; K. Peru, J. Roy, Environment Canada; A. Scarlett, University of Plymouth / School of Earth, Ocean & Environmental Science, University of Plymouth / School of Geography, Earth and Environmental Sciences; M. Hewitt, Environment Canada / National Water Research Institute. The rapid expansion of oil sands development, especially within the past 10 years, has raised many concerns regarding the potential impacts on the environment and downstream communities. Extensive research is currently underway to identify a “chemical fingerprint” of oil sands compounds that will enable the differentiation of industrially and naturally derived oil sands materials. Recent advancements in chromatographic separations and high resolution mass spectrometry analyses are beginning to allow for the elucidation of specific classes of compounds as well as some individual structures contained within complex mixtures of oil sands organic acids. Between 2009 and 2011, samples collected from several sites within the Athabasca River system, containments of oil sands process-affected water (OSPW), groundwater interceptor well systems near basins containing OSPW, and groundwater wells and seeps outside of industrial leases were screened by synchronous fluorescence spectroscopy (SFS). A unique SFS fingerprint for a naphthenic acid extract (NAE) from fresh OSPW has been identified and subsequent analysis by GCxGC-TOF-MS indicated that classes of polycyclic acids with one or more aromatic rings are contributing to this fingerprint. SFS analysis of groundwater samples collected on industrial leases from interceptor well systems, as well as from groundwater wells outside of these collection systems, exhibited spectra consistent with NAE and OSPW. Although the majority of samples collected beyond industrial leases did not exhibit the SFS

fingerprint, several groundwater samples collected adjacent to OSPW containments displayed this profile. To examine the contributions of oil sands NA mixtures originating from both natural and lease sources further, selected samples were profiled by electrospray high resolution mass spectrometry and GCxGC-TOF-MS, with the intention to identify instrument-specific “chemical fingerprints”. Both techniques are proving to be complimentary, and allowing for the first differentiations between naturally and industrially derived oil sands naphthenic acids.

**522 New analytical strategies for monitoring of oil sands tailings ponds and natural waters in the lower Athabasca Region of Alberta, Canada** M.S. Ross, A. dos Santos Pereira, University of Alberta / Division of Analytical and Environmental Toxicology; J.W. Martin, Trent University / Division of Analytical and Environmental Toxicology. Oil sands process affected water (OSPW) is acutely and chronically toxic to aquatic and terrestrial organisms, but the chemicals responsible for the adverse effects are unknown. Furthermore, increasing concerns over potential seepage of OSPW to surface and groundwaters have lead to increased monitoring efforts in the Athabasca River watershed. Many of the primary constituents of OSPW, such as naphthenic acids, also occur naturally in bitumen and may enter receiving waters naturally through groundwater transport or erosion of exposed oil sands formations. A key question to be addressed in monitoring efforts is whether such constituents arise from natural processes, or due to oil sands development. Herein, we report on several new analytical strategies developed with the aim of characterizing the complex mixture of chemicals in OSPW, identifying key toxic components, or for differentiating sources in the environment. In the first study, a liquid chromatography-high resolution mass spectrometry method was used to fingerprint classical O<sub>2</sub>-naphthenic acids in surface and groundwater from the Athabasca Region. Downstream sampling sites were clearly discernable from upstream sites based on the increased proportion of bitumen derived acids, whereas groundwaters were identifiable based their higher percentage of unsaturated, or multi-cyclic, acids. Next, a comprehensive two-dimensional liquid chromatography method was developed, which provided greater chemical formula group-type separations than previously achievable by one-dimensional chromatography, and which also provides fingerprinting capabilities. Finally, ultrahigh resolution Orbitrap mass spectrometry was coupled to liquid chromatography, facilitating the discovery of several isomers and a novel non-naphthenic acid class of O<sub>2</sub> compounds in OSPW. These methods have increased our understanding of the chemical complexity of OSPW, and together add to the toolbox of methods that will be needed to explain the toxic effects of OSPW or unravel the sources of contaminants in surrounding natural waters.

**523 Comparison of extractable acids from Athabasca oil sands tailings ponds, interceptor wells and groundwaters using GCxGC-MS** A. Scarlett, University of Plymouth / School of Earth, Ocean & Environmental Science, University of Plymouth / School of Geography, Earth and Environmental Sciences; C.E. West, Plymouth University / SoGEES, University of Plymouth / Biogeochemistry Research Centre; S.J. Rowland, D. Jones, University of Plymouth / SoGEES. Recent analyses using tandem gas chromatography – mass spectrometry (GCxGC-MS) of oil sands process-affected waters (OSPW) from Alberta Canada has started to reveal some of chemical structures present in the acid-extractable fraction of these highly complex mixtures. Some of these compounds were demonstrated to have very unusual diamondoid acid structures and these may be of use for differentiation between environmental samples and tracking leakage from tailings ponds into groundwaters. More recent studies using “reverse phase”, i.e. polar primary with apolar secondary columns, GCxGC-MS have shown that as well as these alicyclic structures, the acid extractable fraction of OSPW (analysed as methyl esters) also contained a sizeable aromatic fraction. Some of the proposed structures of these aromatic acids have been modelled to be hormonally active and acutely toxic to fathead minnow (LC<sub>50</sub> ca 1 µM). These polycyclic monoaromatic structures may also provide a means by which environmental samples may be differentiated. In the present study, 14 environmental water samples were analysed by both normal phase and reverse phase GCxGC-MS. The water samples (5 ml) were collected from the Athabasca region of Alberta Canada, including tailing ponds from two oil sands extraction sites, interceptor wells, on-lease and off-lease groundwaters. Despite the very small quantities of water extracted, the analyses showed distinctive patterns in the 2D chromatograms. Individual resolved peaks with good mass spectra allowed comparison between the samples and revealed that some of the aromatic acids present in the OSPW acid extracts

were also present in the on-lease groundwaters and some of the off lease water samples. This current study has shown that analyses by GCxGC-MS can not only differentiate between environmental samples but can also track individual, potentially toxic, compounds.

**524 Weighing” the Evidence: Relevance and Transparency in the Evaluation of Endocrine Activity”** C. Borgert, Applied Pharmacology and Toxicology Inc.; E.M. Mihaich, Environmental and Regulatory Resources, LLC; L.S. Ortego, Bayer CropScience / Ecotoxicology, Bayer CropScience; S. Marty, The Dow Chemical Company; J. Brausch, F. Hess, BASF Corporation. There are several key elements to a scientifically based weight of evidence (WoE) process, including the development of a priori specific hypotheses, a systematic review of relevant literature including an evaluation of data quality and reliability, and an assessment of consistency, specificity and reproducibility of effects. These elements all focus on the relevance and transparency of the data and the assessment process. To this end, a conceptual framework for conducting weight of evidence (WoE) evaluations of endocrine screening and testing data (Borgert et al., 2011) was developed. The framework was designed to be broadly applicable, but with an emphasis on data emerging from the US EPA's Endocrine Disruptor Screening Program (EDSP), and specifically tailored to accommodate endpoints measured in the eleven Tier 1 Endocrine Screening Battery (ESB) assays. The framework calls for a transparent process whereby specific hypotheses are formulated and data quality is evaluated with respect to overarching scientific principles, including primary validity of the measurements, reliability of data reporting, and probative capability of the study design to evaluate causation. The framework also calls for assigning quantitative weighting factors to assay endpoints ( $W_{REL}$ ) that reflect their relevance for deciding specific hypotheses in relation to in vivo endocrine activity and effects. This is an important step in the WoE framework as it explicitly recognizes the fact that some assays are very specific and sensitive for evaluating certain hypotheses related to endocrine activity but may be irrelevant for evaluating others. For example, an increase in thyroid follicular hyperplasia, as assessed in the amphibian metamorphosis assay, would be expected to have a very high  $W_{REL}$  for evaluating the hypothesis that a chemical has potential thyroid antagonist activity, but would have a very low  $W_{REL}$  for evaluating the hypothesis that a substance has potential estrogen or androgen agonist or antagonist activity. Example derivations of rank ordered  $W_{REL}$  values for evaluating Tier 1 EDSP hypotheses will be presented for compounds tested in the validation phase of the EDSP, such as methoxychlor, flutamide and/or phenobarbital, with particular emphasis on endpoints measured in the fish screening and frog metamorphosis assays.

**525 ortho-Phenylphenol: Results of the Amphibian Metamorphosis Assay and the Fish Short Term Reproduction Assay** C. Lehman, The Dow Chemical Company, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; K. Coady, R. Currie, T. Marino, J. Fiting, K. Hutchinson, D. Louch, N. Malowinski, L. McFadden, J. Thomas, The Dow Chemical Company / Toxicology and Environmental Research and Consulting. *ortho*-Phenylphenol (OPP), an antimicrobial agent found in many disinfectants, was evaluated for potential endocrine disrupting activity in both the Amphibian Metamorphosis Assay (AMA) and the Fish Short Term Reproduction Assay (FSTRA). In the AMA, tadpoles were exposed to several OPP concentrations in a continuous flow-through test system for either 7 or 21 days. In the FSTRA, fathead minnows were exposed to OPP under continuous flow-through conditions for 21 days. In the AMA, there were no significant differences observed on day 7. On day 21, tadpoles exposed to the highest OPP concentration showed a significant developmental delay; no other endpoints were statistically significant at this timepoint nor were there signs of asynchronous or advanced development. Compared to the thyroid glands from control organisms, there were no treatment-related histopathological effects observed in the thyroid glands from OPP-exposed tadpoles. Therefore, OPP is considered “likely thyroid inactive” in the Amphibian Metamorphosis Assay. In the FSTRA, there were no significant differences between control and OPP-exposed fish in regard to fertility, fecundity, male and female wet weight and length, male and female gonado-somatic indices, tubercle scores, or blood plasma concentrations of VTG in male or female fish. Except for a single male fish from the highest OPP concentration with a single ovum found in its testes, there were no treatment-related changes in any OPP exposed fish either histopathologically or with respect to gonadal stage. In the absence of other effects, this intersex male can likely be attributed to a non-treatment related

spontaneous change. Thus, because there were no significant effects on assay endpoints observed at any concentration of OPP, the results from this assay indicate that OPP does not have potential for endocrine activity in the hypothalamic-pituitary-gonadal (HPG) axis of fish.

**526 Perfluorooctanesulfonate (PFOS) Exposure Alters Reproduction and Endocrine Function in Fathead Minnows (*Pimephales promelas*)** D. Fort, Fort Environmental Laboratories, Fort Environmental Laboratories, Inc.; J. Autry, Fort Environmental Laboratories, Inc.; M. Mathis, C. Fort, H. Fort, L. Meysing, B. Todhunter, Fort Environmental Laboratories; P. Guiney, J. Weeks, SC Johnson & Son. Exposure of *Silurana tropicalis* to perfluorooctanesulfonate (PFOS) during development was previously found to increase the proportion of phenotypic males, alter steroidogenesis during sexual differentiation, and induce abnormal ovary development. To determine if DE-71 altered reproduction and endocrine function in fish, the Tier 1 EDSP 21-day Fish Reproduction Screen with fathead minnow (*Pimephales promelas*) was used. Reproductively-active male and female fish were exposed to DE -71 ( $< 0.03$ , 0.05, 0.12, 0.29, 0.62, and 1.1 mg/L) via flow-through exposure for 21-d and evaluated for survival, reproductive behaviour, and secondary sexual characteristics. Reproductive fecundity and fertilization success were monitored daily. At termination, the status of the reproductive endocrine system was assessed by the gonad-somatic index (GSI), gonadal histology, plasma steroids (estrogen [E2], testosterone [T], and 11-keto-testosterone), plasma vitellogenin (VTG) and CYP19 (aromatase) activity. Results indicated that the PFOS exposure did not affect survival or body weight, but reduced female GSI. Reproductive fecundity, gonad histology, and endocrinological measures of reproductive status were altered. Increased T was detected in both male and female minnows, and increased 11-KT was detected in male minnows. Decreased plasma levels of E2 and VTG, and CYP19 (aromatase) activity were observed in female minnows. These results demonstrate the anti-estrogenic effects of PFOS on the reproductive system of fathead minnows.

**527 Glyphosate: Amphibian Metamorphosis Assay for the Detection of Thyroid Active Substances** S. Schneider, Wildlife International, LTD / Aquatic Toxicology; H. Krueger, Wildlife International, LTD / Aquatic Toxicology, Wildlife International, LTD; J. Claude, Wildlife International, LTD / Aquatic Toxicology; T. Ross, S. Gallagher, T. Springer, M. Jaber, Wildlife International, Ltd.; J. Task Force, JGTF. An amphibian metamorphosis assay was conducted by Wildlife International, Ltd. for the Joint Glyphosate Task Force at the Wildlife International, Ltd. aquatic toxicology facility in Easton, Maryland from October 24, 2011 to November 14, 2011. African clawed frog (*Xenopus laevis*) tadpoles were exposed to glyphosate at mean measured concentrations of 0.13, 0.79, 4.3, 20 and 90 mg a.e./L for 21 days under flow through conditions. Endpoints that were evaluated to determine if the test substance impacted the HPT axis included survival, gross morphological abnormalities, developmental stage, wet weight, body length, snout-to-vent length, normalized hind-limb length, and thyroid gland histology. There were no treatment-related effects on survival, stage, or normalized hind limb length during the 21-day test. Histopathologic analysis showed no treatment-related changes in the thyroid glands of *Xenopus laevis* tadpoles when compared to negative control animals. There was a slight increase in wet weight in the 90 mg a.e./L treatment group and in snout-to-vent length in the 4.3 and 90 mg a.e./L treatment groups at the end of the 21-day test. However, since there were no effects observed on normalized hind-limb length, stage, or thyroid histology, these increases are not indicative of a thyroid effect. Glyphosate was not found to interfere with the normal function of the hypothalamus.

**528 Glyphosate: Fish Short-Term Reproduction Assay (FSTRA) with the Fathead Minnow (*Pimephales promelas*)** S. Schneider, Wildlife International, LTD; H. Krueger, Wildlife International, LTD / Aquatic Toxicology, Wildlife International, LTD; J. Claude, T. Ross, S. Gallagher, T. Springer, M. Jaber, Wildlife International, LTD; J. Task Force, JGTF. A fish short-term reproduction assay was conducted by Wildlife International, Ltd. for the Joint Glyphosate Task Force at the Wildlife International, Ltd. aquatic toxicology facility in Easton, Maryland from December 21, 2011 to January 11, 2012. The objective of this assay was to determine if glyphosate might impact the hypothalamus-pituitary-gonadal (HPG) endocrine axis resulting in the disruption of reproduction in fish. Breeding groups of fathead minnows (*Pimephales promelas*) were exposed to glyphosate under flow-through conditions at mean measured concentrations of 0.046, 0.23, 1.2, 6.2 and 33

mg a.e./L for 21 days. Endpoints that were evaluated for endocrine disruption of the reproductive system included fecundity, fertility, secondary sex characteristics (including tubercle and fatpad scores), gonadosomatic index (GSI), histopathology of gonads, as well as plasma vitellogenin. Other endpoints included survival, general observations of health, weight, and length. There were no apparent effects on survival, growth, reproduction, secondary sex characteristics, GSI, VTG or gonad histopathology in male or female fish exposed to glyphosate for 21 days. Based on the endpoints evaluated, glyphosate does not appear to impact the function of the hypothalamus-pituitary-gonadal (HPG) endocrine axis in fathead minnows.

**529 Tier 1 EDSP Assays and Regulatory Safety Studies Provide a Weight of Evidence that Glyphosate is Not an Endocrine Disruptor** S. Levine, Monsanto Company / Regulatory Sciences, Monsanto; D. Saltmiras, E. Webb, Monsanto; C. Holmes, S. Mortensen, BASF; J. Honegger, Monsanto; J. Bailey, Dow. The EPA's Endocrine Disruptor Screening Program (EDSP) includes 11 validated Tier 1 *in vitro* and *in vivo* screening assays that evaluate the potential for a chemical to interact with endocrine pathways. The endocrine screening system was designed to have redundancy between the mammalian and aquatic systems. Glyphosate was in the initial group of compounds that received test orders for screening under the EDSP. The compounds in this initial group were selected based on exposure potential and not on known or suspected interaction with the endocrine system. Results from the *in vitro* assays determined that glyphosate is not (anti)-estrogenic or (anti)-androgenic and does not impact steroidogenesis. These findings are fully consistent with peer-reviewed studies using functionally equivalent *in vitro* assays and predictions from structure activity relationships. Additionally, the *in vitro* results from the Tier 1 assays are consistent with the *in vivo* results from existing regulatory safety studies that provide information of the same nature. These higher Tier regulatory studies can provide definitive evidence of endocrine disruption or lack thereof, and are the most powerful tool for hazard identification. Consistent with the results from several multigeneration rat studies, glyphosate exposure had no impact on estrogenic, androgenic, steroidogenic and thyrogenic endpoints in *in vivo* mammalian assays, including the Uterotrophic, Hershberger, and male and female pubertal assays. Consistent the pubertal assays, the amphibian metamorphosis assay found no impact on thyroid-driven developmental endpoints. Results from the short-term fish reproduction study were consistent with the results of an existing fish full life cycle and showed no impact on all measured endpoints. From the weight of evidence provided by the Tier 1 assays, performed at independent labs, under the EDSP along with the higher Tier regulatory safety studies, it can be concluded with a high level of confidence that glyphosate is not an endocrine disruptor.

**530 Assessment of 4,4'-methylenedianiline (MDA) with regard to potential for endocrine modulation effects** R. West, The Dow Chemical Company / Toxicology and Environmental Research & Consulting; R. Jaeger, Bayer Pharma AG / Global Drug Discovery- Product Stewardship: Industrial Chemicals & Operations; M. Collins, Global Isocyanates Limited / Scientific Office. Methylenedianiline (MDA; CAS No. 101-77-9) is included among the U.S. EPA proposed List 2 of substances to be screened for endocrine disruption potential. Assessing chemical substances for possible effects on the endocrine system has become a high profile activity around the world. Definitions, specific assay systems, and tiered testing are still being developed. Nevertheless, the possibility of endocrine modulating effects is one to be considered using the new knowledge against the existing datasets that were in the past not specifically designed to test such endpoints. This presentation first reviews the existing data from animal toxicity studies with MDA for evidence of possible endocrine modulating (EM) effects. In addition, the American Chemical Society Chemical Abstracts databases were searched to identify substances having structural similarity to MDA, and these substances were queried for available studies of endocrine-related effects. The insights from this direct and indirect evidence are summarized to provide a weight-of-evidence which indicates MDA to be of low concern for potential endocrine modulating effects.

**531 Endocrine Disruptor Testing and Screening Program (EDSP): New Data and Implications for Human Health Risk Assessment** K. Connor, ARCADIS. The U.S. EPA Endocrine Disruptor Testing and Screening Program (EDSP) is proceeding with an aim of screening hundreds of chemicals in commerce. The EDSP employs a two-tiered testing regime, where the results from short-term, or *in vitro* assays will determine the need

for longer-term, whole animal studies, with these results presumably serving the development of new or revised Reference Doses (RfDs) for the purpose of human health risk assessment. This paper undertook an evaluation of how the data generated by the EDSP are likely to feed into human health risk assessment, based on the testing regimen and data that are available for several stereotypical endocrine active compounds (EACs). Despite >20 years of intense study, EAC-type effects are hardly influencing the development of RfDs, with only 2 to 3 of the nearly 400 RfDs posted on IRIS having an hormone-like response as the basis. Our review of the underlying data found that even where an endocrine effect, or an outcome that might have an endocrine effect as the basis, e.g., reproductive toxicity, these effects are often not the most sensitive endpoints. Moreover, the RfDs for 7 stereotypical EACs, namely, bisphenol-A, chlorpyrifos, o,p-DDT, methoxychlor, di(2-ethylhexylphthalate (DEHP), PCBs, and vinclozolin, are derived based on endpoints that bear no relationship to their EAC-like activity. The one example of an EAC-like effect being used to derive an RfD is that for TCDD (dioxin) and this RfD is based on human, not animal data. Many have also questioned the value of the EDSP with respect to human health risk assessment, where the Tier 2 testing comes down to standard two-generation reproductive toxicity studies in rats. Based on our review of the 7 above-named EACs, we corroborate this view, finding that there is doubtful connection between hormone-like activity *in vitro* and reproductive toxicity. In conclusion, our findings support the prediction that the EDSP is unlikely to identify substantial numbers of new EACs, and where new EACs are identified, the regulatory path towards a change in RfDs may not be as expected. However, it can be predicted that some positive findings in Tier 1 tests, whether or not corroborated by Tier 2 testing will prompt additional research and heightened public awareness. The need for human health risk assessment addressing the results of short-term, *in vitro* test results and possibly human data will still exist and still present a challenge to risk assessors.

**532 Overview of the Workshop on Ecological Soil Clean-up Values** R. Wentzel, U.S. EPA, ORD / Contaminated Sites/Resource Conserv, Exponent; A. Fairbrother, Exponent. This paper will present an introduction to a recently held workshop to develop a process for establishing ecological soil clean-up values (EcoSCVs). The goal is to progress from ecological soil screening values (EcoSSLs) to final clean-up values by providing regulators with the methods and processes to incorporate bioavailability, normalize toxicity thresholds, address food-web issues, and incorporate background concentrations. Recent major terrestrial research projects, primarily to address REACH requirements in Europe, have significantly advanced our understanding of the behaviour and toxicity of metals in soils. These projects developed large data sets that are useful for risk assessment of metals in soil environments, and were used by workshop participants as case studies in the development of the ecological standards for soils. The workshop attendees discussed scientific advancements in bioavailability, soil biota and wildlife case studies, soil processes, and food-chain modeling. In addition, one of the workgroups discussed the processes needed to frame the topics to gain regulatory acceptance as a directive or guidance by U.S. EPA or the states.

**533 Improvements in frameworks for developing bioavailability-based soil quality standards for metals and metalloids** M. McLaughlin, CSIRO Land and Water/University of Adelaide; S. McGrath, Rothamsted Research / Soil Science Department; R. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; R.C. Santore, HDR|HydroQual, Inc.; B. Duncan, US EPA / Region 10. Internationally, most ecological soil quality standards for metals and metalloids are based on total concentrations in soils and take little account of the large effects of soil properties on metal bioavailability and toxicity. This leads to both over-protective and under-protection guidelines depending on the soil conditions encountered. Significant advances have been made in the last decade in our understanding and ability to predict the bioavailability and toxicity of metals and metalloids in soils, and new approaches to developing soil quality standards are now emerging. A workshop was held in September 2012 that explored these recent scientific advances in developing frameworks to improve ecological soil quality standards, and to examine the development of ecological soil cleanup values (Eco-SCVs). One workgroup examined a range of techniques to incorporate bioavailability and long-term fate issues into Eco-SSVs and the appropriate methods to use at each tier of a risk assessment process. Key issues discussed were the general applicability of soil bioavailability normalization relationships, their limitations and data gaps for key metallic contaminants. The state of the science of mechanistic

modeling approaches (terrestrial biotic ligand model – t-BLM) was compared to empirical approaches and key requirements for implementation of the t-BLM for development of Eco-SSVs outlined.

**534 Existing Substance Regulation and REACH in Europe – catalysts for research and improvements in the risk assessment of metals and metalloids in soils** L. Schoeters, Rio Tinto Minerals, Rio Tinto; F. Van Assche, International Zinc Association; K. Delbeke, European Copper Institute; C. Schlekert, Nickel Producers Environmental Research Association; V. Verougstraete, Eurometaux; S. Carey, International Molybdenum Association. Environmental regulations in Europe like the Existing Substance Regulation (793/93/EEC) and more recently REACH (EC 1907/2006) have been catalysts for extensive research projects to better understand the ecotoxicology of metals and metalloids in the environment, including the terrestrial compartment. Under these regulations, risk assessments have been performed on chemicals, including metals, at continental, regional and local scales to ensure they are produced and used safely. At the outset of the Existing Substance Regulation – the predecessor of REACH – the guidance was largely focused on organic chemicals. Experience showed that specific properties of metals such as their natural occurrence, essentiality, and bioavailability had to be considered, but very little guidance was provided for implementing these concepts. Traditional methods such as the application of assessment factors on the lowest ecotoxicity value and even the more advanced Species Sensitivity Distribution method for data-rich substances resulted usually in threshold values below background concentrations of metals in soils. To account for bioavailability in soil risk assessments, the soil parameters influencing metal ecotoxicity first needed to be identified. Equally important was developing representative monitoring databases on distributions of these soil parameters and background soil metal concentrations. The metals industry supported research projects, which allowed the development of models to predict the ecotoxicity of zinc, copper, nickel, molybdenum, cobalt and vanadium in soils. Furthermore, an extensive European database on background metal soil concentrations and soil properties driving the bioavailability and fate of metals has been developed. These findings have resulted in major improvements in the risk assessment methodology for metals in soils, which have subsequently been incorporated into REACH guidance. An overview will be given in this presentation of the regulatory background and the work undertaken by industry to advance the science on ecotoxicity of metals and metalloids in soils to comply with regulations such as REACH.

**535 Recommendations to Improve Wildlife Toxicity Reference Value (TRV) Selection Processes for Soil Cleanup Values** J. Burris, CDM Smith; A. Fairbrother, Exponent / EcoSciences, Exponent, Inc. / EcoSciences; M.S. Johnson, US Army, Public Health Command / Health Effects Research Program, US Army Institute of Public Health / Health Effects Research Program, Army Institute of Public Health / Health Effects Research Program, US Army Ctr for Health Promotion & Preventive Med. / Health Effects Research Program; D.B. Mayfield, Gradient; S. McMurry, Oklahoma State University / Department of Zoology. An integral component of the development of media-specific ecological values for risk assessment involves the derivation of safe levels of exposure for wildlife. Though the derivation and subsequent application of these values can be used for screening purposes, there is a need to identify the threshold for effects when making remedial decisions. A workshop was held in the fall of 2012 that evaluated existing methods and explored recent science for the development of improving ecological soil levels. The purpose of this meeting included a review to improve methods for setting ecological soil screening levels (Eco-SSLs) and to develop ecological soil cleanup values (Eco-SCVs). This required a focused session on the development and derivation to Toxicity Reference Values (TRVs) for wildlife (e.g., birds, mammals, reptiles, amphibians). Topics that were examined included: methods for toxicological endpoint selection, techniques for dose-response assessment, approaches for cross-species extrapolation, and tools to incorporate environmental factors (e.g., metal bioavailability and chemistry) into a reference value. Based on this review, a process was developed to derive wildlife TRVs, using best available science, for setting regulatory soil cleanup values. This TRV process was assessed through a series of case studies for selected metals (e.g., nickel, lead) but is generally applicable to all metals and organic pollutants. The workshop also included recommendations to regulators for how to incorporate the wildlife TRV selection process into the development of soil cleanup levels.

**536 Recommendations to Improve Wildlife Exposure Estimation for Development of Soil Screening and Cleanup Values** B.J. Adams, Rio Tinto / Product Stewardship; C. Menzie, Exponent, Inc., Exponent / EcoSciences; J. Rauscher, U.S. EPA / Region 6; B. Sample, Ecological Risk, Inc.; C. Schlekert, NiPERA. An integral component of the development of media-specific ecological values for risk assessment involves the derivation of safe levels of exposure for wildlife. Though the derivation and subsequent application of these values can be used for screening purposes, there is a need to identify the threshold for effects when making remedial decisions. A workshop was held in the Fall of 2012 that evaluated existing methods and explored recent science for the development of improving ecological soil levels. The purpose of this meeting included a review to improve methods for setting ecological soil screening levels (Eco-SSLs) and to develop ecological soil cleanup values (Eco-SCVs). This required a focused session on the methods for quantifying contaminant exposure for wildlife (e.g., birds, mammals, reptiles, amphibians). Topics that were examined included: methods and models for estimating contaminant bioaccumulation and trophic transfer; contaminant bioaccessibility; possible influence of biodilution on exposure; approaches for addressing essential metals; spatial integration of exposure; dietary vs body burden-based estimates of exposure; and methodological differences between Europe and North America. A process for estimating wildlife exposure for setting regulatory soil screening and cleanup values, based on best available science, was developed based on this review. Applicability of this exposure estimation process was evaluated through a series of case studies for selected metals (e.g., cadmium, nickel, lead) to develop a tiered approach that provides appropriate refinement for metals based on the degree of biomagnification shown by the metal in question. The tiered approach should be generally applicable to all metals and organic contaminants. Recommendations to regulators for integration of exposure estimation methods into the development of soil screening and cleanup levels were developed.

**537 Development of Tier 2 Approaches for Ecological Soil Clean-up Values (EcoSCVs) Protective of Soil Biota and Plants** R. Checkai, The Ohio State University / School of Environment and Natural Resources, U.S. Army Edgewood Chemical Biological Center / Environmental Toxicology, U.S. Army Edgewood Chemical Biological Center / Environmental Toxicology Branch, U.S. Army Edgewood Chemical Biological Ctr / Dept. of Environmental Toxicology; E. Smolders, Katholieke Universiteit Leuven. Significant improvements in test methodology and the development of the new approaches to setting threshold values have gained acceptance in the past 10 years, since the development of Ecological Soil Screening Levels (Eco-SSLs) by the U.S. Environmental Protection Agency. These improvements have provided a basis for further efforts on soil criteria, including a Workshop on Ecological Soil Levels—Next Steps in the Development of Metal Clean-up Values. This workshop, which draws upon experts from Government, Industry, Consultants, and Academia, is organized to provide responsible parties and regulators with methods and processes for moving from screening values to utilization of Tier 2 approaches for establishing soil clean-up values. Development of Ecological Soil Clean-up Values (EcoSCVs) will build upon the Eco-SSL methods and data sets, and incorporate new knowledge and methodologies for soil toxicity testing, addressing and testing for bioavailability, background concentrations, and tools for normalizing toxicity thresholds. In continuity with the existing Eco-SSL methodology that focuses on three receptor groups (terrestrial plants, soil invertebrates, and wildlife), the EcoSCV approach retains a focus on Soil Biota and Plants (Workgroup 2; WG-2). WG-2 will review metals case studies involving plants and soil biota, with side-by-side comparison of Eco-SSL and REACH frameworks. Case studies selected will involve the metals zinc, copper, nickel, and the metalloid molybdenum. The goal of WG-2 will be achieving consensus for Tier 2 soil approaches, evaluating whether methods are appropriate for use in the U.S. decision making; recommendations will be developed on how regulatory agencies should implement use of the proposed methods for EcoSCVs.

**538 Development of Ecological Soil Clean-up Values (EcoSCVs) Protective of Biologically-Mediated Soil Process** R.G. Kuperman, U.S. Army Edgewood Chemical Biological Center / Environmental Toxicology; S.D. Siciliano, University of Saskatchewan / Department of Soil Science; J. Roembke, ECT Oekotoxikologie GmbH; K. Oorts, ARCHE. Significant improvements in test methodology and the development of the new approaches to setting threshold values have gained acceptance in the past 10

years, since the development of Ecological Soil Screening Levels (EcoSSLs) by the U.S. Environmental Protection Agency. These improvements have provided a basis for further efforts on soil criteria, including a Workshop on Ecological Soil Levels—Next Steps in the Development of Metal Clean-up Values. This workshop is organized to provide responsible parties and regulators with methods and processes to move from screening values to clean-up values that address food-web issues, and incorporate bioavailability, background concentrations, and tools for normalized toxicity thresholds. Development of Ecological Soil Clean-up Values (EcoSCVs) will build on the EcoSSL methods and data sets, and will incorporate new knowledge and methodologies for soil toxicity testing. In addition to the three receptor groups used in the EcoSSL methodology (i.e., terrestrial plants, soil invertebrates, and wildlife), the EcoSCV approach includes soil processes that are addressed by Workgroup 5 (WG-5). The main objective of WG-5 is to review the most widely used national and international methods related to the assessment of metal contamination effects on soil processes, and evaluate whether these methods are appropriate for use in the U.S. decision making. The WG-5 will review case studies, the current practices, endpoints, and available data for Zn, Cu, Ni and Mo, and will provide recommendations for regulatory agencies on implementing utilization of the proposed methods for developing EcoSCVs for these metals.

**539 Regulatory considerations for the potential development and application of metal clean-up values** M.S. Greenberg, U.S. EPA Environmental Response Team; I. Schoeters, Rio Tinto; R.S. Wentsel, Exponent; R.G. Stahl, DuPont / Corporate Remediation Group; D.W. Charters, U.S. EPA. A workshop was held in September 2012 to advance the use of soil contaminant bioavailability data, soil parameter data, concentration response relationships, and other newer methodologies in the determination of ecologically protective soil clean-up values (EcoSCVs) for metals that moves us beyond sole reliance on soil screening values as a basis for decisions. This presentation will report on the outcome of the workgroup focused on regulatory applications of the approaches available for developing scientifically defensible EcoSCVs. The U.S. EPA and EU-REACH's, intent and policies and methodologies on ecological risk assessment, derivation of soil screening levels (EcoSSLs), and baseline soil assessments will be discussed with regard to their similarities and differences in how each can lead to site-specific or national management decisions. The utility of Tier 2 processes, common to the REACH guidance for the derivation of soil predicted no effect concentration (PNEC) values and Australian methodology for determining ecological investigation levels on contaminated soils, will be explored through case study examples and discussion of how such a process could be used within the U.S. EPA Superfund process and other regulatory programs to derive EcoSCVs. Additionally, the pros and cons for regulators and the regulated community from the inclusion of such Tier 2 processes for determining EcoSCVs will be discussed. Recommendations from the workgroup on next steps toward additional technical guidance to inform policy-makers will be shared.

**540 Consequential Life Cycle Analysis of Green vs. Grey Infrastructure for Stormwater Management** R. Wang, Yale University; M. Eckelman, Northeastern University; J. Zimmerman, Yale University. A life cycle analysis of four green to grey infrastructure technologies for stormwater management was performed as compared to a baseline of the current situation in many urban areas, combined sewer overflows. The four interventions include sewer separation, porous pavement, bioretention, and green roofs. Four impact categories were considered (greenhouse gas emissions, toxicity, eutrophication, and resource depletion) under four precipitation scenarios that increase in quantity and intensity to mimic predicted impacts of climate change on storm events. Life cycle credits were also considered for offsetting the traditional technology (i.e., asphalt pavement versus porous pavement). A sensitivity analysis was performed and demonstrated that infrastructure lifetime and storm event quantity and intensity were the most significant drivers for the life cycle implications of these systems.

**541 Development and Use of Fundamental Service Life Models for LCA of Advanced Infrastructure Materials** M.D. Lepech, Stanford University / Department of Civil and Environmental Engineering. Concrete transportation infrastructure lies at the nexus of two significant sustainability challenges; global greenhouse gas emissions associated with cement production and vehicle energy consumption and toxic tailpipe emissions. The use of advanced engineering materials in infrastructure can significantly reduce

these impacts through reduced material consumption, improved durability leading to reduced congestion traffic emissions, and enhanced end-of-life management. Engineered Cementitious Composites, or ECC, are a new cement-based infrastructure material that exhibits ductility over 300 times that of conventional concrete. Such ductility can lead to significant reductions in material use and vehicle impacts through extended maintenance and replacement timelines. Previous studies have demonstrated the potential environmental impact reductions associated with this increase in life cycle performance. While Life Cycle Assessment (LCA) is a powerful tool for quantifying the sustainability benefits of advanced materials in highly durable applications such as infrastructure, it remains unconvincing due to the high uncertainty of the future performance of unproven materials. Recent work in service life modeling of reinforced concrete and ECC materials is addressing this shortcoming. Based on fundamental, multi-phase porous media transport and electrochemistry modeling, new service life models for both existing and new infrastructure materials are presented. These models capture the time-dependent deterioration of reinforced concrete infrastructure materials from initial transport of corrosive species, to electrochemical depassivation of reinforcing steel, to active corrosion, and up to end of service life and replacement. Integrating such fundamental deterioration and service life models into life cycle assessment of infrastructure can more clearly demonstrate the long term benefits of advanced materials over existing infrastructure construction. Such models enable probabilistic characterization of expected service life of new materials, such as ECC, thus allowing for more rational consideration of future uncertainties. More generally, the benefits of integrating fundamental service life modeling with LCA is discussed in the context of unproven, yet highly promising advanced materials for a variety of applications.

**542 The misunderstood role of construction technologies in the GHG mitigation of the building stock** J. Heinen, Aalto University / Department of Planning and Surveying; S. Junnila, Aalto University. Building energy use is accountable for approximately 40% of the global greenhouse gas (GHG) emissions. In Finland housing energy is by far the most dominant sector in the carbon footprint of an average consumer. Construction phase emissions, on the other hand, are generally held unimportant compared to the use phase emissions. Based on this, often drawn policy implication is that increasing the building energy efficiency would be a very effective GHG mitigation strategy. Accordingly, the efficiency requirements on residential heating energy consumption in Finland have tightened from 185 kWh/sq. m in 1985 to 80 kWh/sq. m in 2012. As a consequence, construction technologies have taken long steps forward to meet these new requirements. While this development gradually reduces the overall energy consumption of buildings as the building stock renews, little attention has been paid to the construction phase emissions in the building life cycle due to the prevailing belief about their insignificant role. However, while construction related emissions of a building may seem small on national level accounts as well as compared to the overall use phase emissions, the situation changes significantly when a certain development project is concerned and the temporal allocation of the emissions is taken into account. With the current rather high energy efficiency requirements in Finland, the construction phase emissions may actually dominate the building related emissions for decades. Furthermore, when the construction phase emissions are taken into account, despite the highly increased efficiency requirements, the current approximately 1% annual renewal rate of the building stock in Finland only leads to an increase in the cumulative emissions up to 2050, the current target year of significant mitigation needs. Thus, it seems that partial optimization of the life cycle emissions without understanding the broader context might lead to weak policy guidelines and unwanted consequences. In this study we demonstrate the above described phenomena with a hybrid life cycle assessment (LCA) model that is able to take into account the temporal allocation of the emissions. We also analyze solutions to decrease the construction phase carbon spike concentrating especially on wood construction technologies. We employ a case study of a new residential development from Finland and broaden the perspective with a bottom-up approach to the national level for the overall conclusions.

**543 LCA Study of Artificial Photosynthesis—hydrogen compression/liquefaction using photovoltaics** P. Zhai, H. Breunig, R. Sathre, J. Greenblatt, Lawrence Berkeley National Laboratory. Artificial photosynthesis (AP), also known as photo-electrochemical devices for solar water splitting, harvests sunlight and converts it to energy stored in hydrogen bonds.

Although AP is still in the early stage of laboratory scale research, AP could change the future energy landscape. LCA and energy balance analyses are essential for evaluating the potential of this emerging technology. We investigate the prospective energy balance of an AP system. The LCA boundary of the system includes embodied energy in raw materials and manufacturing processes of AP panels; and energy requirements for hydrogen compression/liquefaction. The latter issue is the focus of this study. Previous studies have reported significant variation of energy requirements to compress or liquefy hydrogen due to differences in assumed final pressure (500 or 1000 psi), modes of transportation (trucks or pipelines), and boundary definitions (inclusion of hydrogen dispensing). We propose several scenarios of energy requirements based on a comprehensive literature review. Our study is unique in that renewable energy will be implemented to minimize the primary energy required to power the compression or liquefaction of hydrogen. We predict that photovoltaics (PV) and AP could work synchronously during day time. We will examine how PV meets the electricity demand to handle hydrogen generated by AP, and assess related embodied energy, cost and land use issues caused by PV installation. Finally, we will compare the life cycle energy balance of an AP system under two cases: first, powering hydrogen compression and liquefaction using PV electricity; second, using electricity from a power grid (assuming U.S. average power mix).

**544 Developing an Electric Vehicle Impact Assessment that Incorporates Uncertainty from the Deployment of Life-cycle Processes** M. Chester, Arizona State University / Civil, Environmental, and Sustainability Engineering. Advancements in transportation environmental life-cycle assessment should incorporate spatial dimensions and more rigorous human health and environmental impact assessment for emerging systems. Using electric vehicles as an example, this presentation will discuss new approaches that have been developed to evaluate the uncertainty in spatial characteristics of future life-cycle inventories and the human health and environmental damage costs of emissions. The electrification of passenger vehicles has the potential to produce fewer greenhouse gas emissions than gasoline, reduce and displace tailpipe emissions, and reduce dependency on imported oil. Federal policy has been created to encourage development and deployment by subsidizing vehicles up to \$7500. Yet the benefits of emerging electric vehicles have been studied with somewhat myopic lenses. Many studies have been developed to evaluate the energy and GHG tradeoffs of electric vehicles over gasoline vehicles, and few have considered human health and environmental tradeoffs. Only a handful of studies to date have attempted to comprehensively quantify benefits and costs. By joining damage cost estimates with an uncertainty analysis of emission release locations, the greenhouse gas, human health, and environmental impact costs of conventional gasoline, plug-in hybrids, and battery electric vehicles are determined for driving in 3,000 U.S. counties. In the short run, vehicles with small battery packs (i.e., HEVs and low-range PHEVs) produce the lowest life-cycle costs and policies that provide larger subsidies to large battery pack vehicles do not generally offer more benefits. For the average U.S. electricity grid mix, a conventional gasoline vehicle produce \$4800 damages in greenhouse gas, human health, and environmental effects, HEV \$3900, PHEV20 \$3600, PHEV60 \$4100, and BEV \$4700. These costs are largely dominated by emissions of greenhouse gases and sulfur dioxide. Combining these costs with oil displacement effects provides a comprehensive and unifying framework for evaluating emerging vehicle impacts. Furthermore, the spatial characterization of effects presents opportunities for avoiding the deployment of direct, indirect, and supply chain processes to high-impact areas.

**545 The role of biofuels in the electrification of US passenger transportation** C.D Scown, Lawrence Berkeley National Laboratory; A. Horvath, University of California, Berkeley / Civil and Environmental Engineering, University of California, Berkeley / Civil & Environmental Eng.; T. McKone, University of California, Berkeley, University of California and Lawrence Berkeley National Laboratory, University of California, University of California and Lawrence Berkeley National Laboratory, University of California. A variety of alternative transportation fuels have been explored over past decades, but most are difficult to produce at the scale of current gasoline demand on the timeframe necessary to meet national greenhouse gas (GHG) emissions reduction goals. Rather than exploring each option individually, potential fuels should be analyzed in combination through long-term scenarios that take advantage of different fuel pathways' strengths while ensuring a smooth transition and a sustainable end state. Electrifying passenger transportation is at present one of the most promising options for

achieving lower carbon emissions, with greater long-term benefits if the US is able to shift from coal and natural gas-fired power plants to renewables such as wind and solar. However, most electric vehicles (EVs) and plug-hybrid electric vehicles (PHEVs) have limited ranges and long recharging times. Their fleet penetration rate is also limited, as these vehicles are more costly than their traditional gasoline-powered counterparts. Cellulosic ethanol, while unable to displace all US gasoline demand without significant land use change impacts, has some advantages over electricity: its storage and distribution can be integrated with existing liquid fuel storage and distribution infrastructure, and flex-fuel vehicle technology that allows for burning of 85% ethanol by volume is relatively inexpensive and already present in many vehicles on the road. Additionally, preliminary results show that low-input high-yield crops such as *Miscanthus* can ultimately result in ethanol with a net negative GHG footprint, with higher-emission scenarios still averaging only 22 g CO<sub>2</sub>e/MJ of ethanol. US county-level scenario analysis extending to 2050 is used to explore the possibility of utilizing crop residues and dedicated cellulosic crops to meet liquid fuel demand as PHEVs gradually penetrate the passenger vehicle fleet. Life-cycle assessment is used to determine possible emissions reductions under conservative, moderate, and aggressive scenarios. Results show that cellulosic ethanol has significant potential to deliver necessary short-term GHG emissions reductions as PHEVs and EVs achieve market penetration, and may also satisfy residual liquid fuel demand in the long term.

**546 Energy Production and Nutrient Recovery from Residual Algal Biomass** W.J Barr, A. Landis, Arizona State University / School of Sustainable Engineering and The Built Environment. Algae biodiesel has been shown to be a promising alternative fuel source. However, the production of biodiesel from microalgae is an energy intensive process and despite being produced from sunlight, still requires fertilizers and other chemical inputs. A significant portion of waste algal biomass remains unused after the lipid extraction process. This lipid-extracted algae (LEA) contains the bulk of the nutrients consumed during cultivation and has the potential to be used for a secondary energy source via methane production. Using a life cycle assessment (LCA) framework, this presentation tracks energy and nutrient production and consumption over the life cycle of algae produced in a photobioreactor. Anaerobic digestion (AD) is used to recover nutrients and energy from LEA. The feasibility of using AD to recycle nutrients and energy within the biodiesel production facility will be assessed through a computational LCA. Alternative technologies will be evaluated to improve AD yields. In addition, the life-cycle implications of improving on the energy recovery and nutrient recycle within the algae biorefinery will be discussed. AD has the potential to improve the net energy balance of algae-based biodiesel production by recycling energy and nutrients inside of the system that would otherwise be wasted.

**547 Baseline effects on carbon footprints of biofuels: the case of wood** E. Johnson, Atlantic Consulting. As biofuel usage has boomed over the past decade, so has research and regulatory interest in its carbon accounting. This paper examines one aspect of that carbon accounting: definition of the baseline, i.e. the reference against which other conditions or changes can be compared. A literature search and analysis identified four baseline types: no baseline; reference point; marginal fossil fuel; and biomass opportunity cost. The fourth one, biomass opportunity cost, is defined in more detail, because this is not done elsewhere in the literature. The four baselines are then applied to the carbon footprint of a wood-fired power plant; all other inputs and calculations are identical. It is found that the footprint of the resulting wood-fired electricity varies dramatically, according to the type of baseline. Baseline type is also found to be the footprint's most significant sensitivity. Other significant sensitivities are: efficiency of the power plant; the growth (or re-growth) rate of the forest that supplies the wood; and the residue fraction of the wood. Length of the policy horizon is also an important factor in determining the footprint. The conclusion is that because of their significance, baseline choices should be made very explicit in biofuel carbon footprints. The 'no baseline' approach is not acceptable. The other three approaches are acceptable, but their suitability to a particular generation plant (of power, heat or both) depends on the type of question to be answered.

**547.1 Introduction to the Proposed Safer Consumer Products Regulations** E. Rodriguez, Department of Toxic Substances Control / Pollution Prevention and Green Technology. California's Green Chemistry law (A.B. 1879) was adopted to accelerate the quest for safer product. The enabling

statue requires the Department of Toxic Substances Control (DTSC) to adopt regulations that reduce or eliminate adverse public health and environmental impacts that may result from the production, use, or end-of-life management of consumer products containing chemicals of concern. This presentation will cover the major steps being proposed to provide a continuous, science-based, iterative process to identify safer consumer product alternatives. First, the proposed regulation will specify the processes for DTSC to identify and prioritize chemicals of concern in consumer products. The initial list of chemicals of concern will be established based on the work already done by other authoritative organizations. DTSC will evaluate and prioritize product/chemical of concern combinations to develop a list of "Priority Products" for which an alternatives assessment must be conducted. The next step in the process requires the manufacturers to conduct an alternatives analysis which compares health, environmental and economic trade-offs of those product/chemical combinations with potentially safer alternatives to replace or eliminate prioritized chemicals of concern in products. Alternative analysis will be required to cover a wide range of factors over the lifecycle of the product. Lastly, based on the findings of the alternatives analysis, DTSC may impose regulatory responses that will effectively limit potential adverse public health and/or environmental impacts, if any.

**548 Multi-State Effort to Create an Alternatives Assessment Guidance** A. Stone, Wa Department Of Ecology / Chemist. In 2008, the Washington Department of Ecology (Ecology) was required by the Washington Legislature to conduct an assessment of alternatives to the flame retardant, decabromodiphenyl ether. If a safer alternative could be identified, a ban would take effect on the use of deca-BDE in specific applications. Ecology used the GreenScreen methodology created by Clean Production Action and based upon the principles developed by EPA's Design for the Environment Program. The Deca-BDE ban took effect in 2011 and Ecology has selected the GreenScreen as the hazard assessment tool it will use in all future alternatives assessments. Subsequently, eight member states of the Interstates Chemical Clearinghouse began working together in August 2011 to create an alternatives assessment (AA) guidance document. The AA guidance consists of twelve modules with each module representing an important component of an AA. Modules include such basic concerns as cost and availability, performance, hazard, exposure, stakeholder involvement etc. and includes more complex issues as life-cycle analysis. Each module consists of a number of levels of increasing complexity and assists the user in identifying what information is needed to contribute to an AA for the specific issue being addressed. During this process, the states have sought out input from a wide range of stakeholders and has worked with business to flesh out a guidance document that can be used by users with varying levels of technical expertise and experience. One important objective of the guidance is to create a document that can be used by small and medium businesses as well as the larger concerns that are accustomed to conducting similar assessments. It will also prove useful to state, local and national governments who may be evaluating AAs in the future. The current schedule has the completion of this guidance document by the end of 2012. The objective of this talk is to provide an update on the process, a description of the guidance and a summary of the experience of the states in working together to create the guidance. In addition, a description will be provided on how Washington State sees the document will assist us in the Agency goal of Reducing Toxic Threats by eliminating or reducing the use of toxic chemicals in consumer products and better protecting human health and the environment.

**549 Substitution and Alternative Assessment Tools Under State Green Chemistry Programs: Learning from the International Experience** D. Graham, Keller & Heckman LLP; D.J. Kent, H. Estreicher, Keller and Heckman LLP. The California Green Chemistry regulation has as its cornerstone the systematic substitution of Chemicals of Concern in consumer products with "safer" chemicals. Washington State leads the development of the Alternatives Assessment (AA) guidance for the Technical Alternatives Assessment Guidance Team (TAAG) which is made up of representatives from the seven states who are members of the Interstate Chemicals Clearinghouse. The idea of substituting chemicals is not new and has long been a core principle in Europe as part of REACH Authorization, which requires the ultimate phase-out of substances of very high concern. Several years ago Canada began its process of identifying high hazard chemicals which it has been listing as CEPA Toxic. As with the EU and Canadian programs, the proposed AA guidance is primarily based on hazard assessments, but does include an exposure module. Recent experience with chemical substitution

including with some products advertised as "Green" indicates that substitution may result in different kinds of exposures and possibly adverse health outcomes. This presentation looks at how California and other states can build on the experience of other jurisdictions in structuring programs that will result in the desired outcome of reducing human and environmental exposure to hazardous chemicals.

**550 Case Study Application on Green Screen for Safer Chemicals to the U.S. Chemical Manufacturing Industry** C.W. Lam, University of California, Davis / Department of Chemical Engineering and Materials Science; C.W. Lam, J.M. Schoenung, University of California, Davis / Chemical Engineering and Materials Science. Heightened societal interest to reduce toxicity potential from chemical products and processes has spurred governmental agencies, company programs and public consumers to procure and use chemicals which are inherently safer. As a milestone effort in defining "safer", the Clean Production Action (CPA) developed Green Screen for Safer Chemicals as a hazard screening tool that considers a comprehensive range of human health, ecological, and safety hazard traits of substances so that benchmark scores, an indication of relative hazard, could be assigned for specific chemicals. Although Green Screen has recently seen increased attention within select regulatory and industrial circles, outside of a limited number of individual chemical case examples, no independent, academic-based published work is available to test Green Screen for a larger range of chemicals. Such an exercise is important to understand, from an aggregate perspective, the potential challenges it has in application for diverse substances. The goal of this research consists of using Green Screen to analyze a select list of chemicals to survey the tool's use and, more importantly, to discuss its attributes and limitations. The evaluation covers over 35 chemicals most commonly emitted to air and water media from the United States' chemical manufacturing industry as reported by the Toxic Release Inventory (TRI). Preliminary results will be presented on benchmark scores of these TRI chemicals using publicly available toxicity information. Toxicity data gaps are highlighted as an issue for developing complete Green Screen assessments, even for regulated TRI chemicals which are common and released in high quantities in the U.S. Despite data gap concerns, benchmark scores are able to be assigned for TRI chemicals, with the majority of substances falling into benchmark 1 (avoid – chemical of high concern) and 2 (use – but search for safer substitute) categories.

**551 Application of LCA in safer products alternatives analysis- a California perspective** B. Boughton, CalEPA / Calif. Dept of Toxic Substances Control, DTSC. Life cycle thinking is an essential component of alternative assessment (AA). As applied to product design and production processes it informs decision-making. The goal of Life Cycle Assessment is to make sure that reducing an impact at one stage in the life cycle does not increase an impact at other parts in the life cycle. Life cycle thinking should be employed in alternatives analysis because it leads to informed substitution and allows one to avoid unintended consequences. Businesses are responsible for many choices about their services and products. Businesses should not only take into consideration how the product is made, but also ways that the product will be used and disposed of by the user. When considering alternatives, they should study how each design and manufacturing decision has a net effect on the environment and human health. By looking at all of the life-cycle phases, businesses can make the best choices for a lower net impact on the environment and society. The current alternative analysis guidance approach to comply with the California Safer Products Regulations (see [www.dtsc.ca.gov/PollutionPrevention/GreenChemistryInitiative/index.cfm](http://www.dtsc.ca.gov/PollutionPrevention/GreenChemistryInitiative/index.cfm)) will be presented. This is a decision framework for evaluating alternatives for products containing chemicals of concern to human health and the environment. Application of life-cycle thinking in alternatives analysis can be done at several levels. The levels described build from a qualitative cursory review of all attributes (using screening tools) to quantitative approaches for the most relevant aspects. With this approach, effort is focused on the attributes that most matter, rather than conducting a full ISO compliant LCA.

**552 Safer surfactants – How to develop chemicals with lower antimicrobial toxicity** N. Gathergood, Dublin City University / School of Chemical Sciences; M. Spulak, Charles University / Department of Inorganic and Organic Chemistry, Faculty of Pharmacy; B. Quilty, Dublin City University / School of Biotechnology; D. Coleman, Dublin City University / School of Chemical Sciences. One of the reasons that the chemical industry has great interest in Green Chemistry is the financial benefits. By developing greener

and cleaner methods and processes, that inherently generate less waste, the costs associated with waste disposal can be reduced. Industry can reduce their environmental impact as well as increase profitability. In their book, Anastas and Warner proposed the 'Twelve Principles of Green Chemistry' primarily to inspire chemists to create environmentally less damaging synthetic methodologies and products. Our own research team in Dublin encompasses a variety of these green chemistry principles to realise environmentally friendly organic synthesis for chemicals of interest to industry. Concurrent assessment of the performance of a new chemical with its potential environmental impact enables our group to focus investigations on 'safer' novel chemicals. The development of reactions with high atom economy, to reduce waste products, combined with low toxicity and biodegradable reaction media, is one example of our benign-by-design philosophy. Recent examples from our search for low toxicity and biodegradable surfactants will be presented. In addition our novel approach for the design of low toxicity surfactants also yielded a MRSA selective antimicrobial drug which is highlighted in Chemistry World and in national press (The Sunday Times).

**553 Experiences with Alternatives Analysis and Product Development in Formulated Products** D. Versteeg, The Procter & Gamble Company / Environmental Science Department; M. Lafronconi, J. Froelicher, B. Percynski, The Procter & Gamble Company. California's Green Chemistry Initiative and Safer Consumer Products regulations seek to enhance the safety of consumer products for humans and the environment by applying an alternatives assessment (AA) process to identify replacements for ingredients of concern. In doing so, the law goes beyond exposure and toxicity concerns related to individual ingredients by including factors such as energy inputs, energy consumption, water conservation, material consumption, etc. The AA is the primary tool used to identify new ingredients and other technical solutions presented by the ingredient of concern. The AA process in California, and the ones evolving in other states, are similar to research and development approaches industry has applied for decades to create new and improved products. The product development process is iterative and necessarily flexible to account for product and consumer specific needs. To be successful, the process must not only consider use and toxicity, but also supply, aesthetics, compatibility, stability, and a range of other manufacturability issues. Experiences with successful and unsuccessful AAs will be shared.

**554 Applying the GreenScreen for Safer Chemicals to Electronics Cleaners** C. Wray, C. Robertson, H. Holder, P. Mazurkiewicz, Hewlett-Packard Company. Hewlett-Packard has been incorporating hazard assessment requirements into its global materials selection process in order to reduce the environmental and human health impact of its products and manufacturing processes. HP utilizes a comparative Chemical Hazard Assessment tool called the GreenScreen for Safer Chemicals (GreenScreen) to ensure that the alternative materials are indeed less hazardous than those being replaced. Based on the principles of green chemistry that focuses on reducing risk by reducing hazard, the Green Screen provides a simple 1-4 benchmark score that can help identify less hazardous chemical and non-chemical alternatives. A business case for screening alternatives using the Green Screen can be made based on the cost savings realized by avoiding multiple substitutions. Substituting materials in a complex supply chain can be costly, and if the replacement chemicals face future regulation, businesses may incur that cost multiple times. This presentation will introduce the GreenScreen as well as discuss its application to the hazard assessment of cleaners used in electronics manufacturing.

**555 A model based adaptive control of pest in agriculture: An application on cotton crop** M. Yanke Nana, Technische Universität Braunschweig / Environmental Systems Analysis, Institute of Research in Health Sciences; O. Richter, Technische Universität Braunschweig / Environmental Systems Analysis. Agricultural pests control is crucial for a better crop yield. Until now, the best method of struggling against pests in agriculture is the use of crop protection products, which can cause huge damages to the environment. Therefore, there is a need for an optimal crop treatments schedule. As such, efforts have been made towards the development of simulation models to forecast pest's population size linked to its response to a dose of a specified pesticide, including the potential contamination of the environment. The simulation model was developed for cotton crop influenced by the pest *helicoverpa armigera* (HA). This model will lead to a more appropriate and adaptive pest control using pesticides in agriculture, with respect to the environment. An integrated concept comprising submodels for cotton growth,

population dynamic of HA and its application to the evaluation of optimal treatment scheme will be presented.

**556 A step towards spatially realistic simulations of pesticide effects on aquatic macroinvertebrate populations** A. Focks, Environmental Systems Research / Mathematics/Computer Science, Wageningen University / Aquatic Ecology and Water Quality Management, Wageningen UR / Aquatic Ecology and Water Quality Management; N. Galic, Wageningen University; H. Baveco, Alterra Wageningen; P.J. van den Brink, Wageningen University. Little is known about ecological risks of chemicals considering spatial heterogeneity on larger scales, especially with regards to the population recovery potential after exposure to chemical stress. This study aims to evaluate the influence of i) persistence and toxicity of hypothetical pesticides and ii) different levels of spatial complexity on effects and recovery times of populations of the water louse *Asellus aquaticus*. To reach these objectives, the MASTEP population model of *Asellus aquaticus* (Galic et al., 2012) was used in a spatially realistic structure of a typical Dutch water ditch network. Spatio-temporal concentration curves were calculated for a set of virtual pesticides. Exposure concentrations were linked with effects on individual organisms by calculating daily mortality probabilities following a simple dose-response relation. Scenarios were simulated in 10 replicates each, and the recovery times have been calculated as the number of days, when population abundances in treated scenarios reached 95% of the level of the abundances in respective control simulations. Our analysis showed the importance of chemical properties in a spatially explicit setting. Both persistence and toxicity of the simulated compounds influenced the magnitude of effects on and subsequent recovery times of the water louse populations. At high toxicities, increasing water network complexities lead to shorter recovery times of the affected populations. This is quite well understood, because recovery can occur via i) recolonisation from unaffected habitats and ii) local population regrowth enhanced by survivors. High toxicities lead to "wipe-out" events in the downstream section, so local regrowth only plays a minor role in the recovery. In this case the connectivity of the affected sections of the water network to unaffected parts is decisive for recovery. The lower the toxicity, the more local regrowth contributes to recovery and hence the spatial structure is less important. Implications of our research are: i) the use of existing population effect models in simplified landscapes are protective within the limitations of any modelling approach, and ii) assessing the recovery potential and quantifying the time to population recovery is very sensitive with respect to changes in pesticide and landscape properties, so integrating the detailed exposure profiles through e.g. pesticide fate model output, will inevitably lead to a more realistic ecological risk assessment.

**557 Adding ecological relevance to risk assessment: modeling the effect of multiple and heterogeneous stress on springtail populations** M. Meli, Roskilde University / Department of Environmental, Social and Spatial Change; A. Palmqvist, Roskilde University / Dept. of Environmental, Social & Spatial Change; V.E. Forbes, University of Nebraska Lincoln / School of Biological Sciences; V. Grimm, Helmholtz Centre for Environmental Research – UFZ / Department of Ecological Modeling. In assessing soil quality and the environmental and ecological risk of contamination with heavy metals, often homogeneous contamination is assumed. However, soils are very heterogeneous environments. Consequently, both contamination and the response of soil organisms can be assumed to be heterogeneous. Moreover, in the natural environment organisms are likely to be confronted with physical stressors, e.g., summer drought. To explore the consequences for populations of soil invertebrates caused by the interaction of chemical and physical stressors, we developed a spatially explicit individual-based model of the collembolan *Folsomia candida*. Individuals in the model can sense and avoid contaminated habitat with a certain probability, which depends on contamination level. Avoidance of toxicant influences the feeding behavior of the organisms, and this in turn affects all the other biological processes. Model rules and parameters are based on previous knowledge of the biology and ecology of the species; for toxicity, data from standard laboratory tests (survival, reproduction and avoidance) are used. Heterogeneity of soil contamination with  $\text{CuSO}_4$  was varied according to the percentage of contaminated area and the spatial autocorrelation of the contaminated patches of soil. In addition, we simulated the effects of drought on collembolan populations, with and without Cu exposure. Preliminary simulation results show that the presence of patches of suitable habitat allows the population to grow, although population size is reduced with respect to the control. Toxic effects are much less than proportional to the concentration,

because avoidance probability increases with increasing Cu concentration. When the uncontaminated area is small (< 5%), stable population size is bigger in the case of spatially correlated distribution of toxicant, whereas as the proportion of clean habitat increases, population growth is higher with uncorrelated contamination. Our results show that a combination of spatial heterogeneity and physical stressors can lead to unexpected effects of toxicants at the population level. Individual-based models can help to understand these effects and therefore can add ecological realism to environmental risk assessment of chemicals.

**558 Density in population-level ecotoxicology and risk assessment: insights, hypotheses and uncertainties from a density dependent simulation model** C.J. Salice, Texas Tech University / Environmental Toxicology, Texas Tech University / TIEHH, Texas Tech University / Department of Environmental Toxicology.

Population models are a powerful way to integrate and assess the ecological impacts of chemical contaminants. A particular challenge, however, lies in understanding and modeling the interaction of contaminant effects and density dependence. How contaminants and density interact and are modeled can have profound impacts on our interpretation of overall population-level responses. While there has been some research on the topic, considerable uncertainties remain. A common view is that density dependent compensation will limit adverse demographic effects of contaminants. Although there is some empirical evidence for this, it is not unilaterally the case. In an effort to better understand the interactions between density dependence and toxicity, I used a previously published amphibian population model that incorporates a four-parameter density dependent function to explore and define under what circumstances toxicants may cause positive or negative effects on the population. I also used the model to explore the utility of several population-level endpoints including population growth rate, population size and extinction risk. The interactions between toxicity and density dependence were simulated as toxicity: (1) reducing maximum survival, (2) altering the functional availability of resources and (3) changing the function inflection (curve shape). Positive population level effects result when toxicants reduce the initial number of individuals thereby lessening density dependent stress. This, functionally, amounts to an increase in resource availability but assumes there is no lasting impact of toxicity. Alternatively, a range of different toxicant and density interactions can result in negative population level effects, stemming from a reduction in maximum survival, a change in the shape of the density dependent function and/or an alteration in functional availability of resources. Hence, simplistic approaches in which density effects are accounted for after a reduction in individuals may not accurately capture population dynamics. The population endpoint that provided the most insight and management utility was population size followed by population growth rate and extinction risk. These results have strong implications for the protection of wild populations and point to the importance of continued research and model development and are further discussed in terms of a critical can of worms: selecting management endpoints.

**559 Determining chemical effects on earthworms at the population level through the use of energy budget and individual based modelling** A.S. Johnston, R. Sibly, University of Reading / Biological Sciences; M. Hodson, University of Reading; P. Thorbek, Syngenta Ltd / Environmental Safety; T. Alvarez, Syngenta / Dept. of Ecological Sciences, SRG / Syngenta / Product Safety. Standard OECD test methods for measuring the toxicity of pesticides on earthworms use optimal laboratory conditions to record specific endpoints e.g. mortality, growth and reproduction. These data are compared to exposure values in accordance with guidelines for registration of agrochemicals, and the resulting risk quotients are compared to arbitrary safety factors for acute and sublethal risks to earthworms. When these triggers are not passed, field trials are required. Field trials are expensive, time-consuming and variable, providing coarse information about population-level effects. Mechanistic population modelling of organism responses to chemicals has the potential to act as a reliable intermediate stage in higher tier risk assessments and can provide greater resolution to help identify key parameters driving population-level effects. Energy budget models relate individual life cycle processes to one another through energy and mass conservation. Organisms uptake resources from their environment and expend assimilated energy on maintenance, growth and reproduction. The allocation of energy to these different subsystems depends on a combination of environment- and organism-specific conditions. Here we present a general energy budget model, based on broadly accepted fundamental principles.

The model is applied within an individual-based model (IBM) framework, which allows individuals to interact with their simulated environment, giving an insight into life cycle processes affected under variable environments and chemical exposure. This enables ecotoxicological inferences to be made about population dynamics under realistic field conditions, as the biology of individuals relates to the ecology of populations through metabolism. Standard toxicity data, including NOEC and EC<sub>50</sub> values, are used as input data to the model to hypothesise possible modes of action, highlighting its usefulness as a method in higher tier risk assessments. We use data for the OECD recommended earthworm species *Eisenia fetida* to validate the model for use in predicting ecotoxicological effects for a variety of chemicals, including carbendazim and copper oxychloride. We discuss the potential of the model in decision-making for pesticide regulation and environmental management, particularly in comparison to alternative modelling techniques. Future studies aim to extrapolate population-level ecotoxicological effects between the varied ecological niches of different earthworm species.

**560 Extrapolating individual reproductive toxicity to long-term population level endpoints using an individual-based model of the wood mouse** C. Liu, Syngenta / Environmental Safety; R.M. Sibly, University of Reading / School of Biological Sciences; V. Grimm, Helmholtz Centre for Environmental Research – UFZ / Department of Ecological Modeling; R.C. Murfitt, P. Edwards, Syngenta / Environmental Safety; P. Thorbek, Syngenta Ltd / Environmental Safety.

In EU pesticide risk assessment of potential chronic effects upon wild mammals, the “two-generation reproduction toxicity study” is commonly used to select a toxicity endpoint for risk assessment. Reproductive performance as well as maternal behaviour of the test individuals is followed under long-term exposure until the second generation are produced, to allow a thorough examination of the full life cycle (i.e. growth, development and reproduction) in the lab. However, such studies focus on individual level effects whereas the protection goal is at the population level. Population modelling can extrapolate such data from individuals to population level endpoints. Here we present an individual-based model of the wood mouse (*Apodemus sylvaticus*) aimed at refining pesticide risk assessments in agricultural landscapes. The full life cycle of female wood mice and their spatial behaviour, in particular the choice of foraging and nest sites, were explicitly modelled. Additionally, the model implemented a dynamic landscape with spatio-temporal variation of the habitat quality as a result of crop growth, rotation scheme and tillage activities. By linking the spatial choice of the mice and the application patterns of the pesticides, the model provided more realistic estimates of exposure in different habitats at different time of the year. We used the model to explore the population level sensitivity (level of exposure, population structure, time to recovery) to different individual level endpoints. We tested different application schemes (foliar and seed treatment) and found that the ecological relevance of these individual level endpoints varied widely. Based on the predictions from the model, we showed how such model outputs can be used to refine higher tier risk assessments.

**561 A simplified AQUATOX ecosystem model for endocrine disruption** L. Clouzet, Université Laval / modelEAU; M. Paterson, A. Dupuis, P. Blanchfield, P. Blanchfield, Fisheries & Oceans Canada. Endocrine disruption is widely studied at the individual level but the effects on population and ecosystem dynamics remain unclear. Mechanistic models can help understand the impact of endocrine disruptors on aquatic environments and assess their ecological risk. However, the issue with modeling endocrine disruption is to find the appropriate endpoints that represent the reproductive disturbances observed in fish. This study takes the challenge to develop an ecosystem model that considers endocrine disruption in fish and the consequences on the whole ecosystem through ecotoxicological interactions, i.e. feeding and competition relationships. The experimental data used to develop this model come from a multi-year whole-ecosystem study performed at the Experimental Lake Area (Ontario, Canada). The synthetic hormone 17 $\alpha$ -ethinylestradiol (EE2), one of the most potent endocrine disruptors, was added during three years in an experimental lake at environmentally relevant concentrations. Experimental data were collected before, during and after EE2 addition. Endocrine disruption was observed in the fish species with a collapse of fathead minnow after the second year of EE2 addition. The ecosystem model that is being developed is an object-oriented model based on simplified AQUATOX equations for the species naturally present in the experimental lake (benthic invertebrates, phyto- and zooplankton, fish). The novelty of the study is to add appropriate equations for endocrine

disruption. In AQUATOX, reproductive endpoints exist for fish with different age- or size-classes. With regards to endocrine disruption, males have to be differentiated from females. Therefore, three sex-classes were first added in the model: juveniles, males and females. Intersex fish are not considered because they can still reproduce and the important endpoint for modeling endocrine disruption is the reproductive ability of fish. Instead, a reproductive factor is associated with adults. For example, a non contaminated fish has a 100% reproductive factor while an intersex fish has a lower value, depending on the contamination level. Further model development will allow predicting the percentage of intersex fish, juveniles, males, and females. In addition to modeling the direct effects of EE2 on fish, the ecosystem model considers the lake dynamics (biomass, physico-chemical properties, hydraulics, etc.) and EE2 biomagnification in the aquatic food web.

**561.1 DEBtox based TK/TD model integrated with Matrix models for mechanistic interpretation of the combined effects chemicals and environmental stressors**

N.T. Hamda, Jagiellonian University / Institute of Environmental Sciences, Jagiellonian University / Environmental Sciences; D. Jevtic, R. Laskowski, Jagiellonian University / Institute of Environmental Sciences. Ecological risk assessment is aimed at predicting adverse effects of chemicals on natural populations. The information on the ecotoxicity is derived from laboratory bioassays in which individual-level effects of toxic chemicals on survival, fecundity, and body growth rate are measured. These bioassays are standardized and are conducted under constant and favorable conditions. However, organisms typically are found in environments that are neither constant nor optimal. Thus, the translation of results of standard toxicity tests to field situations is difficult because many factors are involved. It is also economically prohibitive or just impossible to experimentally assess all possible interactions. Thus, we need tools that can help to understand combined effects of environmental and chemical stressors on individuals and further assist us in assessing effects on populations in their natural environments. In this study, we combined DEBtox framework based TK/TD model with population dynamics models for the mechanistic interpretation of the combined effect heavy metals and external ecological stressors (temperature & density dependence) upon *Folsomia candida* population, a standard species for risk assessment of soil invertebrates. The modelling technique outlined here allowed us to interoperate the combined effect of chemicals and key ecological factors at individual-level mechanistically. Further the technique enhances the applicability of age and stage based matrix models to extrapolate these individual-level effects to the population level. Our model results prevail that the 20°C OECD based standard toxicity test underestimates both the individual and population level effects of Cd on *F. candida*. Exclusion of density dependence factor in extrapolating effects from individual-level to population level might overestimate or underestimate effects at population-level.

**562 A Mass Balance for Natural Estrogens on a Swine Farrowing CAFO**

E. Yost, North Carolina State University / Environmental and Molecular Toxicology; M.T. Meyer, United States Geological Survey / Organic Geochemistry Research Laboratory; B. Lee, Duke University / Nicholas School of the Environment; S.W. Kullman, North Carolina State University / Environmental and Molecular Toxicology. The waste from concentrated animal feeding operations (CAFOs) is known to contain appreciable quantities of steroidal estrogens, which are naturally produced by livestock and eliminated in their excreta. Here, we take a mass balance approach to track the fate of these compounds within the waste management system of a swine farrowing CAFO, which houses 5000 pregnant and lactating female swine. Analysis of estrogens was made in relation to: 1) estrogen excretion by individual animals; 2) the stability of estrogens in open pit holding lagoons during waste storage; and 3) mobility and attenuation of estrogens following sprayfield application of swine waste as fertilizer. LC/MS-MS results indicate that the excretion of natural estrogens by the swine increases dramatically during the late stages of pregnancy, highlighting the importance of sow reproductive status in determining the estrogen load of the waste. Estrogen output per volume of waste ranged from  $>1\text{ ng/l}$  to  $27\text{ }\mu\text{g/l}$  in sow urine, and  $>1\text{ ng/kg}$  to  $428\text{ }\mu\text{g/kg}$  in sow feces, with a defined gradient of increased estrogen output associated with advanced stages of pregnancy and lactation. During storage in the lagoon, the natural estrogens contained in the raw swine excreta (e.g.  $17\beta$ -estradiol,  $17\alpha$ -estradiol, estrone, estriol) appear to undergo a biotic and/or abiotic transformation, resulting in the emergence of estrone as the predominant form of natural estrogen in the lagoon. Total estrogen concentrations in the lagoon wastewater average  $9.2\text{ }\mu\text{g/l}$ , with concentrations remaining relatively constant across all sampling seasons. Due to sorption of estrogen to solids in the lagoon, concentrations of estrogen in the lagoon sludge are elevated ( $\sim 20$ -fold higher) compared to concentrations in the lagoon wastewater. Following the land application of lagoon wastewater to sprayfields, the natural estrogens are attenuated relatively quickly (half life = 3.3 days); however, estrone was found to persist in soil at parts-per-trillion concentrations for up to 2 months following the land application. An expected outcome of this project is an increased understanding of the operational practices that affect the fate of estrogens on a swine CAFO, and prioritization of practices that may mitigate the off-site transport of these compounds.

**563 Dissipation of three veterinary antimicrobials in stockpiled feedlot manure**

A.J. Cessna, National Water Research Institute / Environment Canada, Environmental Health National Program / Agriculture and Agri-Food Canada; S. Sura, Agriculture and Agri-Food Canada (AAFC) / Food and Bioproduct Sciences; D. Degenhardt, Alberta Innovates – Technology Futures; F.J. Larney, A. Olson, T.A. McAllister, Agriculture and Agri-Food Canada (AAFC). Large quantities of veterinary antimicrobials are used in animal production as a result of therapeutic uses to treat disease and sub-therapeutic uses to prevent disease and promote growth. Up to 80% or more of administered antimicrobials can be eliminated in the feces or urine either as parent compounds or their metabolites. Consequently, they are introduced into the environment mainly through application of manure as fertilizer to agriculture fields or through leaching or runoff from manure storage locations (stockpiles, windrows, lagoons). There is worldwide concern that environmental contamination by these chemicals may result in widespread bacterial resistance to antimicrobials used in human medicine. Aerated windrow composting has been shown to decrease antimicrobial concentrations in beef cattle (*Bos taurus*) manure; however, it is unclear whether concentrations would dissipate to the same extent if the manure was stockpiled. Consequently, a study was conducted at Agriculture and Agri-Food Canada Research Centre, Lethbridge, AB in fall 2010 to investigate the dissipation of three antimicrobials, commonly used in beef cattle production, in stockpiled manure. Beef cattle (10 steers per pen) were administered one of the following treatments in the research feedlot situated on the Research Centre: (1) 44 mg of chlortetracycline  $\text{kg}^{-1}$  feed (dry-weight), (2) 44 mg of chlortetracycline + 44 mg sulfamethazine  $\text{kg}^{-1}$  feed, (3) 11 mg of tylosin  $\text{kg}^{-1}$  feed and (4) no antimicrobials (control). Manure was collected from the feedlot pens and stockpiled (2 replicates per treatment = 8 stockpiles). Because the stockpiles were not regularly turned, manure samples were collected periodically from three locations (top, center, and bottom) within the stockpiles over a period of 140 d. The samples were extracted using accelerated solvent extraction and the extracts analyzed for chlortetracycline, sulfamethazine and tylosin using LC/MS/MS analysis. The antimicrobial

concentration data will be used to determine the dissipation kinetics of the three antimicrobials when beef cattle manure is stockpiled.

**564 Impact of animal manure separation technologies on steroid hormone distribution – consequences for agricultural practices**

M. Hansen, University of Copenhagen, Faculty of Health and Medical Sciences / Section of Advanced Drug Analysis, Toxicology and Environmental Chemistry Laboratory; O. Popovic, University of Copenhagen; E. Bjorklund, K.A. Krogh, University of Copenhagen, Faculty of Health and Medical Sciences; L.S. Jensen, C.S. Jacobsen, University of Copenhagen; B. Halling Sorensen, University of Copenhagen, Faculty of Health and Medical Sciences. When steroid hormones are emitted into the environment, they may have harmful effects on the reproduction system of aquatic life. Until now, research has primarily focused on human excretion, demonstrating that steroid hormones reach the aquatic environment due to insufficient removal in waste water treatment processes. However more recently, it has been revealed that agricultural practices also may add to the environmental burden of steroid hormones. So far, research activities have mainly focused on steroid estrogens, but also androgens, progestagens and glucocorticoids, expressed in the vertebrate steroidogenesis, may occur at substantial levels in animal manure and should be addressed. In agricultural practices the animal manure can be applied to the soil as raw manure, but also as a solid or liquid manure fraction, since current livestock production facilities utilizes a recently developed technology, which separates raw animal manure into a solid and a liquid fraction. This technology offers an improved handling and refined distribution of the manure nutrients to the farmlands and the possibility to reduce the environmental impact of manure nutrients, especially avoiding the surplus load of phosphorous. In the present work we investigated the distribution of 9 steroid hormones (pregnenolone, progesterone, dehydroepiandrosterone, androstenedione, testosterone, dihydrotestosterone, estrone,  $17\alpha$ -estradiol and  $17\beta$ -estradiol) in raw manure and manure separates from 10 to 15 different pig farms in Denmark utilizing 4 different separation technologies. Furthermore, we investigated a possible relationship between the steroid hormone concentration and the different manure fractions and separation technologies. The chemical steroid hormone analysis was done by inverse and integrated clean-up pressurized liquid extraction, and further cleaned by a two step solid-phase extraction before derivatization and finally analyzed by GC-MS/MS. It was found that the steroid hormones were predominant in the solid manure separate calling for manure management strategies to reduce the content of steroid hormones in separated manure solid fraction. This could potentially be achieved through composting or anaerobic digestion for biogas production of the solid fraction; however, the effects of these technologies on steroid hormones need to be verified.

**565 Occurrence of polybrominated diphenyl ethers (PBDEs) and 2,2',4,4',5,5'-hexabromobiphenyl (BB-153) in landfill leachate in Cape Town, South Africa**

A.P. Daso, Cape Peninsula University of Technology, Cape Town, South Africa / Environmental and Occupational Studies, Cape Peninsula University of Technology / Food and Agricultural Sciences; O.S. Fatoki, Cape Peninsula University of Technology, Cape Town, South Africa / Department of Chemistry; J.P. Odendaal, Cape Peninsula University of Technology, Cape Town, South Africa / Department of Environmental and Occupational Studies. An assessment of the concentrations of selected PBDE congeners as well as BB 153 in leachate samples collected from three landfill sites within the City of Cape Town was conducted. A liquid-liquid extraction technique was employed for the isolation of all the target compounds from the leachate samples. Extracts obtained were further subjected to multilayer column chromatography employing different forms of silica gel. The prepared samples were analysed using a high capillary gas chromatograph equipped with a micro-electron capture detector (GC- $\mu$ ECD). The overall mean concentrations of the total PBDEs, including BDE 209 ranged between 5.65 – 2243.93, 0.28 – 20.51 and 1.66 – 1169.53 ng/L for Bellville, Coastal Park and Vissershok landfill sites, respectively. The mean concentrations of BB 153, which were generally low in most of the samples analysed, were 70.35, 7.14 and 8.16 ng/L for Bellville, Coastal Park and Vissershok sites, respectively. The influence of precipitation on the characteristics and quantity of leachate produced from the landfill sites investigated was most pronounced during the August/September sampling regime. Generally, the trend observed in this study clearly indicated a wide variation in the levels of these contaminants in all the landfill sites studied from one sampling period to the other. However, the principal component analysis revealed that release of these contaminants might be associated with two or

three possible sources. This study further confirmed the relevance of landfill leachate as an important source of PBDE contamination of the environment, especially the groundwater and surface water sources.

**566 Photochemical Degradation of Pharmaceutical Compounds in Wastewater Effluents** F. Rosario-Ortiz, University of Colorado; M. Dong, University of Colorado Boulder. The photochemical fate of pharmaceuticals in wastewater effluents is of interest as these effluents constitute one of the most important sources of these compounds into the environment. The photochemical degradation of five pharmaceuticals was studied in two secondary wastewater effluents (WWA and WW B) collected over two sampling events (February and March of 2012). The samples were exposed to direct sunlight for a total of five days and collected daily for analysis. The pharmaceuticals evaluated were atenolol, carbamazepine, meprobamate, phenytoin and primidone. The overall degradation of these pharmaceuticals was dependent on both direct and photosensitized photolysis. The contribution of each process was determined by the chemical properties of the compounds. For the photolysis tests, the contribution of direct photolysis was evaluated by exposing the samples to sunlight in buffered lab water. Photosensitized degradation was evaluated by quantifying the degradation of the compounds in wastewater. In photosensitized degradation, the concentrations of the hydroxyl radical (HO•) and singlet oxygen (<sup>1</sup>O<sub>2</sub>) were quantified using the hydroxylation of benzene and degradation of furfuryl alcohol, respectively. No significant direct photochemical degradation was observed for all five compounds investigated during time of exposure. After a 5 day exposure, the photosensitized degradation of the compounds ranged from 69 to 91% for atenolol, 67 to 98% for carbamazepine, 16 to 52% for meprobamate, 44 to 85% for phenytoin, and 34 to 88% for primidone in both wastewaters. The large variation in removal could potentially attribute to the difference in their reactivity with oxidants generated in the wastewaters. The average steady state HO• concentrations were 1.2

**567 Removal of Perfluorochemicals and Personal Care Products in Drinking Water Treatment Processes** Y. Tsai, G. Wang, C. Chen, National Taiwan University / Institute of Environmental Health. The issues of using reclaimed water are getting important because of water shortage; however, the information on eliminating emerging contaminants from drinking water treatment is still limited. This study focused on the efficiency of conventional and ultraviolet (UV) treatments to remove eight perfluorochemicals (PFCs) and 27 personal care products (PCPs). Raw water spiked with three levels of the analytes were investigated on processes with laboratory scales: pre-chlorination, coagulation/sedimentation, rapid filtration, post-chlorination, and UV radiation. Water samples were adjusted to pH 3.0 then went through disk-type solid-phase extraction (SPE). The analytes were eluted with 0.1% ammonium hydroxide in methanol and 50% methanol/50% dichloromethane (v/v). The eluents were concentrated by a SpeedVac and were analyzed by ultra-high performance liquid chromatography/tandem mass spectrometry. Chromatographic separation were done at a flow rate of 0.5 mL/min with aqueous mobile phases of 5 mM ammonium acetate and 10 mM *N*-methylmorpholine, respectively, for basic and acidic analytes. Most PFCs were removed at 9-81% by coagulation/sedimentation; the rapid filtration eliminated about 40-90% of the PFCs but the effects of chlorination were very minor. Over 45% of most PFCs were eliminated through the whole procedure; nevertheless, PFCs did not degrade after UV radiation. Over 75% of most PCPs were degraded after the treatments of pre-chlorination or post-chlorination except for DEET and caffeine (lower than 10%), but the coagulation/sedimentation process did not have significant removal on PCPs. The rapid filtration step took out over 80% hormone compounds but only over 20% of analgesics. Most of the PCPs could be removed for over 80% through the whole treatment procedure as well as after the UV radiation.

**568 Survey of Emerging Contaminants in Biosolids Treated under Aerobic and Anaerobic Conditions** K. Dasu, Purdue University / Department of Agronomy, Crop, Soil and Environmental Sciences, NRC Post Doc at US EPA / Office of Research and Development, National Risk Management Research Laboratory, U.S. Environmental Protection Agency / National Risk Management Research Laboratory; M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development. Emerging contaminants (ECs) are detected globally in wastewater treatment plant (WWTP) effluents and biosolids. These

matrices may play an important role in the transport of these contaminants into the environment. There is a growing concern about the potential risks associated with the land-application of biosolids to the aquatic ecosystems and humans, as many of the ECs are shown to have endocrine disrupting properties and other harmful effects. Once land-applied, the emerging contaminants present in biosolids can enter the surface and ground waters or carry over to the plants grown on such soils and this increases the potential exposure of humans and aquatic ecosystems to these compounds. The main objective of the current study is to evaluate the occurrence, concentrations and composition of ECs and their precursors or degradation products in different biosolids treated under aerobic and anaerobic conditions. Classes of chemicals to be monitored include perfluorinated chemicals and their precursors and total fluorine content in the surveyed biosolids, alkylphenol ethoxylates and alkylphenols, steroid hormones and pharmaceuticals and personal care products, along with metals and pathogens. The data will aid in understanding the fate and transport of ECs in wastewater matrices and in the assessment of the risk associated with the land-application of biosolids. The biosolid samples treated under aerobic and anaerobic conditions at the surveyed WWTPs are extracted and analyzed separately for all the selected ECs. A grab sample of effluent from the same WWTPs is also analyzed. From the current occurrence study, the data on the concentrations and composition of different ECs and their precursors or metabolites in biosolids treated under different conditions will be discussed in detail.

**569 The degradation of antidepressant pharmaceuticals in aerobic municipal wastewater sludge** M.M. Schultz, College of Wooster / Department of Chemistry; M. Murphy, K. Sullivan, S. Strand, M. Snider, The College of Wooster. Public and regulatory interest regarding the presence of pharmaceuticals and personal care products (PPCPs) in the environment is increasing. Human pharmaceuticals may enter into the environment through wastewater treatment plants by domestic waste from human excretion or direct disposal of drugs in toilets. Many of these untreated PPCPs may enter aquatic and terrestrial environments and negatively impact metabolic pathways of the ecosystem's organisms. Within wastewater treatment there are many routes by which chemicals are transformed; however, biodegradation due to the metabolic activities of microorganisms during the treatment process is the predominant route of PPCP breakdown. Consequently, it may be possible to decrease the amount of biologically active PPCPs entering the environment by augmenting WWTPs with microbes capable of more efficiently degrading these molecules. However, few microbes with these abilities have yet to be identified; therefore, this is an important area for discovery. To establish a model system for exploring the biodegradation of PPCPs, initial studies investigated the degradation of two PPCPs that are ubiquitous wastewater contaminants: sertraline and venlafaxine, both widely prescribed antidepressant pharmaceuticals. To learn whether microbial communities in the wastewater sludge environment have the ability to degrade sertraline and venlafaxine and, thus, consequently reduce their environmental loads, microcosms containing aerobic sludge were spiked with deuterated sertraline and venlafaxine. Samples collected over 36 days were analyzed for the depletion of the added pharmaceuticals by microscale solvent extraction followed by liquid chromatography tandem mass spectrometry. Municipal aerobic wastewater sludge was found to degrade sertraline and venlafaxine by over 90% over the course of 36 days, whereas no change in the added sertraline and venlafaxine concentrations were observed in abiotic control microcosms. Two venlafaxine metabolites, *o*-desmethylvenlafaxine and *n*-desmethylvenlafaxine, were observed as early as day 2 of the microcosm experiment. Further metabolite identification is underway.

**570 The Curve is the Measure of Toxicity** W.G. Landis, Western Washington University / Institute of Environmental Toxicology, Western Washington University / Institute of Environmental Tox. & Chem.; D.R. Moore, Intrinsik Environmental Sciences, Inc. (US). The foundational principle of environmental toxicology is that the exposure-response curve describes the interaction between a toxicant and the endpoint of interest. A number of papers since the 1940s have demonstrated that curve fitting as the best description exposure response. So it has been established the dominant paradigm is that curve fitting is the best description of the exposure-response relationship. The response can be mortality, reproduction, induction of enzymes, changes in species composition in a microcosm, or alteration in an ecosystem service. The assumption of the exposure-response curve as the fundamental model of toxicity means that experimental data should be

taken that describes the entire curve. There are a number of computational tools that can be used to describe the parameters of the curve ranging from programs in R to Bayesian curve fitting algorithms. If predicted by QSAR, extrapolation from molecular interactions or data from tests from other species, the exposure-response curve is a testable hypothesis. The slowness of the adoption of curve fitting as the primary method of reporting exposure-response appears to be a cultural, not scientific issue.

**571 NOECs are Needed** J.W. Green, DuPont / Applied Statistics Group; T.A. Springer, Wildlife International, Ltd. The conceptual advantages for ECx estimates from regression models fit to concentration-response data from toxicity experiments are clear. Among the advantages cited for the use of ECx estimates in risk assessment is that there is no need for post analysis discussion of the biological significance of statistically significant differences between control mean and treatment mean responses. It is also often suggested that ECx estimates will identify biologically important effects that can be missed by an analysis to determine a NOEC because the effect may not be large enough to result in statistically significant differences. Criticisms of NOECs have been pointed out in numerous papers. It is the goal of this presentation to present evidence that the criticisms of NOECs and the advantages of ECx estimates have both been exaggerated. While ECx estimates are certainly valuable, even preferable, under the right conditions, those conditions do not always exist and it is foolish to call for the removal of an important tool from the statistician who must analyze a wide range of responses from many types of ecotoxicity experiments. Appropriate statistical models and tests will be presented to demonstrate that hypothesis testing has much more to offer than is indicated by the performance of suboptimal techniques often presented as evidence for why NOECs should be discarded or even banned. These will include types of responses for which no regression models have so far been proposed or accepted within the ecotox community. Some recent criticisms of NOECs suggest a need to make the ecotox community more aware of the advances in multiple comparison methods relevant to ecotox studies over the last 15 – 20 years and this talk will attempt to rectify that. Furthermore, limitations on regression estimates will be discussed which make them unsuitable for some datasets where one would expect ECx to be a viable approach. In addition, some realities of GLP experiments to meet regulatory guidelines appear not to be appreciated.

**572 Just Say No to NOELs** D.R. Moore, Intrinsik Environmental Sciences, Inc. (US); W.G. Landis, Western Washington University. Several recent articles and editorials have recently appeared in the literature arguing for the abolition of NOELs and LOELs in ecotoxicology journals. The goal would be to replace these hypotheses testing endpoints with regression-based ECx values. There are a number of reasons why NOELs and LOELs have been criticized, most of which date back over 25+ years: (1) the NOEL and LOEL are always treatment levels and no correspond to consistent effect levels, (2) poor experimental design will mistakenly indicate that a substance is less toxic than it really is, and (3) most of the information from the toxicity test is not used and thus the investigator has no means of determining confidence in the estimated effects metrics or using the results to estimate risks of differing severity. The alternative is to use a regression-based approach to generate concentration-response relationships. A variety of easy-to-use software packages can be used to conduct such analyses. Further, the regression-based approach is highly flexible and can be used for quantal, count or continuous response variables. It can also be used to estimate toxicity thresholds (e.g., using a hockey stick model) or account for hermetic responses. Thus, there is no reason for continuing to use NOELs and LOELs in ecotoxicology. In this talk, we will illustrate the ease and flexibility of the regression-based approach for estimating effects metrics.

**573 Problematic Responses from Ecotoxicity Experiments** T.A. Springer, Wildlife International, Ltd.; J.W. Green, DuPont / Applied Statistics Group,. The advantages of ECx estimates relative to use of the NOEC in expressing results of laboratory ecotoxicity experiments for endpoints such as length, weight, and mortality, where data are collected from studies designed to support regression analysis, are well known. Recognition of these advantages has led some authors to call for a ban on reporting of NOEC values, and use of hypothesis testing in general, for all ecotoxicity studies. However, proponents of this ban fail to consider that there are types of responses that are not amenable to regression analysis to determine an ECx value, that there are some risk assessment questions that are as well or better

answered by providing a NOEC value, and that there are experiments that cannot be practically designed to support regression analysis. This presentation will demonstrate why a much broader consideration of the merits of reporting ECx values instead of NOEC values is needed, and why a ban on use of NOECs and hypothesis testing is not advisable. Four classes of responses that arise in ecotoxicity experiments that present challenges to statistical analysis will be discussed. For these classes of responses, generally accepted methods for calculating ECx values are unavailable, and often, a meaningful ECx cannot be estimated. Indeed, it is not always clear what the meaning of an ECx value would be for the responses in question. On the other hand, statistical methods (typically based on trend analysis) that can identify a meaningful and protective no observed effect concentrations (NOEC) are available. Use of modern methods for the derivation of NOEC values will be compared to use of regression methods for determining ECx values for (1) severity scores that arise in histopathology assessments of fish studies to detect endocrine disruption [e.g. OECD TG 229], (2) analysis of serum vitellogenin (VTG) concentrations measured in the fish short term reproduction assays [OECD TG 229], (3) analysis of first day of egg hatch in fish early life stage tests [OECD TG 210], and (4) sex-ratio in the fish sexual development test [OECD TG 234]. In each case, the rationale for use of NOEC values instead of ECx values in a regulatory/risk assessment context will be explored.

**574 EPA's Test of Significant Toxicity: Impact on the Permit Compliance of Honolulu's Wastewater Treatment Plants** L.C. Vazquez, C&C of Honolulu / Department of Environmental Services. The U.S. Environmental Agency has developed an alternative statistical approach, based on bioequivalence, to address the limitations associated with the use of No Observed Effect Concentration (NOEC) for interpreting whole effluent toxicity (WET) data. The traditional hypothesis testing may deem small effects with no environmental consequence as significant or fail to detect unacceptable toxicity when data precision is low. The test of significant toxicity (TST) corrects these anomalous conclusions by determining whether there is a biologically relevant difference between the effluent at the critical concentration and the control and by integrating both Type I and Type II error rates in the statistics. This new approach is under consideration by the State regulatory agency for inclusion in permits issued to Hawaii dischargers. Such change in the permits could affect the City & County of Honolulu's regulatory compliance. The City operates four wastewater treatment facilities that are required to monitor effluent toxicity with EPA chronic protocols using *Ceriodaphnia dubia* and a local sea urchin, *Tripneustes gratilla*. Data sets from 820 tests meeting acceptability criteria, collected over a five year period of WET monitoring of the City's treated discharges, were analyzed using the NOEC method and the TST approach. The NOEC method, even when subjected to percent minimum significant difference limits-based criterion, declared a remarkably greater number of toxic incidences particularly with the more sensitive urchin fertilization method. On the other hand, the TST approach found toxic effects in *C. dubia* reproduction data from some effluent samples that the NOEC method declared acceptable. Conclusions derived using these two statistical approaches on WET data from wastewater facilities with different levels of treatment will be compared.

**575 Biological arguments for selecting ECx values in chronic aquatic toxicity testing** C. Mebane, US Geological Survey / NOAA Fisheries Liaison, US Geological Survey/WRD / NOAA Fisheries Liaison. A fundamental purpose of chronic toxicity testing is often to predict "safe" levels of a substance in sustained exposures for organisms in aquatic environments. Early-life stage and other chronic toxicity testing customarily have been statistically evaluated through hypothesis testing to estimate no-observed-effects concentrations (NOECs) and lowest-observed-effects concentrations (LOECs). Hypothesis testing has been roundly criticized as being inferior to regression-based approaches for making point estimates of specified levels of effect (ECx). However, the selection of just what levels of effect (x) would be acceptable has sometimes followed circular reasoning using comparisons back to NOECs or LOECs rather than considering what ECx value would likely be sustainable in populations or communities in the wild. Effects studied in early-life stage toxicity testing with aquatic organisms (reduced growth, fecundity and survival) were reviewed in the context of responses of wild fish populations to disturbances associated with changes in mortality or growth rates. The review suggests that different ECx values would be appropriate for different endpoints and for species with different life histories. With some temperate, freshwater fish, differences in size (as length) of as

little as 5% can determine inter- or intra-specific contests which in turn may disproportionately determine survival for contest winners or losers. Growth reductions of the magnitude of 20% could predict extremely high indirect mortalities for juvenile fish. In contrast, under strong density dependence such as that often occurring in temperate stream-resident salmonid populations where juveniles have to compete for limited shelter to survive their first winter, much greater than 20% loss of the young-of-year is routinely absorbed. These observations suggest, for example, that when interpreting lethal and sublethal effects from toxicity test data, an EC20 for fecundity or first-year survival in density-dependent fish populations would conceptually be sustainable, yet for reduced growth (as length of juvenile fish) an EC5 would be a more appropriate endpoint.

**576 Bioaccumulation of gold nanomaterials by *Manduca sexta* through dietary uptake of surface contaminated plant tissue** J.D. Judy, University of Kentucky; J.M. Unrine, University of Kentucky, University of Kentucky / Department of Plant and Soil Sciences, University of Kentucky / Department of Plant & Soil Sciences, University of Kentucky / Savannah River Ecology Laboratory, University of Kentucky / Department of Plant and Soil Sciences, University of Georgia / Savannah River Ecology Laboratory; P.M. Bertsch, University of Kentucky. Mass loading of soil particles by wind, rain, biota, and/or mechanical disturbance onto plant surfaces is a pathway by which contaminants can potentially enter terrestrial food webs. Previously, we demonstrated trophic transfer and biomagnification of manufactured nanomaterials (MNM)s from tobacco plants (*Nicotiana tabacum*) to a terrestrial secondary consumer, tobacco hornworm (*Manduca sexta*). In this study, we investigate the potential for bioaccumulation of MNMs from contaminated plant surfaces by tobacco hornworm caterpillars and compare the results of direct dietary exposure with the results of our previous trophic exposure study. We hypothesize that the caterpillars will not bioaccumulate as large a mass of MNMs through direct exposure as they did through trophic exposure. Caterpillars were fed tomato leaf tissue that had been surface contaminated with 12 nm tannate coated gold (Au) MNMs. Caterpillars received a dose of up to 3 µg of Au MNMs over 7 d. After dosing was complete, bulk Au concentrations in individual caterpillars were measured using inductively coupled plasma mass spectrometry (ICP-MS) after 0, 1, 4, and 7 d of depuration. Growth, mortality, and ingestion rate were monitored over the 14 d exposure. Spatial distribution of Au in caterpillar tissue samples was determined using scanning x-ray fluorescence microscopy (µXRF). No conclusive evidence was found suggesting that ingestion of plant material surface contaminated with Au MNMs affected caterpillar growth, mortality, or ingestion rate compared to controls. We found that caterpillars bioaccumulate Au MNMs, but that the assimilation efficiency of bioaccumulation was low. The caterpillars accumulated a much smaller mass of MNMs in this study than in the trophic transfer study, supporting our *a priori* hypothesis. Caterpillars eliminate ingested Au MNMs rapidly from 0–24 h, but very slowly from 1 d to 7 d. The retention of Au MNMs in the caterpillar tissues after 1 d depuration was confirmed by µXRF. These data indicate that MNMs resuspended from soil onto plant surfaces are bioavailable to terrestrial consumers, a result with important implications for the potential risk of nanotechnology to ecoreceptors in terrestrial ecosystems.

**577 Behavior of fullerene nanoparticles (nC<sub>60</sub>) in the terrestrial environment: studies on the potential release of fullerenes from biosolids** D. Navarro, R. Kookana, CSIRO / Advanced Materials Transformational Capability Platform, Land and Water; M. McLaughlin, CSIRO / Land & Water, University of Adelaide / School of Agriculture, food and wine, CSIRO / Advanced Materials Transformational Capability Platform, Land & Water; J. Kirby, CSIRO / Advanced Materials Transformational Capability Platform, Land & Water. In recent years, there has been increasing interest on the fate of nanoparticles (NPs) in wastewater treatment plants. Indeed, among different stages involved in wastewater treatment, the presence of NPs in sludge materials has often been reported. With sludge being a potential sink for most NPs, the release of NPs from these sludge materials is still unknown. Application of biosolids (treated sludge) as soil amendments/fertilizers, hence, presents another important route for NPs to be remobilized and enter the environment. In this study, the release of fullerenes (C<sub>60</sub>) from biosolids spiked with different forms of fullerene nanoparticles (nC<sub>60</sub>) was examined across a wide range of soils. Results showed that different levels of C<sub>60</sub> could be released from different biosolid-soil systems, suggesting that soil properties influence the mobilization of C<sub>60</sub> in the terrestrial environment. The form of nC<sub>60</sub> used, on the other hand, had negligible effect on

the levels of C<sub>60</sub> detected in released fractions. Aging nC<sub>60</sub> in these systems only slightly increased the release of C<sub>60</sub>. Even after 8 w of aging, majority of the biosolid-soil systems only released approximately 3% of the initial nC<sub>60</sub> spike. The application of biosolids to soil favored the retention of C<sub>60</sub> rather than release. Though the exact release mechanism in these complex systems is still unclear, it is apparent from the data that both pH and natural organic matter played a part in controlling the binding and release behavior of fullerenes in soils.

**578 Examining single walled carbon nanotube distribution in live fish during gavage and feeding studies using near infrared fluorescence detection** J.H. Bisesi, Clemson University / Institute of Environmental Toxicology (CU-ENTOX), University of Florida / Department of Environmental and Global Health; J. Merten, Arkansas State University / Department of Chemistry and Physics; A.N. Parks, Duke University / Nicholas School of the Environment; L. Ferguson, Duke University / Department of Civil and Environmental Engineering, Duke University / Nicholas School of the Environment, Pratt School of Engineering / Department of Civil & Environmental Engineering; T. Sabo-Attwood, University of Florida / Department of Environmental & Global Health. Single-walled carbon nanotubes (SWNTs) are emerging as one of the most commercially important and technologically relevant nanomaterials in research and consumer industries. However, their potential release has raised concerns about their impacts on environmental health and safety. Carbon nanomaterials are challenging to detect in organic matrices; limiting our ability to assess systemic distribution and elimination in model organisms. Excitation of SWNTs with visible light produces a distinctive fluorescence emission in the near infra-red range. The use of near infra-red fluorescence (NIRF) is emerging as a highly sensitive and selective technique for accurate quantification, purification, and tracking of these materials in biological organisms, with robust discrimination against endogenous fluorescence. Using this technology, we have constructed a highly sensitive and selective custom NIRF imaging system for tracking SWNTs in fish. This system utilizes a 30 watt Visotek 808 nm laser for deep tissue excitation coupled with a Princeton Instruments InGaAs spectroscopy array detector. We have optimized this system to be able to detect SWNTs with real-time repeated measurements in live fish. For these studies, fathead minnows (*Pimephales promelas*) were gavaged with 2.5, 5, and 10 µg of SWNTs and imaged at 2, 4, 8 and 24 hours post exposure. Following each time point, replicate fish were euthanized and necropsied for imaging of individual organs as well as quantification of SWNTs using the Applied NanoFluorescence NS1 NanoSpectralyzer. Results of these studies reveal that SWNTs remained primarily in the GI tract and were undetectable after 8 hours. These data suggest that the majority of SWNTs do not get absorbed in the GI tract and are likely depurated. This was confirmed by the complete loss of fluorescent signal when the intestinal tract was removed. We also were able to quantify the SWNTs in homogenized intestines using near-infrared spectrometry. We have begun to assess the distribution of SWNTs in fish maintained on SWNT-containing feed stocks. The use of this NIRF imaging system is a powerful tool for assessing in vivo distribution and potential toxicological target sites for SWNTs in organisms. Data from these studies can lead to a more targeted approach in the understanding of the biological fate, mechanisms of action, and health impacts associated with SWNT exposures, which is invaluable in the assessment of risk for these materials.

**579 Nanoparticle Fate Assessment and Toxicity in the Environment – Initial findings from phase 1 of the NanoFATE project** C. Svendsen, Centre for Ecology & Hydrology, Monks Wood / Pollution and Ecotoxicology, NERC Centre for Ecology & Hydrology / Hails Section, NERC Centre for Ecology & Hydrology / Ecotoxicology; M. Diez, Centre for Ecology and Hydrology; A. Crossley, University of Oxford / Department of Materials; G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology; M. Hasselov, Goteborg University / Chemistry Dept; S. Loureiro, Universidade de Aveiro / department of Biology & CESAM, Universidade de Aveiro / Departamento De Biologia; S. Lofis, NERC Centre for Ecology & Hydrology / Shore Section; K. van Gestel, Vrije Universiteit Amsterdam / Institute of Ecological Science, Vrije Universiteit Amsterdam / Department of Animal Ecology; F. Dondero, University of Piemonte Orientale Amedeo Avogadro / Department of Science and Technological Innovation; A. Johnson, R. Williams, L. Walker, Centre for Ecology and Hydrology; D. Spurgeon, NERC Centre for Ecology and Hydrology. This presentation will outline the main data and findings from the first 2.5 years

of the EU FP7 project NanoFATE. The project is a multi-disciplinary effort to assess the environmental risks posed by engineered nanoparticles (ENPs) and test the applicability of current fate and risk methodologies and identify possible improvements required for application with ENPs. The work is undertaken using commercial ENPs from high-volume products for which recycling is not an option, e.g., fuel additive, personal care and antibacterial products (CeO<sub>2</sub>, ZnO, Ag of varying size, surface and core chemistries). These are being followed through their post-production life cycles i.e. from environmental entry as “spent product”, through waste treatment to their final environmental fates and potential toxic effects. In the initial phase, cross-disciplinary work has been used to determine how ecotox exposures (soil and aquatic) can best be set up and whether it is possible to follow current standard protocols. Material scientist, environmental chemists, ecotoxicologists, fate modellers and risk assessors have worked together to: 1) assess what a realistic exposure of ENPs is likely to be and how best to reflect this in hazard testing, and; 2) how spatial predicted environmental concentrations (PEC) estimates can best be made including demographic and geographical variations across Europe. Specific properties that need principal consideration during the development, adaptation and validation of environmental fate models for nanoparticles have been identified and prioritised. Based on this initial basic fate models have been completed and the initial worst case environmental concentration estimates been supplied serving to inform exposure design. While the main focus of the talk will be detailed fate and effects results from soil experiments looking at the consequences of soil chemistry and long term behaviour of ZnO and Ag ENPs on the uptake and ecotoxicological effects observed, it will also include the current risk assessment results for all 3 ENP types in both water and soil environments including example risk maps. The main problem areas encountered with applying current “standard chemical” fate and risk assessment methodology to ENPs during the project will be highlighted in the conclusions.

**580 Life-stage-dependent response in zebrafish (*Danio rerio*) to phototoxicity of TiO<sub>2</sub> nanoparticles** H. Ma, U.S. Environmental Protection Agency / Mid-Continent Ecology Division, Mid-Continent Ecology Division, USEPA; S.A. Diamond, U.S. EPA / MED, U.S. EPA / Mid-Continent Ecology Division, U.S. EPA / MED. The zebrafish, especially its embryo stage, has been increasingly used as a model to evaluate toxicity of manufactured nanomaterials. However, many studies have indicated that the chorion may protect developing embryos from the toxic effects of nanomaterials, suggesting that post-hatch life-stages may be more susceptible to nanomaterial toxicity and should continue to be tested to fully discern the potential hazard and risk of nanomaterials. The current study aimed to identify the “window of susceptibility” (the life stage that is most sensitive to toxicity) of zebrafish to phototoxicity of TiO<sub>2</sub> nanoparticles. To this end, 96-h toxicity tests were conducted to zebrafish at different life-stage (embryo [ < 2-h post fertilization, “yolk-sac” larvae [ < 48-h post hatch], “free-swimming” larvae [21-d post hatch], and juvenile [50-d post hatch]) by exposing test organisms to TiO<sub>2</sub> nanoparticles under simulated solar radiation (4 h within every 24 h during the 96-h exposure period). Toxicity endpoints included hatching rate, % malformation, and % mortality for embryonic test, and mortality only for all other tests. For zebrafish embryo, TiO<sub>2</sub> concentration at 1-20 mg/l caused no mortality, had no impact on 72-h hatching rate, but induced malformation in fish embryos/larvae by up to 20%. TiO<sub>2</sub> at higher concentration (up to 200 mg/l) caused mortality to fish embryo/larvae with a 96-h LC50 of 34.4 mg/l (95% CI: 24.5, 48.4), but had no impact on hatching rate, suggesting that mortality mainly occurred after hatching. The “yolk-sac” larvae had a 96-h LC50 of 20.3 mg/l (95% CI: 18.9-21.8) and the “free-swimming” larvae had a 96-h LC50 of 134.6 mg/l (95% CI: 103.7, 174.7). For juvenile fish, TiO<sub>2</sub> concentration up to 200 mg/l caused mortality less than 25% after 96-h exposure. The finding that newly hatched zebrafish larvae (i.e., < 48-h post hatch) are more sensitive than fish embryo in response to TiO<sub>2</sub> phototoxicity suggest that zebrafish embryo test may not always be appropriate to evaluate toxicity of nanomaterials and relying on embryo toxicity data alone may substantially underestimate the potential risk of nanomaterials. These results will be discussed relative to risk assessment for TiO<sub>2</sub> nanoparticles.

**581 Transcriptional-level response and sub-cellular modifications of cyanobacteria induced by nano-titanium dioxide exposure** C. Cherchi, Northeastern University / Civil and Environmental Engineering; A. GU, Northeastern University / Department of Civil & Env Engineering, Biotechnology Initiative Program, Department of Civil & Env Engineering

/ Biotechnology Initiative Program. Progress of nanoscience poses an urgent need for fundamental understanding of the potential environmental effects of engineered nanomaterials such as nano-titanium dioxide (nTiO<sub>2</sub>). nTiO<sub>2</sub> have already been detected in wastewater effluents and will likely impact aquatic ecosystems (e.g. algae). The objective of this study was to investigate the impact of sub-lethal concentrations of titanium dioxide nanomaterials (nTiO<sub>2</sub>) on the nitrogen status of *Anabaena* PCC7120 using transcriptional-level information of biomarker genes involved in global response (*ntcA*) and in nitrogen fixation- (*nifH*, *nifK*), nitrogen assimilation- (*glnA*, *all2934*) and nitrogen storage-specific pathways (*cphA*, *cphB*). Additionally, intracellular nitrogen metabolites (aminoacids) were also monitored along with gene expression trends, to reveal subcellular changes and their contributions to the regulation of nitrogen metabolism and dynamics of nitrogen accumulation. Results indicated nTiO<sub>2</sub> dose-dependent patterns in the expression of the majority of the genes studied. During the light cycle, exposure to nTiO<sub>2</sub> at higher concentration (10 mgTiO<sub>2</sub>/L) led to distinctive up-regulation in the gene expression, in comparison to control. Overall down-regulations of these nitrogen metabolism genes were seen at the end of the dark cycle as a result of the low cell metabolism and energy (ATP) levels. The dose-dependent production of metabolites (aminoacids) involved in the GS-GOGAT pathway of nitrogen assimilation and in the intracellular nitrogen storage suggests that other pathways involving aminoacids biosynthesis or degradation might be activated or repressed in response to nTiO<sub>2</sub> exposure. The increase in total proteins was also observed and found to be, for the most, both time- and nTiO<sub>2</sub> concentration-dependent, reaching as high as 50% increase (of the control) in the sample exposed to 10 mgTiO<sub>2</sub>/L. This overproduction of aminoacids and proteins might partially contribute to the synthesis of newly synthesized proteins needed to carry out stress response mechanisms likely induced by nTiO<sub>2</sub> treatment. In conclusion, the subcellular modifications observed and the unbalanced genetic regulatory mechanisms of cyanobacteria under the environmental perturbations generated by nTiO<sub>2</sub> exposure are likely to modify their intracellular C/N ratios, thus impact, at larger scale, ecological trophic interactions and food web dynamics within complex ecological systems.

**582 Impacts of nanomaterial chemistry on the genomic response of the immune system of rainbow trout** R. Klaper, University of Wisconsin-Milwaukee / School of Freshwater Sciences, University of Wisconsin-Milwaukee / Great Lakes Water Institute; D.A. Arndt, University of Wisconsin Milwaukee / Great Lakes Water Institute, University of Wisconsin Milwaukee / School of Freshwater Sciences; J.P. Crago, Great Lakes WATER Institute, University of Wisconsin-Milwaukee, / Student; J. Chen, F. Goetz, University of Wisconsin-Milwaukee. The immune system is the first line of response of a vertebrate to a foreign substance and protects the organism from damage and rids it of unwanted chemicals and materials. This project assessed the innate immune reaction of an aquatic model, the rainbow trout (*Oncorhynchus mykiss*) to manufactured carbon nanomaterials (fullerenes and nanotubes) that were either unfunctionalized or functionalized with various chemical groups. Gene expression of macrophage cells from the head kidney of the trout were evaluated using single biomarkers and a global genomic approach using a microarray specific for the trout immune system. Concentrations that did not induce cellular toxicity were evaluated to determine 1) if nanomaterials in general were equally stimulatory of the immune system 2) how changes in the core of the nanomaterial impacted its effects on immune related gene expression 3) whether changes in the surface chemistry impacted the immune related response and 4) the impact of dose of nanomaterials on genomic response. We examined cell viability as well as gene expression of genes associated with a pro-inflammatory or antiviral response in a well-studied trout macrophage primary cell culture system. There was a significant difference among different carbon nanotube based nanomaterials in their level of pro-inflammatory gene expression behavior and the dose at which they became stimulatory. Functionalization to create water soluble particles caused a variable effect. As we decrease the concentration of nanomaterials we begin to see differences in inflammatory responses in a dose-dependent fashion and in global gene expression studies we found that the type of immune response differed with nanomaterial functionalization where there is little overlap in the genes expressed among treatments. Dose of nanomaterial also caused differences in global gene expression patterns. This would indicate that the dose that ultimately enters the organism will be extremely important to determine potential immune responses. The goal of this research is to create a mechanism with which to test other nanomaterials, provide data to support ecological risk assessments, and ultimately

inform decisions as to which materials will be the safest to industrialize and use with respect to aquatic environments.

**583 Uptake routes of metal nanoparticles in earthworms** M. Diez, Centre for Ecology and Hydrology; C. Svendsen, S. Dave, Center for Ecology and Hydrology; C. Van Gestel, Vrije Universiteit Amsterdam. This study aims at quantifying the contribution of dermal and oral uptake of silver (AgNP) and zinc (ZnONP) nanoparticles in earthworms. With the greater production and incorporation into consumer products, it is expected that increasing amounts of NPs will be released to the environment. These NPs will end up in soil through wastewater and sewage sludge or may directly be deposited on land, thus being of environmental relevance for terrestrial ecosystems. To assess their risk in soil, besides their dissolution and speciation it is important to investigate the mechanisms by which the different metal species (single nanoparticles, aggregates and metal ions) interact with biological membranes and enter the body of the organisms exposed. Earthworms are representative test organisms for ecological risk assessment. They will be exposed to contaminants in soil both through the skin (dermal) and by ingestion (oral). To assess bioavailability of metal nanoparticles in soil to earthworms, it is necessary to know the contribution of each pathway. For that reason, experiments will be performed with the earthworm *Lumbricus rubellus*, applying oral sealing with medical histoacryl glue to block the ingestion of soil particles. Glued and unglued earthworms will be exposed to Lufa 2.2 soil spiked with AgNPs and ZnONPs for 7 days. An exposure of glued and unglued earthworms to soil spiked with AgNO<sub>3</sub> and ZnCl<sub>2</sub> will also be included to address the interaction of silver and zinc ions with earthworm tissues. By measuring total silver and zinc body concentrations at different sampling times in these exposure scenarios it will be possible to assess the contribution of the different routes of exposure.

**584 Helping Contaminants Emerge: P & B Commercial Chemicals, Pharmaceuticals, Starting Materials, Impurities, By-Products and Degradation Products** P.H. Howard, Syracuse Research Corporation / Environmental Sciences Center; D. Muir, Environment Canada / Aquatic Ecosystem Protection Research Division, Environment Canada / Aquatic Contaminants Research Division. The Great Lakes and other North American regions have always been in the forefront in terms of identification of new environmental contaminants, particularly persistent (P) and bioaccumulative (B) organic chemicals. However, the identification has been by detailed analytical chemistry and is focused largely on structural analogs of previously identified compounds with only limited application of "in silico" approaches. Of particular concern are those substances that are P and B as defined by screening criteria for persistent organic pollutants (POPs). Such chemicals can move off shore from urban source regions and accumulate in waters and sediments of the open lakes and rivers where they can result in exposures of top predator fish and fish-eating birds. With improved instrumental capabilities, the past 10 years has seen a large number of new chemicals identified, mainly halogenated organics. However, the chemicals identified represent only a small fraction of the organic chemical substances in commerce. We have identified over 600 P&B chemicals using quantitative structure-activity relationships (QSARs) and expert judgment from a database of 22,000 commercial chemicals used in North America. In addition, we identified 58 High Production Volume (HPV) pharmaceuticals as well as 364 pharmaceuticals of unknown production volume that are potentially P&B and have not been detected in the environment. Presently, we are examining starting materials, impurities, by-products, and degradation products/metabolites of the P&B commercial chemicals that may be P&B chemicals themselves. Most commercial chemicals are synthesized from starting materials and reagents and result in the desired product plus leftover starting materials and by-products. These leftover starting materials or by-products can be environmental contaminants just like the desired commercial products. By reviewing the commercial synthetic pathways, we were able to identify possible leftover starting materials, impurities, and by-products. In addition, once a commercial chemical is used, it may be released to the environment in a variety of ways. Using available software and databases, we were able to predict potential degradation products/metabolites. Examples of impurities, by-products, and degradation products as well as some prediction successes (chemicals predicted to be P and B for which measurements has subsequently shown to be present) will be presented.

**585 Identification of unknown persistent halogenated compounds in environmental samples** E. Reiner, University of Toronto; L. Shen, Brock University; A. Muscalu, K. Jobst, A. Boden, P. Helm, Ontario Ministry of the Environment; C. Marvin, E. Sverko, Environment Canada; I. Brindle, Brock University. There are currently over 100,000 industrial chemicals and chemicals of commerce in use today[1]. Many of them as well as their degradation products can find their way into the environment. Due to limitations in analytical methods and technology, most labs currently monitor only a small fraction of these compounds which include the persistent organic pollutants (POPs) that are targeted under international treaties like the Stockholm agreement [2]. The majority of POPs are halogenated compounds that are persistent, toxic and bioaccumulative. Many of them as well as their degradation products undergo long range transit to remote areas where they were not manufactured or used. Mass spectrometry has been used as an analytical tool for 100 years, but not as a common environmental technique until the last 2 decades. High resolution mass spectrometry (HRMS) is an excellent tool for identifying unknown compounds groups that do not contain congeners or isomers. Unfortunately, environmental samples contain many thousands of compounds therefore requiring chromatographic separation to obtain pure mass spectra. Techniques like multidimensional gas chromatography (GCxGC) can greatly enhance analytical selectivity by resolving isomeric compounds enabling pure mass spectra to be obtained. The procedures involving advanced analytical techniques like GCxGC, HRMS and Ultra HRMS to identify halogenated POPs and their degradation products will be discussed.

**586 A non-targeted GCxGC/TOF-MS method, data analysis tools, and data reporting system for the advancement of environmental monitoring** E. Hoh, San Diego State University / Graduate School of Public Health; N. Dodder, SCCWRP; K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP. Analytical methods for environmental contaminant monitoring are generally targeted. Contaminants that are either unknown or those not usually considered for analysis will not be observed by these targeted methods. Humans and wildlife may therefore be exposed to these unknown or uncommon contaminants without warning. In environmental contaminant monitoring, the ideal analytical method should concurrently determine both the known contaminants from the large number of possibilities, and have the ability to identify unknown contaminants. Comprehensive two-dimensional gas chromatography coupled with time of flight mass spectrometry (GCxGC/TOF-MS) is superior to conventional gas chromatography/mass spectrometry (GC/MS) for certain applications, particularly those which require the chromatographic separation of mixtures of similar compounds and/or the identification of compounds from their full-scan mass spectra. We developed a GCxGC/TOF-MS analytical method to identify and document unrecognized and novel marine contaminants in dolphins, a high trophic level sentinel species. The method characterized a broad array of non-polar, persistent and bioaccumulative contaminants. More than 130 uncommon contaminants, which are potentially bioaccumulative, were identified in addition to the typically monitored persistent organic pollutants. Due to the volume and complexity of the identification data, it was necessary to develop custom data organization/analysis software to document the evidence for the identifications and provide a mechanism for data sharing. We applied the non-targeted analysis to two ecotypes of bottlenose dolphins (coastal vs. offshore) and will describe the contaminant identification process for group of samples. Finally, we will discuss how non-targeted analysis may be incorporated to environmental monitoring networks to advance their effectiveness.

**587 Highly sensitive non-targeted screening for anthropogenic and naturally produced organohalogen contaminants using quadrupole systems** N. Rosenfelder, National Institute of Standards and Technology / Hollings Marine Laboratory; W. Vetter, University of Hohenheim; J. Kucklick, National Institute of Standards and Technology / Hollings Marine Laboratory. A large number of persistent and bioaccumulative organohalogen compounds of anthropogenic and natural origins are widely distributed in marine environments. These compounds pose a global threat to the environment and their thorough determination is an important task in environmental science. Most analyses of organohalogen compounds in environmental samples focus only on specific groups of substances while unknown or non-targeted compounds are overlooked or ignored. Comprehensive gas chromatography coupled to time of flight mass spectrometry (GC x GC TOF-MS) has been suggested as an alternative method. However,

this technique is currently not available to most laboratories. For this reason, we recently developed an alternative approach using a simple quadrupole system which is virtually found in all analytical laboratories (Rosenfelder et al., Anal. Chem 82 (2010) 9835-9842). The lower sensitivity of this method was overcome by switching to the selected ion monitoring (SIM) mode. The resulting GC/electron ionization-quadrupole-MS-SIM method (GC/EI-Q-MS SIM) was based on the fact that the retention times of most organohalogen compounds correlate with their molecular mass on non-polar GC-columns. Since the most important structural information is derived from the molecular ion, we screened only the high mass range ( $> 300$  u) in the SIM mode with  $\Delta u = 1$ . The method provided very high sensitivity and excellent mass spectra. It also featured an identification scheme for unknown organohalogen compounds. The benefits of this method were explored by the thorough analyses a commercial salmon sample which originated from a region with no direct persistent organic pollutant (POP) sources. Over 20 compounds with a molecular weight  $> 300$  u could be detected while only  $\sim 10$  could be detected in the full scan chromatogram of GC coupled to electron capture negative ion mass spectrometry (GC/ECNI-MS). Furthermore, the GC/EI-Q-MS SIM method provided univocal mass spectra down to 5 pg/compound and in most cases the molecular ion could be detected. PCBs, HCHs and other legacy POPs were only in low abundance. Instead, the most abundant compound in the sample was the naturally produced mixed halogenated monoterpene MHC-1. In addition, several unknown polyhalogenated compounds were detected in the early retention time range by GC/EI-Q-MS SIM. The structures and their toxic impact are currently unknown.

**588 Target and non-target screening using HPLC-Orbitrap to evaluate the contamination pattern along the River Rhine** M. Ruff, Eawag – aquatic research / Environmental Chemistry; H. Singer, M. Mueller, M. Loos, E. Schymanski, Eawag – aquatic research; J. Mazacek, AUE Basel; J. Hollender, Eawag – aquatic research. The Rhine is one of the most important rivers in central Europe, with 58 million inhabitants living in the catchment area. The river is used intensively economically and is a major source of drinking water following bank filtration. An international network of monitoring stations along the river permanently observes the river water quality. Besides their long-term monitoring activities, the stations focus on the detection of accidental spills, which requires powerful techniques for comprehensive daily analysis and real-time processing of the datasets. Organic micropollutants are subject to major political and public discussions, and tons of these chemicals daily enter the river via different sources. In the past, monitoring stations were mostly dominated by well-established gas-chromatographic MS techniques focusing on rather non-polar substances. As water is a strong polar solvent, this left a significant gap in water quality analysis. In order to address this deficit and be able to focus more on polar organic micropollutants, the implementation of liquid chromatography coupled to high resolution mass-spectrometry (LTQ-Orbitrap) techniques at the international monitoring station in Basel was supported. The adjustment of analytical methods and development of an automated data analysis tool (enviMass) allowed not only to extend the number of daily monitored chemicals to more than 300 but also to focus on the detection and prioritization of non-targeted chemicals. The data of a study where we followed a 7-day wave of the river Rhine over a distance of 900 km downstream, including the main tributaries, will be presented. A detailed spatial contamination pattern of hundreds of substances and unknown substances was obtained along the river. The load dynamics of targeted contaminations will be illustrated as well as regional sources of specific chemicals. With the non-target analysis, hundreds of unknown substances were prioritized along the river and a few of these could be identified and finally confirmed using standard compounds.

**589 Non-targeted analysis of emerging contaminants in wastewater and wastewater impacted aquatic environments** G.J. Getzinger, Duke University / Nicholas School of the Environment; L. Ferguson, Duke University / Department of Civil and Environmental Engineering, Duke University / Nicholas School of the Environment, Pratt School of Engineering / Department of Civil & Environmental Engineering. The identification of new and emerging contaminants in environmental media has been hindered by the need to utilize targeted mass spectrometric techniques, relying on the availability of analytical standards for each analyte. The emergence of high-resolution mass spectrometry (HRMS) and its application to the field of environmental chemistry has for the first time made possible identification

of emerging contaminants in complex environmental mixtures without *a priori* knowledge of contaminant identity or occurrence. In this study, we present a strategy and analytical workflow based on LTQ-Orbitrap Velos HRMS and MS/MS in conjunction with newly developed software (e.g. Thermo ExactFinder) and informatics tools (e.g. spectral library searching, literature data) for the identification of emerging environmental contaminants in the aquatic environment *without* the aid of user defined molecular databases. In this approach, high resolution ( $R > 100,000$ ) accurate mass (mass error  $< 2$  ppm) chromatograms of wastewater extracts are subjected to recursive peak assignment, adduct grouping, isotope pattern scoring, and molecular formula assignment. Chromatographic features and molecular formulas are culled using empirical indices (e.g., chromatographic peak shape, mass accuracy, isotopic pattern fit) and heuristic rules for the assignment of probable molecular formulas (e.g., Seven Golden Rules). Filtered chromatographic features are subjected to confirmation criteria for tentative identification. To this end, we demonstrate the capabilities of rule based *in silico* fragmentation and hydrogen/deuterium exchange experiments to aid in the structural elucidation of unknown contaminants without the benefit of reference standards. We have utilized this approach to identify novel organic microcontaminants in wastewater and wastewater-impacted surface waters. Results illustrate our ability to identify a broad range of organic contaminants in water, including several compounds that have not been previously reported to occur in environmental systems.

**590 Bridging environmental mixtures and toxic effects** S.E. Allan, / Environmental and Molecular Toxicology, Oregon State University / Graduate Researcher; B. Smith, Oregon State University / Environmental and Molecular Toxicology; R.L. Tanguay, Oregon State University / Environmental & Molecular Toxicology, Oregon State University / Department of Environmental & Molecular Toxicology; K.A. Anderson, Oregon State University / Environmental & Molecular Toxicology, Oregon State University / Dept. of Environmental & Molecular Toxicology. BRIDGES is a bioanalytical tool that combines passive sampling with the embryonic zebrafish developmental toxicity bioassay to provide a quantitative measure of the toxicity of bioavailable complex mixtures. Passive sampling devices (PSDs), which sequester and concentrate bioavailable organic contaminants from the environment, were deployed in the Willamette and Columbia Rivers within and outside of the Portland Harbor Superfund site in Portland Oregon. Six sampling events were conducted in the summer and fall of 2009 and 2010. PSD extracts were analyzed for PAH compounds and screened for 1,200 chemicals of concern using deconvolution reporting software. The developmental toxicity of the extracts was analyzed using the embryonic zebrafish bioassay. Significant spatial and temporal differences in the concentration of contaminants at the sites were observed. Similarly, significant differences in the developmental toxicity of the samples were recorded. This demonstrates the importance of utilizing an environmental monitoring tool, such as BRIDGES, that can provide site-specific, temporally resolved information about environmental contaminants and directly link environmental samples to toxicity. Multivariate modeling approaches were applied to paired chemical-toxic effects data sets to help unravel chemistry-toxicity associations. Although this research highlights the complexity of discerning specific bioactive compounds in complex mixtures, it demonstrates methods for associating toxic effects with chemical characteristics of environmental samples.

**591 Formation of Disinfection By-Products in a Drinking Water Treatment Plant: Bioanalytical and chemical tools provide complementary information** B.I. Escher, Entox, The University of Queensland / National Research Centre for Environmental Toxicology; P. Neale, Entox, The University of Queensland; A. Antony, The University of New South Wales / UNESCO Centre for Membrane Science and Technology; M.E. Bartkow, Seqwater / Queensland Bulk Water Supply Authority (trading as Seqwater); M. Farre, AWMC, The University of Queensland / Advanced Water Management Centre; A. Heitz, I. Kristiana, Curtin Water Quality Research Centre, Curtin University; J.Y. Tang, Entox, The University of Queensland / National Research Centre for Environmental Toxicology. Disinfection of drinking water is the most successful measure to reduce water-borne diseases and protect health. However, disinfection by-products (DBPs) formed from natural organic matter and disinfectants like chlorine and monochloramine may cause bladder cancer and other adverse health effects. Despite epidemiological evidence and identification of more than 600 individual DBPs, not all of the causative agents have been identified. We report on a pilot study that

uses bioanalytical tools to evaluate the water quality and the formation of DBPs through a full-scale water treatment plant serving a metropolitan area, which employs coagulation and sand filtration, followed by chlorination and chloramination. Water quality changes through the treatment process were investigated using *in vitro* bioassays (focusing on nonspecific and reactive toxicity), quantification of adsorbable organic halogens (AOX), characterization of organic matter as well as analytical quantification of selected regulated and emerging DBPs. Non-specific toxicity peaked mid-way in samples after the chlorination and storage steps. The general trend of all the quantified DBPs followed a pattern similar to the one seen for AOX with maximum concentrations observed in the final treated water. The mostly chlorinated and brominated DBPs formed during treatment also caused reactive toxicity to increase throughout treatment. Both genotoxicity with and without metabolic activation showed the same pattern as the non-specific toxicity with a maximum activity mid-way during the treatment train. The *E. coli* biosensors strains indicative of protein damage and glutathione depletion responded strongly to the chlorinated samples, while a bioassay indicative of the oxidative stress response did show some, albeit very small, activity. Despite the fact that bioassays were not optimized yet for volatile DBPs, the bioassays indicated an increase in toxicity associated with the formation of DBPs at the various stages of the treatment chain in this drinking water plant. It must be noted, though that cell-based bioassays are early warning indicators of an onset of effect or of repair and defense mechanisms. Thus their effect cannot be directly translated to an adverse health outcome but rather to the presence of groups of chemicals that exhibit reactive modes of toxic action.

**592 Monitoring Cap Effectiveness Using Bulk Sediment and Passive Porewater Sampling at the Wyckoff/Eagle Harbor East Harbor Superfund Site** D.D. Reible, The University of Texas-Austin, University of Texas / Environmental and Water Resources, The University of Texas at Austin / Dept. of Civil & Environmental Eng.; C.L. Thomas, The University of Texas-Austin / Civil, Architectural and Environmental Engineering, The University of Texas at Austin; X. Lu, The University of Texas-Austin / Civil, Architectural and Environmental Engineering; M. Michalsen, U.S. Army Corps of Engineers / Environmental Engineering & Technology Section; J. Wakeman, US Army Corps of Engineers / Biologist/Risk Assessor; T. Thompson, SEE, LLC. A 3-5 ft cap of clean sediment and borrow material was used to isolate PAHs introduced by a former creosote wood-treatment plant located on the east side of Bainbridge Island, Washington. As part of long-term monitoring, sediment cores and passive samplers were used in 2011 to measure bulk sediment and porewater PAH concentrations. Porewater concentrations were determined using solid phase microextraction (SPME) profilers with polydimethylsiloxane (PDMS) as the receiving phase sorbent. After review of the cores' bulk sediment PAH concentrations, SPME profilers were placed in areas where cap performance was suspect. Results were corrected for non-equilibrium conditions at the time of extraction by using deuterated PAHs to estimate absorption kinetics. Equilibrium correction factors ranged from 0.36 (dibenz[a,h]anthracene) to 0.91 (naphthalene). Corrected porewater and surface water (SW) SPME results were compared to surface water quality standards (SWQS). No near-surface intervals exceeded SWQS. Only one deep interval, at a depth of 33 in., exceeded the SWQS for benzo[a]pyrene. Three SW locations were examined to determine if levels near the cap compared to background levels. Depth averaged SW concentrations for one of two cap SW locations was greater than the background SW level by ~20%. No SWQS exceedances were noted at SW locations. Thus, the cap is currently effective at preventing recontamination of overlying water from deeper contaminated sediment. Observed porewater profiles showed no evidence of contaminant migration except in two anomalous locations. One location showed higher concentrations of LPAHs in the near surface suggesting a recent exposure to source-like material. Another location showed evidence of migration from below into the lower portions of the cap. Where SPME profilers and sediment cores were co-located, the profiler's upper 10 cm were compared to a porewater concentration converted from the core's bulk sediment concentration by equilibrium partitioning (EqP). Approximately 65% of the EqP predictions exceeded SPME measures by an order of magnitude, and about 5% exceeded by two orders of magnitude. This is commonly observed and likely attributable to the apparent reduced availability of the contaminants in the bulk solids due to stronger sorption to hard or black carbon phases. The results suggest that the direct measurement of porewater provides a better indication of contaminant migration and availability than bulk solid measures.

**593 Monitoring exposure of brown bullheads and macroinvertebrates to contaminated sediments in the Ashtabula River before, during and after dredging** J.M. Lazorchak, U.S. EPA, US Environmental Protection Agency / Office of Research and Development, U.S. EPA Office of Research and Development / National Exposure Research Laboratory, U.S. EPA / Molecular Indicators Research Branch, U.S. EPA / Molecular Ecology Research Branch; J. Meier, P. Wernsing, U.S. Environmental Protection Agency / NERL, Ecological Exposure Research Division; M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development; P. Baumann, Retired USGS. The Ashtabula River in Northeastern, Ohio has been designated by the International Joint Commission as a Great Lakes Area of Concern ([www.epa.gov/glnpo/aoc](http://www.epa.gov/glnpo/aoc)), based on the listing of six beneficial use impairments (out of 14 possible) in the lower two miles of the river. In 2007, approximately 550,000 cubic yards of contaminated sediments were removed through remedial dredging. The primary objective of this field investigation was to monitor contaminant exposure in selected biota before, during, and following dredging. This was done by measuring PCB and PAH accumulation in whole fish tissue (brown bullheads) and in benthic macroinvertebrates, assessing changes in DNA damage in liver and blood of the fish, and scoring external and histopathological lesions (including tumors) in the fish. Sediment and water samples were also collected in conjunction with the biological sampling to evaluate contaminant residuals. Levels of DNA damage in indigenous brown bullheads were measured using the Comet assay and compared to levels in fish collected at a reference site, Conneaut Creek. Benthic macroinvertebrates were collected using Hester-Dendy artificial substrates by deployment at three locations in the dredge area as well as at an upstream reference site. The pre- and during-dredging characterizations have been completed and four years of post-dredging data have been collected. Results thus far confirm a reduction in fish tissue and macroinvertebrate levels of PCB and PAHs following dredging, indicating the effectiveness of the remediation in reducing exposure of biota to the primary contaminants of concern. Similarly, although initially higher in fish collected pre- and during dredging, DNA damage levels in the Ashtabula fish post-dredging are similar to those seen in fish collected from the Conneaut reference site. When completed, the methods used in this study can be used by regulatory agencies, remedial project managers, and dredging practitioners to evaluate and assess the effectiveness of environmentally-prudent remediation techniques for contaminated sediment sites around the country. Although this work was reviewed by USEPA and approved for publication, it may not necessarily reflect Agency policy.

**594 Monitoring of Contaminated Sediments Before and After Dam Removal on 12 Mile River; Pickens County, SC** C. Zeller, US EPA – Region 4 / Environmental Engineer. In 1994, the Region 4 Office of the United States Environmental Protection Agency (EPA) issued a Monitored Natural Recovery (MNR) Record of Decision (ROD) for the Sangamo Weston/12 Mile River/Lake Hartwell Superfund Site located in Upstate South Carolina. Annual monitoring conducted since the ROD was issued indicates a steady decline of PCB concentrations in surface sediments of the 12 Mile Arm of Lake Hartwell that is attributed to physical processes such as burial, mixing, and dispersion. PCB concentrations in surface sediments have been below the 1 mg/kg cleanup level for the past several years. PCB levels in *corbicula* tissue have shown a 90% decline since source control efforts were largely completed in the mid-1990s, although additional studies have shown the need for further source control work. However, declines of PCB concentrations in fish tissue have not kept pace with those observed in surface sediments and *corbicula*. A Federal Consent Decree was issued in 2006 to settle Natural Resource Damage claims. A major component of the Trustee agreement involved the removal of two, turn of the century textile mill dams from 12 Mile River. This work was completed in 2011 and generally included hydraulic dredging/mechanical excavation of approximately 450,000 cubic yards (CYs) of sediment entrained behind the dams, sediment processing, water treatment, material disposal in a 10 acre Sediment Management Unit (SMU), and stream restoration. Concerns regarding PCB concentrations in residual sediments that remained in the 12 Mile River channel post dam removal has required EPA to initiate a Supplemental Remedial Investigation 18 years after the ROD was issued. This presentation will discuss the 12 Mile River dam removal project and how the monitoring program for the Sangamo Weston/12 Mile River/Lake Hartwell Superfund Site has been modified pre- and post-dam removal.

**595 Monitoring Sediment Cap Performance with Profiling SPME** D.D. Reible, The University of Texas-Austin, University of Texas / Environmental and Water Resources, The University of Texas at Austin / Dept. of Civil & Environmental Eng.; C.L. Thomas, The University of Texas-Austin / Civil, Architectural and Environmental Engineering, The University of Texas at Austin; X. Lu, The University of Texas-Austin / Civil, Architectural and Environmental Engineering; D. Lampert, Argonne National Laboratory. Sediment caps reduce the risk posed by the fate and transport of contaminants by stabilizing the underlying sediments, physically isolating the water column from sediment contaminants, and reducing contaminant flux to the benthic organisms and water column. Evaluating the performance of a placed cap is challenging, however, due to the long time frames associated with migration of hydrophobic contaminants through a cap. In addition, the non-sorbing nature of most sediment caps limits the usefulness of bulk solid phase measurements of contamination. Here, the freely dissolved contaminant concentrations can be measured using solid phase microextraction (SPME) profilers with polydimethylsiloxane (PDMS) as the receiving phase sorbent. The use of SPME profilers results in lower detection limits (ng/L) and in the ability to construct vertical concentration profiles that assist in the determination of the mechanisms and rates of transport within a sediment cap. This approach has been used at the University of Texas at a variety of contaminated sediments sites including the McCormick and Baxter Portland Harbor Site (Portland, OR), Pacific Sound Resources (Seattle, WA), Tennessee Products (Chattanooga, TN), Wyckoff/Eagle Harbor (Seattle, WA), San Jacinto River Waste Pits (Baytown, TX), and Roxana Marsh (Roxana Marsh, IN). Contaminants of concern at these locations include the 16 polycyclic aromatic hydrocarbons (PAHs) on the EPA's Priority Pollutant List, dioxins, and furans. This presentation will summarize the implementation of the approach and results at these contaminated sediment sites to illustrate the utility and usefulness of the approach. Approaches to evaluate kinetics of uptake onto the sorbent fibers by extrapolation from a few performance reference compounds will be presented. Results illustrating the nature and extent of contaminant mobility, intermixing during cap placement and recontamination at these sites will be summarized.

**596 Remediation and Monitoring of PCBs in the Upper Hudson River: Observations and Successes of the Second Year of Operations** E.A. Garvey, Louis Berger Group, The Louis Berger Group, Inc. / Site Assessment and Remediation; S. Gbondo-Tugbawa, J. Atmadja, The Louis Berger Group, Inc.; G. Klawinski, D. King, B. Conetta, US EPA Region 2. The 2002 Record of Decision for the Hudson River PCBs Site called for environmental dredging of approximately 2.65 million cubic yards of PCB-contaminated sediment in two phases. As part of the implementation of the remedy, performance standards for resuspension, residuals, and productivity were developed to promote accountability and ensure that the cleanup meets the human health and environmental protection objectives. Phase 1 of the remediation was conducted by General Electric from May 15 to December 13, 2009, including the removal of 280,000 cy of sediment and an extensive monitoring program. Based on the observations and lessons of Phase 1, as well as the input of a peer review panel, USEPA revised the performance standards and the monitoring requirements for Phase 2, which GE signed on to in December of 2010. GE began Phase 2 of the remediation in May of 2011. As a result of the revisions to the performance standards, GE made a number of modifications to sequencing and operation of the dredges. At the same time at the direction of the USEPA, GE also conducted extensive monitoring of water column PCB levels to document the transport of PCBs away from the various dredging operations. By the close of the dredging season in November 2011, GE had succeeded in removing more than 360,000 cy of sediment and 27,000 kg of PCBs. At the same time, GE also succeeded in remaining below the performance standard for PCB resuspension for the entire season, based on both water column concentrations and dredging-related PCB loads. This presentation will highlight the important successes of the Phase 2 operation as well as the important modifications to the dredging operations that led to the successful second year of dredging. Among the more important improvements believed responsible for the success was the requirement to target the depth of removal slightly below (about 6 inches) the estimated depth of contamination. Additionally, the operations were conducted so as to minimize the time from the start of a dredging area to its closure so as to minimize the resuspension of disturbed sediments. To facilitate these improvements, the performance standard for residual sediment contamination was streamlined so as to permit a rapid assessment of each dredging pass. The end result of the various improvements

was to yield dredging losses at the compliance monitoring locations that were less than 1% of the mass removed, more than a 50% improvement over the Phase 1 operation.

**597 Selenium Management at Cane Ridge Unit of the Patoka River National Wildlife Refuge and Management Area 2007 – 2011** D.W. Sparks, U.S. Fish & Wildlife Service. Cane Ridge management unit was created in 2004 to provide an alternate nesting site for the federally endangered interior least tern (*Sterna antillarum*) that been nesting on Duke Energy's Gibson Generating Station (GGS) located adjacent to the Wabash River, Gibson Co., Indiana. GGS consists of 5 coal-fired steam generating units (650 megawatts each) and a 3,000 ac man-made industrial surface impoundment used for providing cooling water to the generating units. Least terns first began nesting on GGS cooling pond center dike in 1986 and on the ash ponds, dredge flats, landfill and facility roads in the past decade. Duke Energy entered into a Habitat Conservation Plan to protect and manage interior least terns at the GGS. Cane Ridge is located immediately southwest of the cooling pond and water for Cane Ridge was supplied via gravity flow directly from GGS cooling pond from 2005 to May 28, 2008. Cane Ridge consists of the Tern Unit (TU) (59 ac), 4 moist soil units (25 – 68 ac), and bottomland forest. The TU includes two nesting islands that least terns have used since 2005. Duke Energy did not reopen Gibson Lake (cooling pond) for fishing on April 1, 2007 due to the presence of elevated levels of selenium (Se) in fish. Later in 2007, Duke Energy began investigating the extent of the Se problem in water and biota samples from all over the GGS and Cane Ridge. Se concentrations in water entering the tern unit from GGS cooling pond ranged from 11 to 14 ppb. TU fish had 14 – 40 ppm Se. Invertebrates in the TU (8 – 50 ppm Se) and moist soil unit C (1.9 – 11 ppm Se) posed an unacceptable risk to birds. The decisive action taken in May of 2008 to prevent further Se contamination of Cane Ridge was the proper decision. Several management actions were taken to reduce risk and exposures. In a little more than 2 years, almost every indicator shows that Se concentrations have significantly declined and are nearing or below concern levels. We appreciate Duke Energy's partnership in this process, and especially for their willingness to provide (at significant cost) a clean source of Wabash River water. It is disconcerting to realize that in just a few years (2005 – 2008), a Se problem could form in the shallow water wetlands created at Cane Ridge. What is worse, and even harder to admit, is that we should have predicted this.

**598 Source identification and tracking using multiple lines of evidence** M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development; D. Walters, USGS / Fort Collins Science Center, USGS / Ecologist; K. Fritz, USEPA; A.P. Mucha, U.S. Environmental Protection Agency / Great Lakes National Program Office; S. Cieniawski, U.S. Environmental Protection Agency / Great Lakes National Program Office; C. Zeller, US EPA – Region 4 / Environmental Engineer; J.M. Lazorchak, U.S. EPA, US Environmental Protection Agency / Office of Research and Development, U.S. EPA Office of Research and Development / National Exposure Research Laboratory, U.S. EPA / Molecular Indicators Research Branch, U.S. EPA / Molecular Ecology Research Branch. A primary tenet in the remediation of contaminated sediments is to assure adequate source control to avoid recontamination of the project area once remediation is complete. However, often the full extent of all sources is unknown or poorly characterized. Methods and approaches to identify and track sources are needed to locate contaminant sources and develop a database of the "signature or fingerprint" of sources contributing to a project area. Source identification and tracking has two primary purposes: 1) identify the sources of contamination and 2) to track and apportion the contribution of multiple sources if possible. Commonly, a historic legacy of contamination in a river, port, or harbor is from multiple sources (historic discharges, landfill plumes, combined sewer overflows, industrial effluents, etc). Apportioning the contribution from multiple sources in these systems can be important in identify responsible parties and liabilities. During the site investigation/site characterization stages of a project, a PM identifies sources to establish source control. Subsequent to source control efforts, demonstrating source control may be required throughout the remediation phase and subsequently during long term recovery and monitoring. Case studies will be presented to demonstrate multiple methods and approaches to conducting source identification and tracking. Sites will include Great Lake Areas-of-Concern

and a Superfund site. The methods and approaches will provide a weight of evidence using biological, chemical, and physical lines of evidence. These methods include such techniques as passive samplers, biological monitoring (bivalves and other invertebrates), sediment traps, bioavailable fraction assessments, etc.

**599 Tree swallows: A tool to assess remedy effectiveness** T.W. Custer, U.S. Geological Survey / Upper Midwest Environmental Sciences Center, U.S. Geological Survey; C.M. Custer, U.S. Geological Survey / Upper Midwest Environmental Sciences Center, U.S. Geological Survey / Upper Midwest Environ. Sciences Center; P.M. Dummer, U.S. Geological Survey. Even though a large investment of resources is often required to clean up contaminated sediment, assessment of how effective these activities are in lowering contaminant residues in resident fish and wildlife is often lacking. One approach to evaluate the effectiveness of sediment removal is to compare contaminant concentrations in bird tissues before, during, and after clean up. Tree swallows are an ideal species for this evaluation. They feed on emergent aquatic insects and concentrations in their eggs and nestlings reflect local sediment contamination. They nest in boxes and can be enticed to nest in a wide variety of aquatic habitats including industrial locations. They also integrate contamination over an appropriate temporal and spatial scale for this type of assessment. Contaminant concentrations in eggs and nestlings and accumulation rates (mass of a contaminant accumulated per day) in swallow nestlings can be compared before and after remediation. For example, mean polychlorinated biphenyl concentrations in tree swallow eggs from lower Green Bay, WI were statistically lower in 2010 (1.7 ppm wet weight) than in 1995 (3.9 ppm wet weight). As part of the Great Lakes Restoration Initiative, contaminant concentrations in tree swallow eggs and nestlings have been collected since 2010 at several sites in the Great Lakes that have or will undergo contaminated sediment removal. We will present an overview of the status of those investigations.

**600 A Computational Model Linking Oocyte Growth and Spawning to the Hypothalamic-Pituitary-Gonadal Axis in Fathead Minnow (*Pimephales promelas*)** K. Watanabe-Sailor, Oregon Health & Science University, Oregon Health & Science University / Environmental and Biomolecular Systems; M. Mayo, US Army ERDC; E.J. Perkins, US Army Engineering Research & Development / Environmental Laboratory, US Army ERDC / Environmental Processes & Effect Division, US Army Engineering Research & Development / Environmental Genomics and Genetics Team; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory. Reproduction is vital to the survival of all living organisms, and reproductive toxicity is an important outcome in determining the ecological risks of chemicals in the environment. To evaluate reproductive toxicity, fathead minnow fecundity, as measured by the average number of eggs spawned, is used as an endpoint. In order to predict the effect of impaired reproduction upon a population, population dynamic models use fecundity as an input. However, when experimental data are not available, there are only a few computational models that will predict fecundity, and they rely primarily upon plasma vitellogenin, a precursor to an egg yolk protein, as an input. These models employ a statistical correlation between plasma vitellogenin concentrations in females and cumulative egg production, or they simulate oocyte growth and spawning based upon the absorption of vitellogenin into oocytes and known statistical distributions for clutch sizes and spawning intervals. However, a detailed physiological understanding of oocyte growth and development exists and could be leveraged to create a more mechanistic computational simulation model for predicting fecundity. Such a model could potentially make use of an increasing amount and diversity of in vitro data that may emanate from a growing emphasis on predictive approaches to toxicity testing in order to extrapolate these data to predicted effects at the individual or population-level. Thus, there is a need to improve existing models of oocyte growth and spawning to better represent biological processes that may be affected by chemicals in the environment, and to utilize a wider variety of data. Toward this end, this presentation will describe the development of a Matlab®-based oocyte growth dynamics model linked to an HPG axis model for fathead minnow (*Pimephales promelas*). It extends a previously developed model for oocyte growth dynamics and links to a model of

the hypothalamic-pituitary-gonadal axis through plasma vitellogenin and selected steroid hormones.

**601 How to Improve Prediction of Contaminant Bioaccumulation by Taking into Account Lag Time: an Example of Selenium in a Flowing System** W. Beckon, U.S. Fish and Wildlife Services / Division of Environmental Contaminants. For bioaccumulative contaminants, such as selenium, efforts to predict concentrations in organisms at upper trophic levels, based on measurements of environmental exposure, are confounded by several factors. Principal among these factors is the appreciable amount of time it may take for bioaccumulation to occur through various pathways and across several trophic transfers. Yet studies of bioaccumulation have hitherto generally ignored this factor, using temporally matched samples of water and tissue, effectively making the unrealistic assumption that bioaccumulation is instantaneous. The study summarized here offers a remedy for this deficiency, demonstrating a simple, objective method of estimating the time required for bioaccumulation, and taking this lag into account to improve predictive modeling of bioaccumulation. Without the need for special tracers or isotope measurements, this method uses a history of conventional measurements of environmental exposure and tissue concentrations of a contaminant to systematically test a large array of potential lag characteristics (both central tendency and spread of lag), selecting the lag that provides the best regression. The method is demonstrated here using an unusually long-term data set of selenium measurements in water and aquatic organisms in sloughs in the San Joaquin Valley in California. Preliminary results of this application of the method indicate that, as expected, more time is required for selenium to bioaccumulate in organisms at higher trophic levels than in those at lower trophic levels. For example, the lag time for the piscivorous largemouth bass (*Micropterus salmoides*) may be more than one year, but only about one month for the filter-feeding threadfin shad (*Dorosoma petenense*). Also as expected, omnivorous organisms display a broader spread in lag time than more specialized feeders. Therefore, the method presented here not only provides a tool for improved prediction of contaminant effects and for more precise targeting of contaminant regulation, it also offers a novel means to estimate both the average trophic level of an organism and its trophic spread (degree of omnivory), when these characteristics are otherwise poorly known. More generally, this method may improve the precision of predictive modeling in a wide variety of cause-effect relationships in which lag time is substantial but inadequately known, in disciplines as diverse as climatology and economics.

**602 Investigation of microfluidic cultures for the assessment of endocrine disruption in fathead minnows** T. Kissane, University of Illinois; D. Crokek, R. Wilson, US Army Corps of Engineers ERDC-CERL. *In vitro* studies on endocrine disrupting compounds (EDCs) commonly focus on individual cell or tissue types. While providing useful information, these systems do not include the impact of other endocrine tissues upon the investigated tissue. Numerous components of the endocrine system were cultured within a microfluidic device, allowing hormone communication among all components. A device was designed to culture the brain (hypothalamus), pituitary, testes, and liver (HPG-L) of fathead minnow (*Pimephales promelas*). By altering flow of media and arrangement of the tissue cultures, the device allows manipulation of tissue hormone communication. Individual tissues can be removed to determine their influence upon endocrine disruption of individual chemicals, while changes in position or flow allow manipulation of when each tissue is exposed to the media and when that tissue alters the media relative to the other tissues in the system. Techniques were designed such that device assembly does not damage tissue viability. Tissues remain viable for 3 days or longer permitting long-term exposure of tissue. Media can be analyzed for key hormones including 11-ketotestosterone and vitellogenin, which are important indicator hormones for endocrine disruption. Future studies can include removal of tissue and determination of changes in protein expression. This device can serve not only as a method of assessing presence of EDCs from a source, but can aid in gaining a better understanding of the HPG-L axis feedback mechanisms.

**603 Population genome scans reveal structural variation that alters gene expression, individual fitness and population-level response to metals** J.R. Shaw, Dartmouth College / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; E. Turner, R.N. Keith, Z. Smith, S.P. Glaholt, S. Paland, Indiana University / The School of Public and Environmental Affairs and The Center for Genomics

and Bioinformatics; J.K. Colbourne, Indiana University / The Center for Genomics and Bioinformatics. *Daphnia*, or the water flea, is a sentinel species of freshwater ecosystems. Their populations are defined by the boundaries of ponds and lakes, are sensitive to modern toxicants in the environment, and thus are used to assess the ecological impact of environmental change. Their short generation time, large brood sizes, and ease of laboratory and field manipulation have assured *Daphnia's* importance for setting regulatory standards by environmental protection agencies, testing chemical safety, monitoring water quality, and as a model for environmental genomics research. A hallmark of the genome sequence is a large number of duplicated genes that are most responsive to ecological challenges and are specific to the *Daphnia* lineage. In this study, we take advantage of maturing genomics tools to understand the molecular basis for evolved tolerance to toxic levels of certain metals. We also test the adaptive significance of *Daphnia's* genome structure. Natural populations that have faced severe chemical challenges for over a century of industrial iron/ore smelting demonstrate evolved tolerance to cadmium. Other reference populations that have no history of chemical stress are clearly harmed by metal exposure, showing slower growth rates, lower fecundity and higher mortality. By measuring the distribution of copy number variants (CNV) and interrogating differential expression of 31,000 annotated genes from sampled populations across chemical conditions, this study provides new insights into the functional interactions between genome structure and environment. We identify a large number of CNV (13.5%), including the metal detoxication protein metallothionein that strongly correlate and are predictive of phenotypic differences between populations. Dynamic networks constructed from these CNV reveal functional relationships between genes that are consistent with mechanism of action. These studies begin to quantitatively link genomic variation with individual fitness and population-level outcomes, and both benefit from and contribute to the *Daphnia* Genomics Consortium.

**604 Quantifying the impact of pesticides on interspecific competition: An application of Bayesian hierarchical modeling to ecotoxicology** R. Erickson, Texas Tech University / Dept. of Environmental Toxicology, Texas Tech University / Department of Environmental Toxicology, Texas Tech University / graduate student; J.L. Oates, T.A. Anderson, Texas Tech University / Dept. of Environmental Toxicology; K.R. Long, Texas Tech University / Dept. Of Mathematics; S.B. Cox, Research and Testing, LLC.. Ecotoxicology has been moving towards the use of population models to study toxicants. These models add realism by allowing for the inclusion of multiple ecological factors and the exploration of different exposure scenarios. Traditionally, these studies have been done with single species and do not explicitly consider interspecific interactions. We examined how different pesticides altered the population dynamics of two different species of *Daphnia*. We tested three hypotheses: 1) Pesticides would change interspecific competition, 2) Pesticides would change resource use and intraspecific competition, 3) Pesticides would change mortality and fecundity. We tested these hypotheses using a laboratory study with two species of *Daphnia*: *D. magna* and *D. pulex*. Populations of each species were raised in monocultures and bicultures. The system was independently exposed to a high and low dose of two different pesticides: malathion and pendimethalin. Doses were chosen based upon a dose response pilot study and were the LC10 and 10% of the LC50 for the more sensitive species, *D. pulex*. The populations were sampled throughout the experiment and these observations were to parameterize a stage-structured matrix population model. A Bayesian hierarchical approach was used for model parameterization. Both doses had minimal effect to the monocultures. Under control settings, *D. pulex* outcompeted *D. magna* in the bicultures. Pendimethalin exposure altered the interspecific competition ability of the species. These led to a change in outcome from the competition study. Malathion altered mortality and fecundity of the two species. However, this did not alter the outcome of the competition study. Our findings demonstrate that ecological effects such as interspecific competition may need to be considered in population models in ecotoxicology.

**605 Reverse engineering the molecular machinery underlying the response of fathead minnow (*Pimephales promelas*) to the endocrine disruptor ketoconazole** E.J. Perkins, US Army Engineering Research & Development / Environmental Laboratory, US Army ERDC / Environmental Processes & Effect Division, US Army Engineering Research & Development / Environmental Genomics and Genetics Team; X. Wang, T. Habib, T. Habib, Badger Technical Service; N. Garcia-Reyero, Mississippi State University / Institute for Genomics Biocomputing and Biotechnology;

D.R. Johnson, U.S. Army Engineer Research and Development Center / Environmental Laboratory, U.S. Army / CEERD-EP-R, US Army Engineer Research and Development Center / Environmental Laboratory, US Army Engineer Research & Development Center / Environmental Laboratory. The low levels of multiple chemicals present in the environment and a poor understanding of compensation mechanisms in fish complicate estimation of the risks posed by endocrine disrupting chemicals. We have applied a systems biology approach to understand effects of endocrine disrupting chemicals in the Hypothalamic-Pituitary-Gonadal axis in the fathead minnow (*Pimephales promelas*). Using network inference techniques we have identified potential pathways and transcriptional regulators underlying compensation responses to endocrine disrupting chemicals. We exposed fathead minnow ovaries in vitro to the fungicide ketoconazole for ten time points over 150 min. Dynamic Bayesian Network analysis of microarray data from these exposures to identified transcription factors and cofactors interacting with key genes involved in steroidogenesis. The transcription factor SF-1 and cofactor MIER-1 were identified as possibly regulating the low-density lipoprotein receptor gene, LDLR. We validated this interaction by co-transfection of a catfish ovary cell line with a zebrafish LDLR promoter-green fluorescent protein fusion with constructs over expressing zebrafish SF-1 or zebrafish MEIR-1 genes. Over expression of either gene resulted in suppression of green fluorescent protein expression indicating that both SF-1 and MEIR-1 can regulate LDLR supporting involvement of these genes in fish responses to endocrine disruptors. This work demonstrates that reverse engineering approaches can be used to identify new regulatory mechanisms underlying chemical responses in ecologically important species.

**606 The Use of Multiple “Omic” Platforms to Evaluate the Effects of Endocrine Disrupting Compounds in Small Fish Species** K.J. Ralston-Hooper, Visiting Dupont Research Scientist at Duke University / Nicholas School of the Environment, DuPont / Haskell Global Centers; G.J. Getzinger, Duke University / Nicholas School of the Environment; M.E. Turner, E.J. Soderblom, M.A. Moseley, Duke University School of Medicine / Proteomics Core Facility; B.L. Escalon, US Army Engineer Research and Development Center; N. Garcia-Reyero, Mississippi State University / Institute for Genomics Biocomputing and Biotechnology; C. LaLone, U.S. EPA; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; R. Hoke, DuPont, Haskell Global Centers, E.I. DuPont de Nemours and Co., Haskell Global Centers for Health and Environment; L. Ferguson, Duke University / Department of Civil and Environmental Engineering, Duke University / Nicholas School of the Environment, Pratt School of Engineering / Department of Civil & Environmental Engineering. Linking molecular changes at multiple levels of biological organization using “omic” methods provides highly complementary, “data-dense” information for predicting outcomes for organisms exposed to environmental contaminants. However, performing separate “omic” analyses on multiple organisms or tissues increases the variability in responses and the uncertainty of the linkages between these levels of organization. Ideally, performing transcriptomic, proteomic, and metabolomic analyses on the same sample of individual tissues of interest from an organism would reduce this uncertainty and biological variation. On-going research in our laboratory has demonstrated the ability to apply multiple “omic” technologies to analyze individual tissues of small fish species. In the present study, transcriptomic and proteomic analyses were performed on hepatic tissues from individual adult female fathead minnows (FHM; *Pimephales promelas*) exposed to the aromatase inhibitor fadrozole. Organisms were exposed to 0, 0.04, and 1.0 µg/L fadrozole for 4 days and tissue extracts were analyzed using an LC-MS/MS based, label-free proteomics approach that identified over 1000 proteins. Many of the differentially expressed proteins in fadrozole-exposed female livers were consistent with published results for fadrozole. Interpretation of the broader proteomic response will be discussed in the context of transcriptomic data collected using mRNA isolated from the same samples used in proteomic analyses. Our data demonstrates the ability to extract high quality RNA and protein samples from small quantities (10 mg) of single tissues for comprehensive ‘omic’ analyses. Overall, our ability to perform multiple “omic” analyses on individual tissues of small fish species provides greatly improved information for connecting various levels of biological organization and elucidating pathways of toxicity. This information provides a more comprehensive

representation of the “systems effects” resulting from chemical exposures and will ideally serve as a basis for advancements in predictive ecotoxicology.

#### 607 Towards a Systems Framework for Defining & Using Adverse Outcome Pathways

S. Edwards, U.S. Environmental Protection Agency, US EPA / Integrated Systems Toxicology Division; R.B. Conolly, U.S. EPA / Integrated Systems Toxicology Division; M. Breen, US EPA; N. Garcia-Reyero, E. Perkins, T. Habib, M. Mayo, US ACE; D. Villeneuve, G. Ankley, US EPA; K. Watanabe, Oregon Health & Science University. High throughput screening (HTS) approaches are increasingly used to estimate chemical toxicity, and so there is a critical need for a robust framework that links the perturbation of these toxicity pathways to population level changes for application in risk assessment. To address this need, the concept of an adverse outcome pathway (AOP) was proposed where the molecular initiating events assayed by HTS are linked to population changes via a series of intermediate events. An open question, however, is how to determine whether specific key events have been missed when defining an AOP. In addition, there is increasing pressure to consider the cumulative effects of chemicals on wildlife populations rather than those of individual chemicals. While the AOP concept can be used for chemicals with an overlapping mechanism, cross-talk among different AOPs is certain to occur and must be considered to fully account for cumulative effects when relying solely on HTS data. Finally, species differences in AOPs will be important given that a limited number of laboratory species/strains will be used to define and characterize each individual AOP. A systems model based on a data-derived transcriptional network from 1,472 ovary samples will be used to show how all of these issues can be addressed through judicious use of discovery experiments leveraging various Omics technologies in combination with targeted experiments to quantitatively define the relationships among key events. First, the data-derived network will be used to evaluate a previously defined conceptual model on the hypothalamus-pituitary-gonad (HPG) axis in *Pimephales promelas*. Second, AOPs will be defined in a network context by leveraging both the literature-based conceptual model and the data-driven network model to evaluate the potential for cross-talk. Third, the network will be used to prioritize key events from the AOPs for inclusion in a computational model of the HPG axis used for predicting the effects of environmental chemicals on fecundity in *Pimephales promelas*. [This is an abstract or a proposed presentation and does not necessarily reflect EPA policy.]

#### 608 Association of carcinogenic PAH Emissions with Lung Cancer Mortality Rates on a Global Scale

O. Motorykin, Oregon State University / Department of Chemistry; M. Matzke, Pacific Northwest National Laboratory / Computational Biology and Bioinformatics; S. Simonich, Oregon State University / Depts. of Chemistry and Environmental & Molecular Toxicology; K. Waters, Pacific Northwest National Laboratory / Computational Biology and Bioinformatics. Four out of five lung cancer cases have been linked to tobacco smoking. Other factors, including diabetes, obesity, and personal income, have been associated with lung cancer rates. Air pollution, containing carcinogenic polycyclic aromatic hydrocarbons (PAHs), may also contribute to lung cancer occurrence and mortality. However, a clearer understanding of the contribution of air pollution (and carcinogenic PAH exposure) to lung cancer occurrence and mortality is need for better risk characterization, especially on a global scale. The estimated number of lung cancer deaths per 100,000 people in 2004 and age standardized lung cancer death rate per 100,000 people in 2004 were regressed on smoking prevalence, cigarette price, GDP per capita, number of people with diabetes, average body mass index (BMI) and carcinogenic PAH emissions (in benzo[a]pyrene equivalence) using multiple linear regression and data from 136 different countries. The contribution of carcinogenic PAH emissions to lung cancer mortality rates was assessed for countries with different socioeconomic groupings. A statistically significant positive correlation ( $p < 0.05$ ) between the estimated number of lung cancer deaths per 100,000 people and benzo[a]pyrene equivalent emissions was found for the high income level group (countries with GDP per capita  $> \$10,065$  USD) and not for low ( $< \$825$  USD per capita), low middle ( $\$826$  to  $\$3,255$  USD per capita), and upper middle ( $\$3,256$  to  $\$10,065$  USD per capita) income level groups. For every 10% increase in the mean BaPeq emissions, a 0.80% increase in the median number of lung cancer deaths per 100,000 people was observed for the high income level group. Similarly, a 10% increase in smoking prevalence resulted in a 4.5% increase in the median number of lung cancer deaths per 100,000 people for the high income level group ( $p < 0.05$ ). There was a statistically significant positive correlation ( $p < 0.05$ ) between smoking

prevalence and lung cancer mortality rates when all income level groups were combined. There was a statistically significant negative correlation ( $p < 0.05$ ) between cigarette price and the age standardized lung cancer death rate per 100,000 people when all income level groups were combined. This study is the first to link PAH emissions with lung cancer on a global scale. Future assessment of lung cancer risks should take into account air pollution.

#### 610 Engagement of Native American Tribes in the characterization of novel PAH dietary exposure pathways, assessment of possible human health risks

N.D. Forsberg, Oregon State University / Environmental and Molecular Toxicology; D. Stone, A. Harding, Oregon State University; B. Harper, S. Harris, Confederated Tribes of the Umatilla Indian Reservation; M.M. Matzke, Pacific Northwest National Laboratory; A. Cardenas, Oregon State University; K.M. Waters, Pacific Northwest National Laboratory; K.A. Anderson, Oregon State University / Environmental & Molecular Toxicology, Oregon State University / Dept. of Environmental & Molecular Toxicology. Although it is known that legacy toxicants, such as polycyclic aromatic hydrocarbons (PAHs), can be introduced into meats via smoke curing, little is known about their prevalence in smoked salmon prepared using traditional Native American smoking techniques. This work sought to characterize the effect of traditional Native American fish smoking methods on dietary exposure to 33 legacy and emerging substituted PAHs and identify possible risks to human health. Salmon smoking events were carried out by Tribal researchers at the Confederated Tribes of the Umatilla Indian Reservation in collaboration with Oregon State University researchers. Fresh caught Chinook salmon were smoked using two commonly used smoking structures (tipi or shed) and two types of traditionally used woods (apple or alder). For the purposes of exposure pathway and risk assessment, all salmon samples were prepared as if to be eaten. Additionally, 20 non-smoked spring-run Chinook salmon were analyzed for background PAH content along with three commercially available smoked salmon. Salmon samples were subsequently analyzed for PAHs. Potential carcinogenic and non-carcinogenic risks to human health were evaluated using Relative Potency Factor and Hazard Index approaches. Across all smoking methods, individual PAH loads ranged between  $< 2 - 3800$   $\mu\text{g/kg}$ , where non-carcinogenic, carcinogenic, emerging, and legacy PAHs generally accounted for 95%, 5%, 20% and 80% of the total PAH load respectively. It was found that neither smoking structure nor wood type accounted for differences in smoked salmon PAH content. However, carcinogenic and non-carcinogenic PAH loads in traditionally smoked salmon were 40 – 430 times higher than PAH loads measured in fresh caught non-smoked salmon and commercial smoked salmon. Exposure to the levels of carcinogenic PAHs measured in traditionally prepared smoked salmon could result in excess life-time cancer risks between  $1\text{E-}5$  and  $1\text{E-}4$  at a daily consumption rate of 5 g/d and could approach  $1\text{E-}2$  at 300 g/d. Exposure to non-carcinogenic PAHs could result in hazard indexes of 0.005 at 5 g/d and approach 0.3 at 300 g/d. Levels of PAHs present in smoked salmon prepared using traditional Native American methods potentially pose elevated cancer risks if consumed at high consumption rates over many years. Study results were shared with the Tribes and are currently being evaluated in order to design a culturally specific Tribal message.

#### 611 Background Polycyclic Aromatic Hydrocarbon Concentrations in Soil

C. Liu, CDM Smith; T. Marcum, CDM Smith / Environmental Scientist; N. Luke, CDM, CDM Smith Inc.. Polycyclic aromatic hydrocarbons (PAHs) are formed through incomplete combustions of most organic material. PAHs are associated with many industrial and municipal activities as well as natural and anthropogenic sources – most notably, combustion of fossil fuels, including automobile and industrial emissions, structural fires, and various industrial activities form PAHs, as do natural occurrences, such as wild fires and volcanic activities. As a result of these many sources, PAHs are found in virtually all surface soils in both urban and rural areas. PAHs are commonly identified as risk drivers in environmental contamination cases because of their high cancer potencies and toxicity. The majority of the risk posed by PAHs is due to the seven carcinogenic PAHs (cPAHs) including benzo[a]pyrene. Risk-based cleanup levels for a residential scenario for cPAHs corresponding to a lifetime incremental cancer risk of one in a million to 10 in a million range from 0.015 to 0.15 mg/kg benzo[a]pyrene equivalents, less than typical background soil concentrations. The U.S. Environmental Protection Agency is proposing to expand cPAHs from seven to 24 compounds, which will result in even more restrictive cPAH cleanup levels. Given their ubiquitous presence in the environment, it is important to

compare risk-based cleanup levels with typical background levels. However, the availability of such data is limited. This paper compiles PAH background levels in soil using state established background concentrations and information from a variety of published studies. The data for PAHs could define the range of PAH concentrations typical of background, provide the scientific data needed for identifying PAH source, and provide the basis for amending the risk-based soil cleanup levels to account for background PAH occurrence.

**612 Critical Evaluation of USEPA's Toxicological Assessment of Benzo(a)pyrene** B.H. Magee, K. Connor, D. Chin, ARCADIS. USEPA's (EPA) draft Integrated Risk Information System (IRIS) Assessment of Benzo(a)pyrene (BaP) is due to be released for public review in June, 2012. The document will present a new Oral Slope Factor that will replace the current value. In addition, EPA will present four new values that are not currently on EPA's IRIS database: an Inhalation Unit Risk, a dermal Cancer Slope Factor, an oral Reference Dose, and an inhalation Reference Concentration. In advance of the document's release, the authors have performed a literature search to identify the available studies that could potentially meet EPA's study quality criteria as critical studies in the IRIS program. In addition, the authors have performed dose-response modeling using EPA's benchmark dose model to identify *point of departure* doses and composite uncertainty factors to derive the five toxicological reference values in accordance with standard EPA policy and guidance. The authors have also evaluated alternative approaches to characterize the uncertainties in deriving the above toxicological reference values. In so doing, the authors have identified the toxicological reference values likely to be presented in EPA's draft document. This research will be used to prepare detailed comments to the EPA docket on EPA's toxicological assessment of BaP. If the document is released as scheduled, the presentation will compare the authors' proposed toxicological reference values to the EPA's proposed values and critically evaluate the scientific merit of the EPA's toxicological assessment of BaP. Specifically, the presentation will summarize the comments prepared for and submitted to the EPA docket. Additionally, the presentation will discuss the implications for the regulated community of the proposed toxicological reference values coupled with the Relative Potency Factors (RPFs) that are due to be issued by EPA in final form in 2012. Updated whole mixture validation exercises of carcinogenic endpoints will also be presented.

**613 Can the wealth of toxicity data for PAHs be a 'goldmine' for drug discovery and/or safer chemicals?** N. Gathergood, Dublin City University / School of Chemical Sciences; T. Hayes, Dublin City University / School of Chemical Sciences; M. Pour, Charles University / Department of Inorganic and Organic Chemistry, Faculty of Pharmacy; T. Garcia, IQAC-CSIC / Department of Surfactant Technology. Our design philosophy is to refine existing models on toxicity and biodegradation of PAHs to aid in the design of safer compounds and to establish a structure toxicity relationship of oxygenated PAH organocatalysts (BINOLs), or ligands for organometallic catalysts. At the same time to combine environmental toxicology screening with medicinal chemistry screening (possible output is a new hit compound). This approach has been shown successful in discovering hit MRSA selective Ionic Liquid during a study to probe toxicity of aminoacid containing ILs. We argue that the search for a better performance catalyst involves modification of ligand/catalyst scaffold. Analogous to medicinal chemistry SAR study. We believe that improved catalyst design can be coupled to the search for (the design of) safer materials and compounds. Toxicity and biodegradation data for oxygenated PAH organocatalysts will assist in the design of sustainable, efficient catalysts for synthesis and the pharmaceutical industry. This approach is possible (and indeed complements) due to the availability of toxicity data of a wide range of PAH compounds. We have successfully identified a highly toxic (antimicrobial and cytotoxic) PAH catalyst, which fails a 'CO<sub>2</sub> HeadSpace' biodegradation test. If this compound persists in the environment this is a significant cause for concern. In addition, based on our results, guidelines on how to reduce toxicity of PAHs (BINOLs) will be presented as well as biodegradation data. Finally, our 'hit' selective antimicrobial drug PAH analogue will be disclosed, which was discovered due to the novel approach outlined above.

**614 Importance of Non-aqueous Hydrocarbon Phases while Evaluating the Toxicity of Polycyclic Aromatic Hydrocarbons in Contaminated Sediments** T.W. Valenti, Syngenta Crop Protection LLC / National Research Council, National Research Council / U.S. Environmental

Protection Agency; L. Heinis, U.S. EPA / MED-Duluth; T.L. Highland, U.S. EPA / ORD, NHEERL, Mid-Continent Ecology Division; J.R. Hockett, U.S. EPA / Mid-Continent Ecology Division; S. Ireland, U.S. EPA / Great Lakes National Program Office; C. Jenson, U.S. EPA; T.J. Norberg-King, U.S. EPA / ORD, NHEERL, Mid-Continent Ecology Division, U.S. EPA / Mid-Continent Ecology Division; D.R. Mount, US Environmental Protection Agency / ORD. Polycyclic aromatic hydrocarbons (PAH) are widely recognized as potential chemical stressors in aquatic environments and often occur as complex mixtures generally affiliated with oils, tars, or other non-aqueous phases. Recent laboratory experiments suggest that non-aqueous hydrocarbon phases like these can contribute to toxicity beyond that attributable to their PAH content alone, which may explain misalignments between predicted toxicity based on PAH concentrations and that measured in sediment toxicity tests. Using mineral oil as a surrogate for non-aqueous phases, we consistently observed toxic effects for *Hyalella azteca* and *Chironomus dilutus*, but little sensitivity of *Lumbriculus variegatus*. In addition, mineral oil toxicity was not affected by addition of activated carbon, thus suggesting that toxicity might be caused by physical contact. Subsequent experiments using reference sediments spiked with mineral oil and a mixture of PAHs showed that toxicity beyond that attributable to mineral oil alone occurred only when very high concentrations of PAHs were present. Ultimately, these findings strongly suggested that while all organisms were susceptible to PAH exposure, *H. azteca* and *C. dilutus* were far more sensitive to non-aqueous phases often associated with environmental PAHs. To compliment these efforts, we exposed 1<sup>st</sup> and 3<sup>rd</sup> instar *C. dilutus* for different durations of time in the laboratory to 1) reference sediments spiked with either mineral oil or a combination of mineral oil and PAH mixture, 2) sediments from PAH-contaminated sites. We conducted experiments with both life stages because previous studies have demonstrated that earlier instars can be markedly more sensitive to contaminant exposure. Oil and grease content of all samples were quantified gravimetrically via solvent extraction and contrasted toxicity measured in unmanipulated sediments or those treated with coconut charcoal to bind PAHs. Overall the study results demonstrate that the toxicity of PAH-contaminated sediments may be underestimated if toxicity associated with non-aqueous phases in field sediments is not considered. This abstract does not necessarily reflect EPA policy.

**615 Ecological Risk Assessment for Decision-making in Restoration of the Bolsa Chica Lowlands, California** H. Ohlendorf, CH2M Hill. An extensive environmental sampling program and ecological risk assessment were important contributors to decision-making for restoration of the Bolsa Chica Lowlands in Orange County, CA. The site is being restored from an operating oil field to more favorable wildlife habitat that includes a range of coastal tidal and non-tidal wetlands as mitigation for development of port facilities in nearby Los Angeles County. The site is large (about 485 hectares [1,200 acres]) and complex. Before restoration there were more than 430 active or abandoned oil wells, along with associated pipelines, former tank farms, waste sumps, roads, and other related facilities on the property. Storm drainage enters from nearby urbanized areas. A Bolsa Chica Technical Committee (which included several federal and state agencies) was formed to evaluate the risks and develop an approach to clean-up and restoration. The environmental sampling effort included characterization of known or suspected sources of contamination and also a stratified random approach to determine if contamination occurred away from those sources (e.g., from waste disposal in unidentified areas). Over 230 chemicals of potential concern were initially identified for the site. Our ecological risk assessment identified 70 chemicals that presented potential risks to plants or animals that are expected to use the site after restoration. Using a weight-of-evidence approach, the Technical Committee developed clean-up criteria that focused on 14 of the risk-driver chemicals. Inclusion/exclusion of chemicals for cleanup was based on correlation with other analytes, detection frequency, co-location of exceedances of criteria, availability of toxicity values, and best professional judgment. Clean-up levels were identified for material to be managed on-site and material to be hauled off-site. In 2004, the U.S. Fish and Wildlife Service initiated the first construction phase of the Bolsa Chica Restoration Project, which was completed in 2006. Major components included removal and clean-up of oil extraction facilities from part of the wetlands area; restoration of full tidal influence through a new ocean inlet, bridge construction, and excavation of a tidal basin; creation and enhancement of aquatic habitats and intertidal wetlands; creation of feeding and nesting areas for threatened and endangered birds; and preservation of non-tidal wetlands.

**616 Post-registration wildlife incident monitoring schemes can be used to evaluate management decisions for pesticides** P. Berny, J. Vein, D. Vey, Vetagro-sup, campus vétérinaire / Toxicology; A. Decors, ONCFS / SAGIR Network. The EU has re-evaluated all the existing pesticides and, as a result, only 300-400 active substances are now available instead of over 900 in the late 90s'. Among the reasons for banning pesticides, ecological effects, including non-target poisoning have been considered. The SAGIR network has been established in 1986 in order to monitor wildlife diseases in France. All toxicological analyses are conducted at the same laboratory. Cases were retrieved from the SAGIR database. Several pesticides were selected for investigation: strychnine, some cholinesterase inhibitors (aldicarb, carbofuran, furathion, mevinphos), and anticoagulant rodenticides. Information regarding species, circumstances of exposure were taken into consideration. Time-series analyses from 1995 until 2010 clearly indicate that banning may be effective if the products are actively eliminated and not available from other sources or countries. Strychnine, for instance, is still detected, although it was partially restricted in 1984 and completely banned in 2000. A surprising result of our analyses is the detection of shifts in pesticide poisoning cases with obvious "re-emerging" toxicants in the recent years, such as lindane and alpha-chloralose. These results will be compared with toxicological accidents observed in domestic animals with the same products. Trends are very similar, and even more pronounced in domestic species. A review of the circumstances of exposure clearly points out that pesticide poisoning is commonly associated with deliberate abuse and that the persisting chemicals, as well as the "re-emerging" ones are all mostly detected in illicit use against wildlife. Most species of concern are protected and/or endangered species. A special focus is made on anticoagulant rodenticides, which are widely used in field control of rodents in France. The appropriate use of these compounds can be monitored thanks to post-registration monitoring and this monitoring clearly pointed out the efficiency of management decisions.

**617 Selenium Exposure and Reproductive Health of Select Avian Species Associated with a Large Iron Mine in Marquette County, Michigan, USA** L. Kaulfersch, Michigan State University Wildlife Toxicology Laboratory, Michigan State University; M. Zwiernik, M. Nadeau, W. Folland, C. Grohman, C. Martz, Michigan State University Wildlife Toxicology Laboratory / Department of Animal Science. Selenium (Se) is a biologically essential mineral that has the potential to illicit teratogenicity in oviparous species when beneficial exposures are exceeded due to the maternal transfer of selenium to eggs. Se tends to bioaccumulate in lentic systems, resulting in increased exposures to organisms occupying upper trophic levels. Birds with a diet consisting of fish and aquatic invertebrates have an elevated potential for exposure due to their consumption of prey items that can sequester excess selenium. Birds that occupy ecosystems near Ishpeming, MI may be exposed to elevated levels of Se due to mine associated surface water discharges. Concentrations of selenium in some of these discharges have exceeded EPA criteria in the past. However, there is significant uncertainty as to whether these concentrations are great enough to result in adverse effects. Measurement endpoints associated with individual health and reproduction were quantified in avian species including: hooded mergansers, wood ducks, tree swallows, eastern bluebirds, black-capped chickadees, house wrens, Canada geese, mallards, eastern kingbirds, and savannah sparrows. Artificial nest boxes were placed both at mine influenced and non-mine influenced watersheds. Fresh eggs were randomly sampled from each active clutch and added eggs were salvaged. Embryos were examined for gross deformities and total Se concentrations were quantified. Elevated selenium levels that exceeded the 16 mg/kg dw TRV for teratogenicity were found in wood duck and hooded merganser eggs at four study areas. Hatching success differed for hooded mergansers between reference (81%) and study (91%) areas. Fledging success for eastern bluebirds varied from reference (100%) and study (86%) areas.

**618 Science tailored to the Natural Resource Damage Assessment and Restoration Program** N. Beyer, U.S. Geological Survey / Patuxent Wildlife Research Center; S. Finger, USGS/BRD/CERC, Geological Survey NRDAR Coordinator / Columbia Environmental Research Center. The U.S. Department of the Interior's Natural Resource Damage Assessment and Restoration Program is authorized under provisions of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), Clean Water Act (CWA), and the Oil Pollution Act (OPA) to restore natural resources that are injured, destroyed or lost as a result of releases of hazardous substances

or discharges of oil. The Program has restored thousands of acres of habitat across the United States and over 1500 miles of shoreline. Natural resources include water, air, soil and biological resources that are held in trust by federal, state or tribal entities. Whether NRDAR cases are resolved through cooperative settlements or by litigation, they rely on the application of principles of environmental toxicology; both the determination of injury and the quantification of the loss of natural resource services and associated damages are based on sound toxicological, ecological, and economic sciences. Determining injury is not solely a scientific endeavor, but must be done within the context of legal regulations and definitions. In practice, sometimes the questions that seem most straightforward are the most difficult for a scientist to answer. Although research conducted under the Restoration Program may increase our general scientific understanding of ecotoxicology, its primary purpose is to provide the data necessary to resolve the case. The research biologist contributes just part of the story, which intertwines with contributions from attorneys, economists, managers and scientists in other fields. This presentation will provide examples of how injuries to both migratory birds and to a forest were related to metal concentrations in soil or sediment, and how those concentrations, in turn, were used to quantify injury and plan restoration.

**619 Improving risk predictions through the integration of space and habitat suitability: an application of the spatially-explicit exposure model (SEEM)** M.S. Johnson, US Army, Public Health Command / Health Effects Research Program, US Army Institute of Public Health / Health Effects Research Program, Army Institute of Public Health / Health Effects Research Program, US Army Ctr for Health Promotion & Preventive Med. / Health Effects Research Program; M. Quinn, US Army Institute for Public Health; T. Wickwire, Exponent Inc.. Interactions of biological entities within the environment occur on spatial and temporal scales. Likewise, the spatial and temporal distributions of contamination within the environment affect the degree to which plants, animals, and humans are exposed and how they respond. These interactions can be complex, however, through the recent advances in geographical information systems (GIS) and other models that integrate spatial considerations, estimates of risk can be more accurately described. Moreover, presentation of contaminated sites on spatial scales allow for a clearer understanding of the problem. The present study describes how a simple three-part delineation of soil lead (Pb) concentrations and three part habitat delineation can provide more accurate risk predictions. Risk predictions were verified through a comparison with blood Pb data from songbirds and small mammals collected from two test sites and compared with a blood Pb toxicity reference value. Both spatial risk predictions and those derived using simple deterministic approaches were compared and evaluated. Positive and negative aspects of each will be described.

**620 Demystifying Toxic Reference Values for Bald Eagles in Assessment of Damages** W. Bowerman, University of Maryland / Department of Environmental Science & Technology; D. Best, U.S. Fish and Wildlife Service / Environmental Contaminants Program. Bald eagles (*Haliaeetus leucocephalus*) are tertiary predators in many polluted aquatic ecosystems in the United States. The effects of many environmental pollutants on reproductive and developmental health of eagles are used in the NRDA process to determine damages. The literature, however, is confusing when determining Toxic Reference Values, since endpoints are inconsistently applied. Reproductive health TRVs for individual compounds have been published that utilize 1.0, 0.7, and near 0 young per occupied nest as reproductive endpoints of effects. These endpoints are based on differing effect levels tied to Federal Endangered Species Act recovery goals, theoretical population stability levels, and total reproductive failure, respectively. TRVs are available for both unhatched eggs and blood plasma levels for individual environmental pollutants. To further confuse the issue, most TRVs are based on field data for reproduction correlated to environmental contaminants in field collected tissues. However, TRVs have been determined from effects observed during periods where eagle populations were declining or stable, but also during the recovery of these populations where near exponential population growth was occurring. No correction factors have been calculated to account for these differences in population dynamics, which can greatly impact the validity of TRVs. In addition, for some compounds, TRVs are based on laboratory concentrations in other avian species used to model bald eagles, which make poor laboratory animal models. This study will demystify the endpoints related to these TRVs and the related problems used to determine damages to this Federal Trustee Species.

**621 Homing pigeons as useful biomonitors for atmospheric environmental decisions** R. Halbrook, Southern Illinois University / Zoology, Cooperative Wildlife Research Laboratory, TG&G Wildlife Consulting/ Southern Illinois University, Emeritus / Cooperative Wildlife Research Laboratory; W. Liu, Laboratory for Earth Surface Processes / College of Urban and Environmental Sciences, Peking University; S. Tao, Peking University / Laboratory for Earth Surface Processes; J. Cizdziel, University of Mississippi / Department of Chemistry and Biochemistry. Atmospheric pollution is a global concern affecting animal and human health. Air monitoring can provide information regarding concentrations of hazardous chemicals in the air; however, biomonitoring provides data not available from air monitoring alone, and can provide governmental and regulatory agencies with useful information for making environmental decisions. Know age, location, and health history information facilitate the use of homing pigeons to evaluate air pollution among various urban areas and regions. Homing pigeons collected from Beijing, China and Manila, Philippines had similar gross lesions, including gray/black discolorations of the lungs and several cases of enlarged and irregular testes (tumors) compared to pigeons collected from Chengdu, China, and Midland, Texas and Los Angeles, California, USA. Concentrations of polycyclic aromatic hydrocarbons (PAHs) in lung and liver tissue from Beijing pigeons were greater than concentrations in Chengdu pigeons, and mercury (Hg) concentrations in lung and liver tissues were greater in pigeons from Beijing compared to those from Chengdu and the USA. Analyses of PAHs and Hg in tissues of pigeons from Manila, and PAHs in pigeons from the USA are ongoing. Our preliminary results suggest that homing pigeons are valuable biomonitors of atmospheric pollution providing regulators with specific location contaminant data useful in environmental management decisions. Available data suggest that atmospheric pollution in Beijing and Manila is adversely affecting the health of avian species in those urban areas, which suggest that local human populations may also be adversely affected.

**622 Effects of Embryonic Exposure to PCBs on heart development in avian laboratory species** T. Carro, University of Maryland / Animal Science; T. Diaz, R. Sclarsky, University of Maryland; K. Dean, University of Lethbridge / Neuroscience, University of Maryland / post-doctoral research fellow; L. Carpenter, University of Maryland; M. Ottinger, University of Maryland / Department of Animal and Avian Sciences. Although the manufacture of polychlorinated biphenyls (PCBs) in the United States ceased in the late 1970s, these compounds remain ubiquitous in the environment and are linked with adverse health effects, such as endocrine disruption, decreased reproductive fitness, reduced immune responsiveness, and inhibition of neurological function. There is some evidence that PCBs adversely impact the cardiovascular system and our previous studies showed embryonic exposure to a coplanar PCB congener in wild birds affected the development of the ventricular wall compact layer, a critical morphological region of the heart, at concentrations that did not impact hatch success. To study the effects of environmentally relevant PCB mixtures on heart development, Japanese quail (*Coturnix japonica*) and broiler chicken (*Gallus domesticus*) embryos were treated with graded doses of PCB mixtures. Both mixtures affected hatching success at higher concentrations. Chicken hatchlings dosed with a 58-congener PCB mixture produced a variety of cardiomyopathies including ventricular hypertrophy, ventricular hypoplasia, abnormal septation, and the most common cardiomyopathy identified: noncompaction of the ventricular wall. Analysis of the Japanese quail hatchling hearts is currently ongoing. The effects noted in these hatchling studies suggest that environmentally relevant PCB mixtures do adversely affect hatch success and cardiac morphology of hatchlings following exposure *in ovo*. The cardiomyopathies identified in PCB-treated chicken hatchlings are consistent with congenital cardiovascular malformations identified in humans, which increase the risk of cardiovascular dysfunction, myocardial infarction, and ultimately contribute to overall heart failure. The conclusions and opinions presented here are those of the authors, they do not represent the official position of any of the funding agencies, the Hudson River Trustees, or the United States.

**623 Effects of copper contamination on aquatic ecosystem health** S. Gardham, Macquarie University / Department of Environment and Geography; G. Hose, Macquarie University / Department of Biological Sciences; A. Chariton, CSIRO / Land and Water. Copper has deleterious effects on the biodiversity and functioning of aquatic ecosystems at elevated concentrations. Guidelines for metals like copper are often derived from whole sediment toxicity tests. Although useful, this approach has been criticized

as it is based on single or a few species and considers neither the biological interactions among species nor environmental factors. Outdoor mesocosm studies complement whole sediment toxicity tests by accounting for these untested factors. This research considered the effects of copper on aquatic ecosystems with twenty 1500-L outdoor mesocosms. Clean sediments were spiked to create a gradient of copper contamination. The Australia and New Zealand Guidelines for Fresh and Marine Water Quality – Interim Sediment Quality Guidelines (ISQGs) were used to define nominal treatment concentrations of 0 (control), 32, 65 (low ISQG), 270 (high ISQG) and 540 mg/kg. The partitioning of a metal between particulate and aqueous phases is one of the most important processes controlling bioavailability. Laboratory spiked-sediments commonly have abnormally high porewater metal concentrations, which could confound the interpretation of results. Consequently, Simpson *et al* (2004) developed methods to create spiked sediments with realistic sediment geochemistry. We upscaled these methods for spiking at the mesocosm level. The concentration of copper in the sediment, porewaters and overlying waters was monitored over time. The majority of copper partitioned to the particulate phase with low µg/L concentrations measured in the porewaters and overlying waters in all treatments. The mesocosms were opened to biotic colonization in November 2010 and the development of the macroinvertebrate community was monitored for 1.5 years. Preliminary data shows the benthic macroinvertebrate community composition was significantly affected at and above the nominal treatment of 65 mg/kg, the low ISQG. Microbial degradation rates were affected above 32 mg/kg. Effects on genetic diversity, population and sub-lethal end points are also being considered. Our results show that we created environmentally realistic partitioning between sediment, porewaters and overlying waters. Under these conditions, concentrations of particulate-bound copper at guideline levels affected both the structural and functional characteristics of the benthic communities within the freshwater mesocosms.

**624 Recovery of a mining-damaged stream ecosystem** C. Mebane, US Geological Survey / NOAA Fisheries Liaison, US Geological Survey/WRD / NOAA Fisheries Liaison. The environmental science literature is replete with case studies of stream ecosystems damaged by metals pollution, but fewer case studies are available with long-term data on the recovery from effects of pollution. Panther Creek, a tributary to the Salmon River in central Idaho, USA, is one such case with a 30-year period of record from about 1980 through 2010. Panther Creek suffered intensive damage from large-scale mining and milling operations in the Blackbird Mining District, primarily from the late 1940s to 1967. The mine drained to two tributaries of Panther Creek, Blackbird Creek and Big Deer Creek, contaminating the streams with copper (Cu), arsenic, and cobalt (Co), as well as altering the physical channel. From the 1960s through 1980s, no fish and few aquatic insects could be found in mine-affected sections of Panther Creek. By the early 1990s, Cu concentrations had attenuated to the point that some natural production of rainbow trout occurred. However, Chinook salmon and resident fish other than rainbow trout remained rare. Species richness of aquatic insects was about half that of reference sites, and mayflies were absent or rare. Concerted efforts to reduce mine contamination began in 1995, and by 2002 Cu and Co levels had been reduced by about 90%. As of 2010, resident fish populations in mining-influenced reaches appeared to have recovered, relative to reference reaches. Rainbow trout were early colonizers, quickly expanding their range as areas became habitable. Sculpin appeared slower to disperse and colonize; but they appeared to fully recover about four years after their first detections. Macroinvertebrate richness in Panther Creek sites downstream of Blackbird and Big Deer Creeks appears to have plateaued at about 70 to 90% of reference. Total abundances of mayflies in locations downstream of mine influences are as high as or higher than at reference locations. However, mayfly diversity remains lower than reference, and Heptageniids and Ephemerellids remain rare. These patterns raise questions of what it means for an ecosystem to be “recovered.” For example, if benthic macroinvertebrates provide a sufficient food base for fish populations, is the ecosystem sufficiently recovered? Or would all major ecosystem components need to be similar to reference?

**625 Context dependent ecotoxicological responses to metals and other stressors** W.H. Clements, Colorado State University / Fish, Wildlife and Conservation Biology, Colorado State University, Colorado State University / Fish, Wildlife and Conservation Biology; C. Hickey, Natl. Inst. of Water & Atmospheric Res. / NIWA Ecosystems; K. Kidd, Canadian Rivers Institute, University of New Brunswick / Biology, University of New Brunswick /

Biology department. One of the major goals of ecotoxicology is to identify patterns that describe population and community responses to contaminants. Our ability to predict these responses is greatest for communities that change consistently in response to a specific contaminant or class of contaminants. However, we know that regional variation in community composition, which may result from environmental, historical, biogeographical and/or climatic factors, complicates our ability to identify general patterns of responses and represents a significant challenge for ecological risk assessment. In situations where responses to contaminants are highly variable, an understanding of the mechanisms responsible for differences among locations has important practical applications. For example, aquatic toxicologists have known for many years that certain physicochemical features of aquatic ecosystems such as pH, water hardness and dissolved organic carbon (DOC) greatly influence the toxicity and bioavailability of contaminants. In contrast to our well-developed understanding of how abiotic factors influence toxicity, we know relatively little about variation in sensitivity among communities. In fact, much of this variation is treated as “noise” and considered an impediment to generalization and to our ability to predict ecological responses. In this paper we suggest that variation among communities and along environmental gradients represents an opportunity to identify ecological factors that influence contaminant fate and effects. We introduce the concept of context dependency, which refers to variation in ecological patterns and processes across environmental or spatiotemporal gradients. We propose that many responses of aquatic communities to contaminants are context dependent and vary along environmental gradients. Specifically, we hypothesize that many of the environmental factors which structure communities in aquatic ecosystems (e.g., food web structure, disturbance, primary productivity, exposure history) also determine their responses to contaminants. Our ability to predict the effects of contaminants in aquatic ecosystems could be significantly improved by recognizing that responses to stressors are often context dependent and by developing a mechanistic understanding of context dependency.

**626 Improving Our Understanding of Ecologically Significant Metal Effects in Aquatic Benthos** A. Burton, University of Michigan / School of Natural Resources & Environment and Cooperative Institute for Limnology & Ecosystem Research; D. Costello, University of Michigan / School of Natural Resources & Environment; K.W. Custer, Wright State University / Department of Earth and Environmental Sciences; M. Li, University of Michigan / School of Natural Resources and Environment, Harvard School of Public Health / Environmental Health; S. Aselage, University of Michigan. A recent review by Brix et al. (2011) concluded there were often discrepancies between laboratory and field studies that assessed divalent metal effects on aquatic insects. The greater sensitivity observed in the field was attributed to inadequate exposure periods in the lab and reductions in primary producer biomass that resulted in indirect effects on grazers. Compiling results from many mesocosm and *in situ* experiments, we find support for complex interactions evident at the community and ecosystem level that may lead to discrepancies between lab and field studies. Under field conditions, spiked metals rapidly shifted their dominant partitioning relationships, thus indicating that short-term static lab exposures may not simulate field exposure. Furthermore, variation in DOC, sediment heterogeneity, and light exposure can modify sediment bioavailability. Sediment metals reduced food (i.e., biofilm) quantity and quality, which in turn affected grazer uptake and effects. Synergistic effects were observed between common stressors (P and Cu) in biofilm-grazer relationships. Finally, toxic effects may be modified by the route of exposure that dominates. More research is needed to better define the importance of these interactions and whether they can be modeled to better predict their ecological significance.

**627 Unraveling the disconnect between laboratory and field responses of aquatic insects to trace metals** D.B. Buchwalter, North Carolina State University / Department of Environmental and Molecular Toxicology, North Carolina State University / Department of Environmental & Molecular Toxicology. Aquatic insects are notoriously unresponsive to metals at ecologically relevant concentrations in laboratory toxicity tests, yet many authors report profound responses of insect communities to metals in the field. There are several potential reasons for this important disconnect, which can be broadly subdivided into three categories – time, diet, and indirect effects. I will present dissolved cadmium and zinc kinetics data (influx and efflux) for several aquatic insect species, demonstrating that the times required for most species to reach steady state tissue concentrations far exceeds the

duration of most toxicity tests. For example, time required to reach steady state tissue Cd concentrations ranges between 28 days in the fast effluxing *Hydropsyche californica* to >5,000 days (well beyond the lifespan) in the slow effluxing *Rhythrogena morrisoni*. Among 19 other species, time required to reach steady state Cd concentrations ranged from 41–716 days (mean = 155). Further, traditional toxicity assays do not consider dietary exposures, yet most studies that compare the relative importance of dissolved vs. dietary exposures in aquatic insects show that diet tends to be the more important exposure pathway in terms of overall metal accumulation. While many assume that diet derived metals are potentially less toxic than aqueous metals, a recent study in our lab shows the contrary: Antioxidant enzyme activities were negatively affected by dietary Cd whereas dissolved Cd exposures did not affect enzyme activities. Finally, little is known about how exposure to metals affects the quality and biomass of primary producers. Periphyton is the base of the food web in many aquatic ecosystems, and is a major sink for metals. Together, these observations suggest that traditional testing paradigms are not adequate for understanding the risks of metals to aquatic insects.

**628 A bioavailability-based approach to modeling metal mixtures: Part 1. model framework and conceptual considerations** A.C. Ryan, HDR | HydroQual; R.C. Santore, HDR|HydroQual, Inc.; J. Meyer, Arcadis U.S., Inc., ARCADIS; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry, Colorado School of Mines. Evaluation of mixture toxicity can be extremely complicated and conclusions regarding additivity, less-than-additivity, or more-than-additivity can be influenced by several factors. For example, assessing metal mixture toxicity on the basis of dissolved metal does not consider the effects of solution chemistry on concentration of bioavailable forms of metals. Further, it does not consider competitive effects that individual component metals may have on one another. Utilization of a tool such as the Biotic Ligand Model (BLM) does consider these effects, and therefore minimizes the potential for error in characterization of exposure. Another factor that is important to consider is the uncertainty associated with concentration-response relationships for the individual metals present in a mixture. It is widely known that repeated single-metal toxicity tests will not consistently produce the same median lethal concentration. Not surprisingly, this implies that there is variability in concentration-response relationships. Characterizing variability in the response curves allows for development of confidence bounds around a central concentration-response relationship. Confidence bounds for the single metal responses can be combined to produce confidence bounds around a predicted response in a metal mixture toxicity test. These confidence bounds can be informative when making conclusions regarding additivity of the components in the mixture. To predict overall responses (i.e., percent mortality) for exposure to metal mixtures, a multi-site BLM was developed. This formulation of the BLM is essentially a simple combination of single-metal BLMs that already exist. Each component in a metal mixture is toxicologically active at a specific biotic ligand, but allowed to bind at all biotic ligands. This accommodates apparent competitive effects between toxicologically active and toxicologically inactive metals at each of the biotic ligand sites. Importantly, this approach is backward-compatible with single-metal BLMs (i.e., application of the multi-metal BLM to a single-metal exposure is identical to application of the single-metal BLM). In this presentation, the conceptual framework for the multi-metal BLM will be described. A companion presentation will describe application to multi-metal laboratory toxicity tests and to toxicity tests conducted in field-collected sediments.

**629 A bioavailability-based approach to modeling metal mixtures: Part 2. model application** R.C. Santore, HDR|HydroQual, Inc.; A.C. Ryan, HDR | HydroQual; J. Meyer, Arcadis U.S., Inc., ARCADIS; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry, Colorado School of Mines. A Biotic Ligand Model (BLM)-based metal mixtures model with the capability to predict percent mortality (or survival) was applied to a number of organisms exposed to a series of binary and ternary mixtures of copper, cadmium, and zinc in laboratory and field settings. The model uses a response-additive approach to combine effects from individual metals. The model also considers uncertainty in each individual metal, and combines uncertainty estimates from individual metals into an overall uncertainty estimate for the mixture, which is characterized as a response envelope. Typically, these response envelopes are wide due to the high variability in responses to single metals and because of the steepness of the single-metal response curves. Most of the data considered fell within the response

envelopes, which are roughly consistent with 95% confidence bounds around a central response prediction, indicating that measured responses were well approximated by simple response additivity of the individual metal responses. Some of the data suggest either more-than- or less-than-additive responses, but the majority of the data suggest that the assumption of simple additivity is adequate. Generally, the mixture model performs reasonably well with laboratory tests with *D. magna*, as it can predict the patterns of responses observed in the toxicity data. For example, the model can account for the apparent beneficial effect of copper and zinc on cadmium toxicity (i.e., cadmium toxicity can be decreased with sub-lethal concentrations of either copper or zinc). The model was also successful in predicting toxicity to *H. azteca* in field collected sediments. This bioavailability-based approach was superior to a simple dissolved metal approach, despite the fact that water chemistry conditions did not appreciably vary in these datasets. In addition, the bioavailability-based approach can account for some of the apparently more-than- or less-than-additive effects of mixtures through consideration of competitive interactions at biotic ligands or competition for binding with inorganic or organic ligands in solution.

**630 Do mechanistic and/or empirical criteria predict toxicity in field collected sediments? An analysis of existing data sets** D.M. Di Toro, University of Delaware / Dept. of Civil & Environmental Engineering. Two methodologies exist that relate chemical concentrations to toxicity in sediments. Mechanistic criteria utilize observed toxicity from water only experiments and models of sediment-pore water partitioning to compute sediment criteria via equilibrium partitioning. Empirical criteria utilize large field collected data sets and develop sediment chemical concentrations that predict the probability of sediment being toxic. This paper examines the ability of both these methods to predict observed amphipod toxicity using three large data sets (I) "NOAA" data from the Status and Trends program (II) The "EPA" data collected and analyzed in "Predicting Toxicity to Amphipods from Sediment Chemistry" by LJay Field, SB Norton, DD MacDonald, CG Severn, CG Ingersoll (III) the "SCCWRP" data from "Sediment Quality Assessment Tools" data base by SM Bay, DJ Greenstein, JA Ranasinghe, DW Diehl, AE Fetscher These are large collections of data with many observations of paired amphipod survival and chemistry: NOAA (2469), EPA (4166), SCCWRP (8979) that have each been analyzed using various methods. The question to be answered in this presentation is: what fraction of the observed toxicity can be predicted using both criteria. The data will be analyzed in two ways. The methodology used to produce the empirical logistic regression models to determine the probability of finding amphipod toxicity will be reviewed and applied to the three data sets. In particular the screening procedure and the resulting logistic models will be examined. For the mechanistic criteria, the question becomes, what fraction of the observed toxicity can be attributed to the modes of actions that are the basis of the mechanistic criteria: SEM-AVS for metals and the total PAH criteria. For the latter criteria, regression models will be employed to estimate the missing data (TOC, SEM, AVS) so that a larger fraction of the data can be examined. The focus of this presentation will be the reverse of the previous approaches that focus on predicting toxicity. Rather the question will be: what fraction of observed toxicity is not explained by either technique. Possible causes and future investigations will be suggested.

**631 Sustainable Water Use: Comparative Evaluation of Widely Acclaimed Water Risk Tools** S. Quinn, The Procter & Gamble Company / Environmental Stewardship Organization; S.D. Dyer, The Procter & Gamble Company / Central Product Safety, The Procter & Gamble Company / Miami Valley Innovation Center, The Procter & Gamble Company / Miami Valley Labs. Growing human populations and economies coupled with global climate change have caused increased pressures on natural resources, including water. The sustainability of growth will require an understanding of appropriate conservation and use of water resources. Given the availability of globally digitized data, it is no surprise that over the past few years, several water risk assessment tools have emerged as a way for water-using entities to examine and promote their water sustainability as well as provide investors with tools that can evaluate the sustainability of various product sectors, even companies. Four of these tools include: the World Business Council on Sustainable Development's Water Global Water Tool, the World Wildlife Fund's Water Risk Filter, the World Resources Institute's Aqueduct Water Risk Atlas and the Global Environment Management Initiative's Local Water Tool. Each tool is designed to receive input data and then provide a risk scorecard based on input and other region-specific data. This

presentation provides results from our evaluation of these four water risk tools. In our evaluation we used manufacturing site data to compare each tool's function and output. These comparisons allowed us to determine the aspects of each tool that could contribute to a holistic and practical water risk assessment. The presentation of our results and conclusions will shed light on the constantly developing methods of water risk assessments and highlight ways that our work could contribute to more meaningful indicators for Life Cycle Assessment modeling (e.g. LCIA).

**632 A Water Analysis of Irrigation Related to Corn-based Ethanol production in the US** J.C. Bare, US EPA / MS-466, US EPA. Since the Renewable Fuel Standard has encouraged the development of biofuels, the US has seen an increase in corn production for conversion to ethanol. In many of these agricultural regions, increased corn production is accompanied with increased irrigation. A water use analysis will be presented that includes one regional scenario analysis of 12 US Midwestern states which is responsible for 88% of the corn production. Additional modeling will be done in the future to expand this analysis projecting two possible future scenarios for land use in 2020. The ArcGIS modeling was conducted with a 30 meter x 30 meter grid defining land use / land cover. Water stress indices were used to provide additional insights into the scarcity of water at each 30 meter x 30 meter location.

**633 Development of an integrated land use indicator in life cycle impact assessment based on ecosystem services** V. Cao, CIRAI, Polytechnique Montréal / Department of Chemistry, CIRAI / Department of Chemical Engineering; M. Margni, CIRAI, Polytechnique Montréal / Department of Mathematical and Industrial Engineering; L. Deschenes, CIRAI, Polytechnique Montréal / Department of Chemistry. In life cycle impact assessment (LCIA), potential impacts due to land use are calculated considering the land quality loss  $\Delta Q$  over area and time. Up to very recently, potential impacts were solely related to the loss of terrestrial biodiversity, which is not representative of all potential impacts generated by the use of land, as described by the JRC. The UNEP/SETAC Life Cycle Initiative project expanded the assessment framework by addressing additional impact pathways and related indicators, namely: biotic production potential (BPP), erosion regulation potential (ERP), fresh water regulation potential (FWRP), (mechanical and physico-chemical) water purification potential (WPP) and carbon sequestration potential (CSP). These represent provision and regulation services, as defined in the Millennium Ecosystem Assessment. Although this novel LCIA framework is more comprehensive, this development adds sophistication and potentially reduces the capacity of LCA to simplify the decision making by providing seven midpoints for land use alone. This project aims to normalize each midpoint to monetary values through economic valuation. Then, these converted midpoints can be aggregated into one stand-alone indicator, representing potential impacts of the land use as loss of ecosystem services natural capital. BPP and CSP are estimated with respectively productivity loss and carbon social cost, while the remaining regulation services are estimated with costs of technology compensation, as they are considered essential. As a local impact category, spatial variability and availability of the compensation systems are taken into account. Uncertainties and economic valuation assumptions will also be discussed. This method will be applied on a case study, the comparative LCA of bio-based polymers. Results show that the integrated impact allows discriminating these polymers, particularly with both the choice of the crop type and the production region.

**634 Historical Life Cycle Assessment of the Carbon Intensity of Oil Sands Production: 1970-2010** J.G. Englander, A.R. Brandt, Stanford University / Energy Resources Engineering. As one of the largest global oil resources, there has been considerable interest in the Alberta Oil Sands as an energy resource. However, as policies regulating the CO<sub>2</sub> intensity of fuels, such as California's Low Carbon Fuel Standard (LCFS) as well as protests surrounding the approval of the Keystone XL pipeline appear to indicate, a challenge to oil sands development may exist due to the comparatively more energy intensive and environmentally damaging extraction techniques required for extracting oil from the oil sands. Using data from Alberta's Energy Resources Conservation Board (ERCB), this paper builds a time-varying life cycle assessment model showing historical trends of greenhouse gas (GHG) intensity from oil sands oil production, from surface mining, in-situ production, upgrading and refining. Primary energy consumption data are collected for all energy sources including natural gas, coke, coal, and electricity, as well

as data on synthetic crude oil (SCO) and raw bitumen production for mining and upgrading operations, as well as steam to oil ratios (SOR), which are used to estimate in-situ production energy consumption. Interpolation techniques are developed to augment some missing data. Using these data, life cycle embodied energy and GHG emissions are estimated per unit of refined fuel produced ( $\text{gCO}_2/\text{MJ}$  Gasoline) from 1970 to 2010. Results suggest that as new technologies have been deployed, energy consumption per unit of liquid fuel produced has declined and there has been a shift to less carbon-intensive primary fuels. Between the beginning of commercial operations until the start of project expansion, the two largest oil sands projects, Suncor and Syncrude, experienced decreases in energy intensity of 56 and 61% respectively (measured as primary energy consumed per unit of SCO), which corresponded to decreases in carbon intensity of 50 and 55% ( $\text{gCO}_2/\text{MJ}$  SCO). However, these gains in efficiency have been attenuated by recent rapid expansions of some mining projects as well as a maturing of technology, which has largely halted the rate of emissions improvement after the year 2000. There are also considerable uncertainties regarding the contribution of emissions from tailings ponds, land use change, and other fugitive emissions.

**635 Assessing the impacts of abiotic resource use: application to electric vehicles batteries** V. De Bruille, CIRAIG – École Polytechnique de Montréal / Chemical Engineering; C. Bulle, CIRAIG – École Polytechnique; O. Jolliet, University of Michigan / School of Public Health, Dpt of Environmental Health Sciences; T. Dandres, CIRAIG – École Polytechnique; C. Gaudreault, NCASI Canada; R. Samson, CIRAIG – École Polytechnique. In this study, a new assessment method is proposed to assess the impacts from resources use, as none of the previously existing methods is considered mature enough to be recommended in the ILCD handbook. Based on resource functionality, future abundance and the financial consequences of the use of resources, this new approach allows impact monetisation. This allows considering an effect factor expressing to what extent the extraction of a certain amount of abiotic resource forces one of the future users to pay a different amount to keep the same functionality of the resource as it becomes scarcer. The effect factor is multiplied by a competition factor, which is a material competition scarcity index (MACSI) varying between 0% and 100%, defined to assess the competition. The MACSI is based on the “remaining years of availability”: the ratio between resource consumption and available known stock (including anthropogenic stock), representing the years left before total dissipation of a resource at current dissipation rate. Resource dissipation is the amount used from which recycling and reuse is subtracted. This choice was made considering that resource will remain (partly-) functionally equivalent, even after the end of a product life through reuse or recycling. Competition factors of about 100 minerals, for which remaining years of availability vary from 25 years (e.g. silver) to over 4000 years (e.g. perlite), are proposed as mid-point indicators for resource use, considering different time perspectives. The current project aims also at identifying the main affected users and include their adaptation capacities into the competition factor as well as the cost raise for competing users to adapt themselves to functionality loss. In order to illustrate the approach, it has been applied to metallic resources used in electrical vehicles batteries to compute impacts on natural resources depletion. Results have been compared with the impacts obtained with other LCIA methodologies to put in perspective advantages and drawbacks of each of them and see to what extend results obtained are consistent when applying different approaches showing different degrees of sophistication. Inconsistencies between methodologies are put into light as the ranking between contributors to the impact differ from one methodology to the other.

**636 How the New National Life Cycle Impact Assessment Standard Handles Resource Depletion** A. Foster, K. Killpack, T. Schultz, Scientific Certification Systems. The new national Life Cycle Assessment (LCA) standard currently undergoing finalization provides protocols for calculating results for category indicators related to the depletion of resources. This presentation will cover the specific methods described in this standard for quantifying resource depletion under four basic categories: energy resources (biotic and abiotic), water resources, minerals and metals, and non-energy related biotic resources. Calculating resource *depletion* takes into consideration more than the level of *consumption*. For each impact category in this group, the ratio of overall use of the resource to the resource reserve base being depleted is established as a measure of the resource's relative abundance, using resource depletion characterization factors (RDFs), and the rate of accretion and recycling is also taken into account. Aside from energy

resource depletion, which can be aggregated on an equivalent unit of oil basis, the aggregation of material abiotic or biotic resources into a single category indicator result is not allowed in this standard because it violates the basic ISO 14044 tenet prohibiting combining different environmental mechanisms under one indicator. For example, aggregation of copper and steel resource depletion into a single category indicator would mask the fact that copper is becoming scarce globally, while the world still has an abundance of steel reserves both in standing inventory and ore reserves, especially when the high recycling rate of steel is factored in. Examples from several case studies in the green building sector and energy sectors will be presented to demonstrate how resource depletion calculations are conducted.

**637 Building reliability, credibility and consensus in Life Cycle Impact Assessment** O. Jolliet, The University of Michigan / School of Public Health, University of Michigan / Environmental Health Sciences, School of Public Health; B.W. Vigon, SETAC; J. Bare, US-EPA; R. Frischknecht, ESU-Services Ltd; T. McKone, University of California, Berkeley, University of California and Lawrence Berkeley National Laboratory, University of California, University of California and Lawrence Berkeley National Laboratory, University of California. In the last five years important progresses have been made in Life Cycle Impact Assessment (LCIA): international collaboration has led to the USEtox consensus model for the human toxicity and ecotoxicity categories, with compatible intake fractions for respiratory inorganics, characterization factors for indoor air emissions and ionizing chemicals as well as metals. The resource use categories have been framed for water use, land use, minerals and energy, looking at consumptive use and competition between various users and resource quality. Recently, the scope has broadened to aim at a world coverage within several efforts such as the LC-IMPACT European project, the IMPACTworld+ method, the Sustainability consortium effort, the next version of the Japanese LIME method, and further development within US-EPA. Characterization factors are becoming increasingly available for various continents and/or world regions. In this context, these converging efforts and in more general the LCIA field would highly benefit to put resources from all interested teams worldwide in synergy towards evaluating the credibility, the reliability of LCIA methods and pursue coordinated research efforts to further develop LCIA scientific methods as a basis for international consensus. This presentation will present a new worldwide effort in LCIA carried out in interaction with the UNEP-SETAC Life cycle Initiative and involving stakeholders worldwide. Building on previous LCIA works, we will identify in a first step the Life Cycle Impact indicators to prioritize based on environmental problems that matter most, problem raised by stakeholders and the quality of existing LCIA methods. An initial scoping workshop will take place in conjunction with the SETAC-Europe meeting in Glasgow to set these priorities, analysing the uncertainty, reliability and credibility of best presently available methods and identifying critical gaps, research and developments needed towards building consensus. Effort towards consensus will then be carried out for a first set of five indicators, eventually leading to their presentation within an ulterior Gordon conference, also involving in the process expert scientist from specific fields related to these indicators. This process represents an important step forward towards enhancing the quality and consensus on a default LCIA method and indicators.

**638 Reclaiming Biomass for use as Fertilizers from Algal Biofuel Production** C.L. Antaya, W. Barr, A.E. Landis, Arizona State University / School of Sustainable Engineering and The Built Environment. Algae feedstocks represent the next generation for sustainable biofuels due in part to their ease of cultivation; algae utilize sunlight and nutrients nitrogen phosphorus, primarily, as well as carbon dioxide, doubling cell mass in a couple of hours. These systems present opportunities for industrial synergies utilizing waste carbon dioxide as well as nutrient rich municipal or industrial wastewater for production and have minimal impact agricultural lands unlike specifically land-derived biofuels. Despite this, the process of producing algal biofuels generates substantial waste biomass post-lipid extraction. Sustainability assessments now focus on reclaiming the downstream biomass as a co-product, rather than discarding it as waste. A small number of applications for the use of waste algae biomass have been proposed, including animal feed and biofertilizers. Prior research has suggested that nutrients, nitrogen and phosphorous, contained in the biomass are readily available for use as a soil amendment without further modification. While preliminary studies conclude that algal biofertilizers are slow-releasing nitrogen fertilizers, they may also contribute significantly to eutrophication impacts.

This presentation evaluates the bio-available nutrient content of waste algae biomass and utilizes a life cycle assessment framework to estimate the environmental impacts related to reclaiming waste algal biomass as a biofertilizer. The system boundaries for this study include the algae cultivation system via a photobioreactor, while agricultural fertilizer offsets were calculated for the use of the reclaimed biomass as a biofertilizer product. Municipal wastewater and agricultural fertilizers were compared as different sources of nitrogen and phosphorous resources for algal growth. The results presented in this study include the environmental impacts from reclaiming the waste biomass as a biofertilizer, the nutrient content of the resulting biofertilizer and an assessment of agricultural offsets as an outcome of algal biofertilizer usage.

### **639 Evaluation of Polyethylene Passive Samplers to Estimate Deep Water PCB Concentrations at the Palos Verdes Shelf Superfund Site**

R.M. Burgess, U.S. EPA / Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, US EPA, U.S. EPA, U.S. Environmental Protection Agency / Ord/Nheerl-Atlantic Ecology Div, U.S. EPA / Ord/Nheerl-Atlantic Ecology Div; R. Lohmann, University of Rhode Island / Graduate School of Oceanography, University of Rhode Island; P. Luey, Narragansett Bay Program; M. Charpentier, Raytheon; C. White, U.S. EPA. The Palos Verdes Superfund site is located in over 50 meters of water on the continental shelf and slope off the coast of southern California (USA). The site includes 27 km<sup>2</sup> of seabed contaminated over several decades by municipal treatment plant effluent discharged via outfall pipes at a depth of 60 meters. Contaminants of concern include industrial chemicals like polychlorinated biphenyls (PCBs) and the pesticide DDT and its degradation products. Planned remediation of the site includes capping of erosive areas designated as hot spots with clean capping material. A risk to the Palos Verdes system is contaminated sediment resuspension as capping material is placed on the seafloor. Resuspension of sediments and resulting desorption of dissolved contaminants into the water column could cause aqueous concentrations of PCBs and DDTs to exceed marine water quality criteria (WQC). For this preliminary pre-remediation investigation, passive sampling polyethylene devices (PEDs) were deployed on current meters one to five meters above the seabed with various levels of sediment contamination for three to six months at seven stations. The objectives of these measurements were to (1) evaluate the use of passive samplers in deep waters and (2) quantify baseline concentrations of dissolved PCBs in water above the sediments and assess their transport from the site. PEDs absorb contaminants from the water column and provide a robust method for estimating dissolved contaminant concentrations at very low levels conventional water sampling procedures would not be able to detect. At this site, PEDs functioned well as monitoring tools with concentrations of total PCBs ranging from 60 to 400 ng/g polyethylene which corresponds to estimated water column dissolved concentrations of 90 to 1000 pg/L. Mean flow measured by the current meters is along the shelf toward the northwest. Water column PCB concentrations were highest above and to the northwest of the most contaminated sediments, suggesting PCBs are partitioning into the water column from the more contaminated sediments and being transported northwest from the Superfund site by the mean current. These preliminary baseline data, along with more extensive water column baseline monitoring data, will be compared to similar measures taken during and after the remediation to access the magnitude of contaminant release and probability of exceeding WQC.

### **640 Using two types of passive samplers to measure dissolved persistent organic pollutants in the water column of the Palos Verdes Shelf Superfund site**

L.A. Fernandez, U.S. Environmental Protection Agency / Office of Research and Development; W. Lao, Southern California Coastal Water Research Project (SCCWRP); K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP; C. White, U.S. Environmental Protection Agency / Region 9; R.M. Burgess, U.S. EPA / Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, US EPA, U.S. EPA, U.S. Environmental Protection Agency / Ord/Nheerl-Atlantic Ecology Div, U.S. EPA / Ord/Nheerl-Atlantic Ecology Div. Passive sampling methods were used to deduce water concentrations of persistent organic pollutants (POPs) in the vicinity of a marine Superfund site on the Palos Verdes Shelf, California, USA. This type of sampling can detect POPs at concentrations that are undetectable by conventional sampling techniques. Pre-calibrated solid phase microextraction (SPME) fibers and polyethylene (PE) strips that were pre-loaded with performance reference compounds (PRCs) were deployed for 32 d along an 11 station

gradient at bottom, surface and mid-water depths. Retrieved samplers were analyzed for DDT congeners and their breakdown products (DDE, DDD, DDMU, and DDNU) and 43 PCB congeners using GC-EI- and NCI-MS. SPME samplers were assumed to have reached equilibrium during the deployment. PRCs were used to calculate compound specific fractional equilibration achieved *in situ* for the PE samplers, using both molar volume adjustments (MVA) and a mass-transfer model with best-fit boundary layer estimation. The highest observed concentrations were for p,p'-DDE, with levels of 2200 pg/L and 990 pg/L deduced from PE and SPME, respectively. The difference in these estimates could be largely attributed to uncertainty in equilibrium partition coefficients or unaccounted for disequilibrium between samplers and water. The concordance between PE and SPME estimated concentrations for DDE was high ( $R^2 = 0.95$ ). PCBs were only detected in PE samplers, due to the much larger polymer mass deployed. Near-bottom waters adjacent to and down current from sediments with the highest bulk concentrations exhibited aqueous concentrations of DDTs and PCBs that exceeded Ambient Water Quality Criteria (AWQC) for human and aquatic health. Continued passive sampling is intended for this site to determine the effectiveness of planned remedial activities taken against the most highly contaminated surface sediments.

### **641 Measuring sediment porewater organochlorine concentration gradients on the Palos Verdes Shelf using passive samplers**

L.A. Fernandez, U.S. Environmental Protection Agency / Office of Research and Development; W. Lao, Southern California Coastal Water Research Project (SCCWRP); K.A. Maruya, Southern California Coastal Water Research Project, SCCWRP; C. White, U.S. Environmental Protection Agency (retired); R.M. Burgess, U.S. EPA / Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, US EPA, U.S. EPA, U.S. Environmental Protection Agency / Ord/Nheerl-Atlantic Ecology Div, U.S. EPA / Ord/Nheerl-Atlantic Ecology Div. The Palos Verdes Shelf Superfund site is in over 50 meters of water on the continental shelf and slope off the coast of southern California (USA). The site includes over 25 km<sup>2</sup> of sediments contaminated over several decades by municipal treatment plant effluent discharged via outfall pipes at a depth of 60 meters. Contaminants of concern include polychlorinated biphenyls (PCBs) and the pesticide DDT and its degradation products (e.g., DDE). Planned remediation of the site includes capping of erosive areas designated as hot spots with clean material. Selection of the specific sections of the site to cap will be based, in part, on identifying areas that represent the greatest risk of contaminant release into the bottom waters. Mechanisms of dissolved contaminant release include diffusion from the sediment interstitial water into the bottom waters. Because of the site's excessive depth, determining which areas to cap is challenging. Passive sampling represents a possible technology for measuring dissolved contaminant gradients between the interstitial waters and bottom waters as well as assessing the effectiveness of capping. In this study, three types of samplers (polyethylene and polyoxymethylene strips, and solid phase micro extraction fibers) were deployed in the sediments and bottom waters of Palos Verdes Shelf Superfund site. The deployment platform was designed to allow sampling of the sediment interstitial waters at 2 cm increments to a depth of up to 20 cm, and to sample the bottom water in the 20 cm above the sediment-water interface. The performances of the three types of samplers were compared. The four platforms deployed performed very well and were successfully recovered after approximately 30 days. Among the sites sampled was an area where a pilot, sand cap was placed several years ago to test the efficacy of the remedial plan. At this station, interstitial water concentrations of DDE increased with depth in the top 4 cm, remaining relatively constant for the next 10-12 cm, then began to increase again. DDE concentrations in the bottom water at this station are slightly lower than those in the mid-depth sediments. To assess the release of dissolved contaminants, and the effectiveness of capping, these results are compared to similar interstitial water concentration gradients at other stations on the shelf where no capping has occurred.

### **642 Deposition and Accumulation of Emerging Contaminants in the Sediments of the Palos Verde Shelf, California**

M.G. Cantwell, / Atlantic Ecology Division; D.R. Katz, US EPA / Atlantic Ecology Division, U.S. EPA / ORD\NHEERL\AED; J. Sullivan, US EPA; R.P. Eganhouse, USGS; M.M. Perron, NRC/EPA; R.M. Burgess, U.S. EPA / Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, US EPA, U.S. EPA, U.S. Environmental Protection Agency / Ord/Nheerl-Atlantic Ecology Div, U.S. EPA / Ord/Nheerl-Atlantic Ecology Div. The

Palos Verdes shelf is located off the Southern California coast and has been receiving wastewater effluents from the Los Angeles County municipal sanitation Districts since 1937. Currently, a large segment of the Palos Verdes shelf is listed as a U.S. EPA Superfund site due to long-term discharge of DDT and PCBs which have resulted in highly contaminated sediments. Although the fate and behavior of these "legacy contaminants" has been extensively studied, little information exists on the presence and historical trends of newer classes of pollutants that are classified as contaminants of emerging concern. Antimicrobial compounds and brominated flame retardants, both of which are used extensively in consumer based products, are two such classes of chemicals. In this study, triclosan, a phenolic antimicrobial additive, and polybrominated diphenylethers (PBDEs), which are used as flame retardants, were measured in a 50-cm long sediment core collected from the Palos Verdes shelf in 2009. Measurable triclosan is present to the base of the core and increases progressively up core to a maximum of 29 ng g<sup>-1</sup> at 5 cm depth, which is consistent with contemporary levels observed in sediments at other marine locations impacted by wastewater effluents. Measurable PBDEs first appear at a depth of 43-45 cm and are comprised of major congeners associated with penta formulations (e.g., PBDE-47, 99, 100), and decabromodiphenylether (PBDE-209). The congeners used in the penta-PBDE formulation account for the majority of PBDEs present throughout the length of the core. In contrast, PBDE-183, a major component of the octa-PBDE technical mixtures is present only at extremely low concentrations. At 31 cm depth, PBDE-209 is the most abundant congener measured, with concentrations increasing up core, demonstrating its increasing use over time. Within 5 cm of the sediment-water interface, all congeners show a decline suggesting that regulations in California banning the use and production of PBDEs along with voluntary phase outs may be responsible for reducing the amount of PBDEs being released to surficial sediment of the Palos Verdes Shelf.

**643 Assessing Bioavailability of DDTs and PCBs in Palos Verdes (PV) Shelf Superfund Sediments** J. Voelker, University of California, Riverside / Department of Environmental Sciences; L. Bao, University of California Riverside / Chinese Academy of Sciences, University of California, Riverside / Department of Environmental Sciences; R. Lavado, University of California Riverside / Department of Environmental Sciences, University of California Riverside / Department of Environmental Science; J. Gully, Environmental Scientist / Ocean Monitoring & Research Section, Supervising Environmental Scientist / Ocean Monitoring & Research Group; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; J. Gan, University of California Riverside. Sediments from Palos Verdes (PV) Shelf are heavily contaminated with DDT and metabolites and to a lesser degree, various PCB congeners. Given that the contamination occurred decades ago and that the contamination spanned over many years in the last century, it is highly likely that the contaminant bioavailability has diminished and that the bioavailability may also vary spatially. Although extensive monitoring has been done in the characterization of PV Shelf sediments, the relative bioavailability of DDTs and PCBs is unknown. Using sediment samples taken from the 8C and 6C sites, we have evaluated the bioavailability of DDTs and PCBs using several approaches, including Tenax extraction, carbon normalization, solid phase microextraction and stable isotope exchange. In addition, we have modified the 8C sediment through amendment of activated carbon or sand to simulate remediation treatments. The bioaccumulation of selected DDT derivatives and PCB congeners was simultaneously measured using the marine polychaete worm *Neanthes arenaceodentata*. Results indicate that DDTs and PCBs in the marine sediment display much reduced bioavailability as compared to freshly spiked compounds, and that amendment of carbon or sand greatly altered the bioavailability.

**644 A Multiple Measures Approach for Screening for Contaminant Effects in Coastal California Fish** K. Kelley, California State University, Long Beach / Environmental Endocrinology Laboratory, California State Univ, Long Beach; J.A. Reyes, Pacific Coast Environmental Conservancy. In our studies in coastal California, including in the central Southern California Bight (SCB) and offshore of Palos Verdes (PV), it is clear that different kinds of physiological effects observed in fish reflect specific types of environmental contaminants. Since different types or classes of chemicals typically act through distinct pathways in organisms, the development of multiple-measures approaches (simultaneously applied in a single sample) have strong potential to serve as screening and diagnostic tools to predict

types or classes of environmental constituents and their specific physiological and health effects. It has therefore been the goal of our studies to develop multiple-measures approaches using proteomics technologies combined with measures of endocrine and physiological status. In coastal fish, proteomes of liver and other tissues are being characterized in relation to residence near regional wastewater treatment facilities, contaminated superfund sites, and other locations, to discover protein biomarkers whose expression are altered in relation to contaminant exposures and endocrine system status (endocrine disruption). Since all parameters are measured within the same individuals, it is possible to evaluate contaminant exposures, effects, and endocrine system status using correlative and multivariate statistical approaches. Identification of protein and endocrine biomarkers and their expression differences in fish have pointed to specific changes in detoxification processes, oxidative stress response, hepatic fuel metabolism, altered signaling systems (endocrine, intracellular), and physiological changes relating to growth and reproduction. This multiple-measures approach is providing novel information on phenotypic effects in animals exposed to different kinds of environmental contaminants, from organochlorine pesticides, PCBs, PAHs, and others, currently present offshore of PV and the SCB. [Supported by NOAA/USC Sea Grant Program]

**645 Long-term, fine-scale movements of teleost fishes in the Palos Verdes Shelf Superfund Site and application for monitoring potential contaminant uptake** B.W. Wolfe, G.N. Teesdale, C.G. Lowe, California State University Long Beach / Department of Biological Sciences. Although the presence of organochlorine contaminants in commercially and recreationally targeted fishes is well documented, the relationship between habitat usage and contaminant uptake in fishes is poorly understood. New advances in acoustic telemetry technology have allowed for high resolution simultaneous tracking of multiple animals over extended periods of time in areas of high organochlorine contamination. We used Vemco VPS technology and traditional passive tracking to record fine-scale movements of 97 white croaker (*Genyonemus lineatus*) and 54 barred sand bass (*Paralabrax nebulifer*) across a 20 km<sup>2</sup> area encompassing the Palos Verdes Shelf Superfund Site (PVSSS) as well as other areas throughout the Southern California Bight (SCB), CA from July 2010 – September 2012. Site fidelity, home ranging behavior and habitat association of the three species were quantified with regards to benthic sediment organochlorine concentration. Barred sand bass showed higher site fidelity to non-spawning season home ranges on the shelf, whereas white croaker ranged over much greater areas. Over 40% of the white croaker tagged on the PVSSS were observed to move into Los Angeles Harbor, while 20% showed periods of extensive activity within the PVSSS. Nearly all tagged barred sand bass left their non-spawning season home ranges within the PVSSS to join known spawning aggregations throughout the SCB. These movement patterns suggest means by which highly contaminated fish have been sampled in areas outside the PVSSS and likely explain the high variability seen in organochlorine body burdens of fish collected at these locations. These data provide a crucially needed understanding of the movements of these economically and ecologically important fishes, especially with regards to contaminant uptake, within the PVSSS and throughout the SCB.

**646 A Bioaccumulation Model of the Effects of DDTs and PCBs at the Palos Verdes Shelf: A Tool to Determine Risk and in Support of Remediation** E. Byron, CH2M Hill / Environmental Services, CH2M Hill; C. Arenal, CH2M Hill. CH2M HILL developed a GIS-based food chain exposure model for DDT and PCB risk to fish, marine mammals, and birds of the Southern California Bight in order to predict ecological risk near the Palos Verdes Shelf (PVS). The model was used as a key component of the Ecological Risk Assessment for current conditions for the PVS area in the RI/FS. Risks from sediment exposure were evaluated for invertebrates, fish, sea lions, and four species of birds. The model was used as a primary tool in demonstrating risk and in evaluating human health and ecological benefits of remedial action scenarios. The key underpinning of the model was the extensive, Southern California bight-wide and Palos Verdes-specific sediment and fish tissue concentration estimates for organochlorine contaminants. This extensive database not only provided direct evidence of risk for the Ecological Risk Assessment, but it allowed the creation of a significant, spatially-based relationship between fish tissue and bulk sediment concentrations for both DDTs and PCBs. Neither regression relationship was significantly improved by organic carbon or lipid normalization of the data. The quantitative relationship between sediment and fish

tissue concentrations allowed the use of the extensive bight-wide sediment database to provide an exposure estimate of bight-wide fish. Once fish were estimated, mechanistic tissue relationships based on diet, ingestion, and assimilation by species could be used to evaluate potential uptake and risk to seabirds, bald eagles, and marine mammals. The known, local foraging ranges of the key receptor species (bald eagle, sea lion, brown pelican) were used to link exposure and risk.

**647 Assessment of PBTs in the EU: A critical review and proposed evaluation scheme with reference to plant protection products** K. Solomon, University of Guelph / School of Environmental Sciences, University of Guelph / Centre for Toxicology, School of Environmental Sciences; M. Matthies, University of Osnabrueck / Institute for Environmental Systems Research; M. Vighi, University of Milano Bicocca / Department of Environmental Sciences, University of Milano / Department of Environmental Sciences. A number of international and national programs classify substances that are persistent (P or very P), bioaccumulative (B or very B), toxic (T), or have the potential for long-range transport (LRT). The oldest of these programs is the Stockholm Convention on Persistent Organic Pollutants (POPs). More recent programs address PBTs for chemicals in general (REACH EC253/2011) and plant protection products (PPPs EC1107/2009). However, these programs used different criteria for classification. We critically reviewed the criteria and process used in the classification of pesticides and noted that EC 1107/2009, in contrast to the Stockholm Convention or REACH, offers no process for carrying out a further more refined assessment of those pesticides that are identified as having PBT properties. Thus, in contrast to REACH, screening criteria are used for final-step management decisions. Guidance on the selection of data is not provided and the criteria used are unclear. For example, no guidance is given as to how the half-lives in soil, water, and sediment should be derived and the term "half-life" is not clearly defined (e.g.,  $DT_{50}^{dissipation}$  or  $DT_{50}^{degradation}$ ). Large amounts of useful data on environmental and toxicological properties are available for PPPs but most of this is not used in the classification. For example, photolysis in water, water-sediment, and on soil, an important environmental degradation process that is particularly relevant to pesticides, is not used as a screening criterion. The criteria for bioaccumulation and toxicity appear to be focused only on aquatic ecosystems and do not address movement from the aquatic to terrestrial species or effects in plants. The classification process under EC 1107/2009 could be made more efficient and reduce false negatives and positives if a formal weight of evidence approach was applied to multiple lines of evidence. This paper presents these ideas and how they can be incorporated into the framework for classification to better classify pesticides in terms of persistence, bioaccumulation, and toxicity.

**648 Ecotoxicological evaluation of soils and sediments of reference and satellite sites of the Mexican National Monitoring Program (PRONAME)** M.D. Guzman Martinez, L. Elizalde Ramirez, A.L. Espejel Pina, I. Arellano Lopez, E. Sierra Hernandez, U.A.M. Iztapalapa / Hidrobiologia; A.D. Nava Montes, Instituto Nacional de Ecología / CENICA; P. Ramirez Romero, Universidad Autonoma Metropolitana / Hidrobiologia, U.A.M. Iztapalapa / Depto. De Hidrobiologia. Mexico is signatory of a variety of international environmental agreements and to comply with some of the commitments acquired a monitoring program was established in 2007. The National Monitoring Program (PRONAME) will monitor in a long term (> 25 years) persistent and bioaccumulative toxic substances in sites with different levels and types of anthropogenic influence. The objective of the present work is to present the results of some bioassays that complement the chemical analysis of two reference sites: Celestún and Manantlan Biosphere Reserves and three satellite sites: Yaqui and Bravo Valleys and Coatzacoalcos. Samples of soils and sediments were obtained and transported to the laboratory. Extracts were obtained through sonication and evaporation; these extracts were diluted in reconstituted fresh water to analyze their toxicity with the lettuce seed bioassay in which germination, root and hypocotyl length were evaluated. Also a direct contact toxicity test using Microtox® was applied to the 2010 samples. In the lettuce seed bioassays germination percentages were high and no toxicity was detected. Microtox® detected toxicity in a small group of samples from the reference sites (Celestun > Manantlan) and even though Coatzacoalcos is an industrial area and Valle del Yaqui an agricultural one, no sample showed toxicity. In contrast a good number of samples from Valle de Bravo were toxic, which is associated with the presence of excess nutrients from the untreated waste waters that this

system receives. To better this evaluation other bioassays are being analyzed as well as to start measuring biomarkers on different organisms at each of the sites.

**649 Enhanced Persistency Assessments: Putting the "bio" back into biodegradation testing** T.J. Martin, Newcastle University / School of Civil Engineering and Geosciences; A.K. Goodhead, Newcastle University / Civil Engineering and Geosciences; M. Daniel, A. Bartram, J.R. Snape, Brixham Environmental Laboratory; R.J. Davenport, Newcastle University / Civil Engineering and Geosciences. Regulatory emphasis has shifted recently towards hazard identification and prioritising chemicals which are persistent, bioaccumulative and toxic (PBT): since chemicals with these properties have previously been shown to be most harmful to human health and the environment. Biodegradation is one of the most important fate processes determining persistence and has historically been assessed using highly prescribed, stringent, standardised tests termed Ready Biodegradability Tests (RBTs). Whilst RBTs have typically formed the core protocol for developing regulatory guidelines for persistency and environmental exposure assessments, the stringent nature and high false negative incidence associated with the tests renders them unsuitable for prioritising on the basis of environmental persistence. Registration, Evaluation, Authorisation and restriction of CHemicals (REACH) guidance has recognised this and advocates the introduction of a new tier of modified and enhanced tests to enable a more effective prioritisation on persistence. Reliable extrapolation from small-scale systems to predict local and regional effects is dependent upon incorporating environmental realism into laboratory scale systems, with better replication of natural ecosystems, including the nature of the microbial populations present. Enhanced tests under REACH allow increases in inoculum density to environmentally equivalent concentrations and increases in test volume, both of which may contribute towards providing a more environmentally realistic microbial community composition and diversity. This presentation describes the effect of inoculum concentration and test volume on biodegradation outcome for a group of compounds with varying persistency in activated sludge (AS) and marine systems. Molecular techniques were applied to investigate the relationship between microbial diversity, its variation within test inocula and the impact on the probability of a positive biodegradation outcome. It is anticipated that this will allow for better predictions on biodegradation with the ultimate goal of using this knowledge to design more robust screening tests for persistence.

**650 Evolving Interpretation of Listing Criteria Leads to Confusion in Stockholm and LRTAP POPs Assessments** D.J. Kent, D. Graham, H. Estreicher, Keller and Heckman LLP. Two major international agreements used to identify and ban persistent organic pollutants have recently experienced an evolution in the interpretation of their listing criteria. The Stockholm Convention on POPs is a global treaty focused on "chemicals that remain intact in the environment for long periods, become widely distributed geographically and accumulate in the fatty tissue of humans and wildlife." Similarly, the goal of the Long Range Transboundary Air Pollution POPs protocol goal is to "eliminate any discharges, emissions and losses of POPs." Both protocols have specific criteria that chemicals must meet to be listed, including evaluation of persistence, bioaccumulation and biomagnification potential, and the ability to be transported long ranges to remote regions. Based on these criteria there are about two dozen chemicals that have been severely restricted or banned, with additional chemicals currently being considered for listing. Recently the governing criteria have been more liberally interpreted such that when the parent chemical does not meet the criteria it may still be considered for listing based on degradation and metabolic products. Such expansion of the criteria has caused some confusion, both with the member state parties tasked with making recommendations and with the manufacturers and downstream users of chemicals under investigation. This confusion can be especially onerous when the degradation product is used to list a parent chemical even when the same degradation product may actually be sourced from a completely different parent chemical that is already well known to long-range transport. This presentation looks at some of the key issues and proposes some harmonization standards that can be applied to ensure consistent science-based listing procedures. These procedures include the need to use reliable data, specific criteria, appropriate long-range transport models, and effective use of biomonitoring information. A key recommendation will be to have procedures in place to fully recognize and assess other sources of degradation and metabolism products

when those products are used to assert listing when the parent chemical does not meet the listing criteria.

**651 Has the time come to revisit, revise and expand PBT criteria?** D. Mackay, Trent University, Trent University / Environmental Studies; J.A. Arnot, ARC Arnot Research & Consulting Inc., University of Toronto Scarborough / Department of Physical and Environmental Sciences. The assessment of the relative hazard of chemicals using PBT and LRT criteria has been largely successful, however, there is little doubt that it can be improved to better identify high priority substances. The expressed need for international harmonization provides an opportunity to revisit and refine the criteria in the light of advances in environmental science. We discuss aspects of the four criteria. Persistence (P) is well expressed by media specific half lives and an overall multimedia persistence, but the use of 'bright line' values can be suspect given the high variability and uncertainty inherent in half lives. There is a need to determine standardized 'recovery' times. Many "non P" substances can also be of concern when exposure is in the 'near field' close to sources. Bioaccumulation (B) presents challenges because, while BCFs can be measured reproducibly, they are not always ecologically relevant. A new dietary uptake BAF/BMF test may provide improved methods of integrating BCFs, BAFs, BMFs and TMFs for fish, mammals and birds using models. Models show the critical need for better estimates of biotransformation rates. Toxicity (T) expressed as LC50s lacks credibility because hydrophobicity creates an illusion of toxicity. Delivered doses, critical body residues or chemical activities are clearly preferable for comparing and ranking toxicities. Chemical specific differences in Long Range Transport (LRT) are well described by the Characteristic Travel Distance (CTD), but the CTD can be misinterpreted and it may fail to include changes in geography and climate that inevitably occur over long distances. The effect of emission rates on exposures in remote regions should be addressed. Finally, there is a need to integrate these metrics into a single 'score'. Rather than simply 'adding' the individual pass/fail criteria, we suggest estimating relative exposures and risks in a standard evaluative environment to both humans and ecosystems using the information contained in the PBT-LRT criteria. Multimedia models of fate and exposure are becoming available and more credible that can address this task, including uncertainty analyses. It is hoped that these suggestions will contribute constructively to improved identification of chemicals of highest priority for further evaluation, reduction of uncertainties and possible regulation including considerations for uncertainty.

**652 Prospects for measuring persistence in the field using chemical benchmarking** H. Zou, M. McLachlan, Stockholm University / Department of Applied Environmental Science (ITM); M. Macleod, Stockholm University / Applied Environmental Science (ITM). Persistence is one of the hazard properties of a chemical that is evaluated in regulatory strategies at national and international levels. Persistence assessments are based on measurements in the laboratory, which could induce great uncertainties when extrapolating to natural conditions. There is no established method for assessing persistence from measurements of chemicals in the field. In this study, the potential of using a benchmarking technique to assess the persistence of chemicals in real lake systems was evaluated by conducting model experiments with a multimedia chemical fate model. The benchmarking technique involves measurements of a set of benchmark chemicals with known fate processes in the lake simultaneously with the test chemicals of interest. The set of benchmark chemicals includes persistent substances that are: 1) non-volatile and water soluble and thus removed by advection in water; 2) very hydrophobic, and thus removed by burial in sediments. These substances are tracers of removal processes that are properties of the lake system. For hydrophobic test chemicals that are removed mainly by burial compared with water advection and volatilization, additional benchmark chemicals with similar hydrophobicities as the test chemicals are required. We used a multimedia fugacity model to establish the ranges of chemical and lake-system properties where the benchmark technique could be applied to estimate persistence from field measurements. Chemical space plots defined by logarithms of octanol-water ( $\log K_{ow}$ ) and air-water ( $\log K_{aw}$ ) partition coefficients of test chemicals were explored, along with a range of lake characteristics such as depth, water residence time, suspended solid concentrations and burial rates. The model experiments show that the benchmarking technique is likely to allow persistence to be measured in the field for chemicals that are not highly associated with particles in lakes with a wide range of characteristics. For particle-associated chemicals that are mainly removed by burial compared with advection and volatilization,

persistence can be best determined in lakes with high burial rates. Uncertainty analysis of model scenarios indicates that the relationship of organic carbon-water partition coefficient  $K_{oc}$  and  $K_{ow}$  determines  $K_{ow}$  boundaries for chemicals whose persistence can be determined using the benchmarking technique. A 'recipe' of how the benchmark technique could be applied in practice will be presented.

**653 Relationship between the BCF, BAF, and the TMF** F.A. Gobas, Simon Fraser University / School of Resource & Environmental Management, Faculty of Environment; A.R. Brisebois, Simon Fraser University / Resource and Environmental Management; H.A. Leslie, Institute for Environmental Studies, VU University; P. Leonards, Institute for Environmental Studies, VU University / Chemistry & Biology. A reasonable degree of consensus exists among bioaccumulation scientists on the use of Trophic Magnification Factors (TMF) as "conclusive" evidence of the bioaccumulative nature of chemicals in the environment. However, regulatory criteria to determine whether a substance is bioaccumulative in most jurisdictions rely on Bioconcentration Factors (BCF), measured in laboratory tests. The BCF is not an ideal measure of bioaccumulation because they do not account for chemical biomagnification via trophic transfer or biodilution. Also, BCF tests are expensive and lengthy, and require the use of many animals. In this paper, we present the final results from laboratory, field, and modeling studies aimed at testing the hypothesis whether the BCF is a good predictor of the TMF. Our studies involved (i) the compilation of BCFs and calculation of BAFs for a range of potentially bioaccumulative substances through literature studies and calculations; (ii) a field study of the food-web bioaccumulation of the same substances in Western Scheldt Estuarine food-web aimed at measuring TMFs in food-webs containing both water and air-breathing organisms; (iii) a modeling study aimed at formulating and exploring the relationship between the BCF and the TMF. We conclude that the BCF can be a useful predictor of the TMF for a range of chemicals with specific chemical characteristics (i.e. fat soluble substances) in an estuarine ecosystem. We also conclude that there are two major types of errors where the BCF does not provide accurate information about the bioaccumulative nature of chemicals in the environment. The first error deals with substances that show a relatively low BCF but have a high TMF such as certain per-fluorinated and brominated compounds. The second error is for chemicals that exhibit a high BCF in laboratory tests, but which do not show biomagnification in food-webs and have a low TMF such as hexabromocyclodecane. Supported by model calculations, we propose a set of simple rules that may be useful in the interpretation of laboratory based bioconcentration factors in terms of their bioaccumulative nature in the environment. These rules may be helpful to regulators involved in bioaccumulation assessments and to scientists that apply bioconcentration studies to study the bioaccumulative nature of chemicals in the environment.

**654 Definition, calculation and measurement of POV and LRTP** D. van de Meent, A. Hollander, Radboud University Nijmegen / Institute of Wetland and Water Research. Overall persistence in the environment ( $P_{OV}$ ) and long-range transport potential (LRTP) have been proposed as operational measures of the "PBT-ness" of chemical substances, but have found little use in regulatory frameworks so far. We believe that this is because  $P_{OV}$  and LRTP do not clearly express entities that (i) can be readily understood or compared to agreed-on criteria, (ii) can be observed in the environment, and (iii) can be calculated from available physical and chemical substance properties. This study contributes to solving this (re)defining  $P_{OV}$  and LRTP in a way that allows validation by measurement and prediction from theory. We propose to define  $P_{OV}$  as the "average life time" of molecules in the environment and to define LRTP as the "average distance travelled" by molecules during their life in the environment. We show that  $P_{OV}$  is the ratio of the total time-integrated mass of the substance in the environment and the total mass released, and that LRTP is a function of the effective advection-, dispersion-, and degradation rates of the substance in the environment, which can be readily calculated from substance properties. We have tested these calculation rules by comparing model simulations of hexachlorobenzene (HCB), polychlorobiphenyls (PCB) and brominated diphenyl ethers (BDE) with reported field data for the same substances. We used the nested multimedia fate model SimpleBox in quasi-dynamic (level IV) mode to simulate time-varying concentrations in air, water and soil at various spatial scales. Our study shows that the average life time of HCB molecules, overall in the environment (air, water, soil) is 20 yr, that on average, PCB- and BDE molecules travel 1500 km into the Arctic during their residence in

the environment. These results are in fair agreement with published field observations of spatial and temporal trends for HCB, PCB's and BDE's. We feel that these results can easily be understood and that, defined, calculated and verified this way, politically acceptable criteria can be formulated. An understandable criteria of one generation (30 yr) seems a useful criteria for  $P_{OV}$ ; a limit value of LRTP could be set to the length scale of a typical remote area (1000 km).

**655 Antibiotic occurrence and antibiotic resistance in microbial communities of three water supply reservoirs** D. Barcelo, ICRA / Environmenta Chemistry, ICRA / Catalan Institute for Water Research, IDAEA-CSIC / Environmental Chemistry Department, Catalan Institute for Water Research (ICRA) / Environmental Chemistry Department; B. Huerta, E. Marti, M. Gros, S. Rodriguez-Mozaz, J. Balcazar, R. Marce, Catalan Institute for Water Research (ICRA). Pharmaceuticals are continuously released in the environment from discharges of wastewater treatment plants or through run-off from fields after application of sewage sludge and animal manure. They attract increasing attention as contaminants because of their potential threat to the ecosystems and public health, even at their very low concentrations and persistence rates. Among these compounds, antibiotics may pose a risk to the environment since they are designed to have a biochemical effect in the microorganisms, and thus can have a significant impact in the processes controlled by them in aquatic ecosystems. One of the greatest concerns about the presence of antibiotics in the environment is the escalation of antibiotic resistance as a consequence of chronic exposure of naturally occurring bacteria to sub-lethal doses of these compounds and the potential impact in public health. The objectives of this study were first to determine the levels of antibiotics in different environmental compartments (water, sediments and fish) of three reservoirs in Catalonia: La Llosa reservoir was chosen for its pristine condition, whereas Sau and Foix are respectively a moderate and a highly polluted reservoir. Antibiotic concentrations were correlated with the composition and functioning of the natural bacterial communities in the reservoirs as well as with the presence of antibiotic resistance genes, not only in water and sediment but also in fish intestine. A general chemical characterization showed a clear difference between the reservoirs in terms of eutrophication and chemical pollution, with exceptional high values in Foix reservoir. Foix samples showed the highest antibiotic content in water and sediment, as it was expected according to the pollution gradient of the target reservoirs. Load was particularly high for macrolides family, which is consistent with data related to antibiotic consumption last years. Antibiotic concentration found was consistent with the quantity of *qnrS* and *sulI* gene copies (index of antibiotic resistance for the quinolone and sulfamide family, respectively) found in the samples. Resistance genes were detected in Foix Reservoir at much higher levels than in the other two, less affected by anthropogenic contamination. The combination of chemical and biological data provided a broader perspective to assess the impact of antibiotics released into the environment and their potential effect as promoters of antibiotic resistance.

**656 Contaminants of emerging concern in source and treated drinking waters from 25 drinking water treatment plants: pharmaceuticals and waste indicators** E. T. Furlong, M.C. Noriega, U.S. Geological Survey / National Water Quality Laboratory; S.T. Glassmeyer, U.S. EPA / Office of Research and Development, U.S. EPA / NERL/MCEARD/CERB; D. Kolpin, USGS. The presence and distribution of contaminants of emerging concern (CECs) in water supplies, and potential consumer exposure to these CECs in drinking water, has been of substantial scientific and public interest. The U.S. Environmental Protection Agency and the U.S. Geological Survey jointly conducted a study of CECs in untreated and treated drinking waters across the United States, sampling ground- and surface-water sources prior to and after treatment processes commonly used to produce drinking water. The timing of sample collection was adjusted for the hydraulic residence time of the water-treatment plant to determine relative removal of CECs during treatment. An extensive quality assurance/quality control design was used to assess precision and accuracy of CEC determinations at environmental concentrations. More than 185 pharmaceuticals and anthropogenic waste indicators (AWIs) were determined by direct aqueous injection LC/MS/MS and by GC/MS, respectively. Pharmaceuticals were detected in both untreated and treated drinking water samples, generally ranging in concentration from 2.5 to 940 ng/L, with more frequent and higher concentrations occurring in untreated water samples. Metformin, tramadol, and carbamazepine were the most frequently detected

pharmaceuticals in untreated water samples at maximum concentrations of 730, 42, and 40 ng/L, respectively. Metformin, carbamazepine and cotinine were most frequently detected in treated water samples at maximum concentrations of 92, 17, and 16 ng/L, respectively. The AWIs caffeine, *N,N*-diethyl-meta-toluamide (DEET), and tri(2-butoxyethyl) phosphate were most frequently detected in untreated water at maximum concentrations of 130, 98, and 470 ng/L, respectively. Bromoform, caffeine, and DEET were the most commonly detected AICs in treated water samples at maximum concentrations of 3,300, 75, and 25 ng/L, respectively. Frequent high concentrations of bromoform likely are due to formation as a disinfection by-product (DBP). Preliminary conclusions from this study indicate that multiple detections of pharmaceuticals and AWIs at concentration below 1,000 ng/L occur in both untreated and treated drinking water. After treatment, detection frequencies and maximum concentrations typically decrease. Treatment processes evaluated in this study reduce many, but not all, determined compounds, although formation of degradates and DBPs warrants future investigation.

**657 Fate of  $^{14}\text{C}$ -Carbamazepine and  $^{14}\text{C}$ -Acetaminophen in Soils and Biosolids-amended Soils** J. Li, University of California, Riverside / Department of Environmental Sciences, University of California, Riverside; J. Gan, University of California, Riverside / Department of Environmental Sciences. The widespread occurrence of human and veterinary pharmaceuticals in the environment has raised growing public concerns because of the widespread use of drugs such as carbamazepine (CBZ) and acetaminophen (ACET) and their ubiquitous occurrence in the environment impacted by wastewater and biosolids. To date few studies have considered the fate and transformation of pharmaceuticals in the environment. The objective of the present study was to characterize the fate of radiolabeled  $^{14}\text{C}$ -carbamazepine and  $^{14}\text{C}$ -acetaminophen in agricultural soils. In soils,  $^{14}\text{C}$ -ACET was found to rapidly form non-extractable or bound residues. Within an incubation period of about 1 h, depending on the soil types, 10-57% of the applied radioactivity was non-extractable using a mixture of acetonitrile and water (70/30, v/v). In a silty clay soil, after 2 days of incubation, the combined total extractability was below 9.8%. The extractability of  $^{14}\text{C}$ -ACET continued to decrease throughout the incubation period. At the end of the incubation period, less than 5% of the applied radioactivity was extractable using the optimized extraction procedures. It is likely that most of the bound residues consisted of transformation products strongly bound or incorporated into the organic matter matrix. Depending on the soil, between 8.9% and 17.1% of  $^{14}\text{C}$ -acetaminophen was recovered as  $^{14}\text{CO}_2$  at the end of the incubation period, however, only 0.37 %-1.18 % of  $^{14}\text{C}$ -carbamazepine was mineralized. Enhanced mineralization was seen in the sandy clay loam or silty clay soil than in a medium loam soil. Soil sterilization and amendment of biosolids significantly decreased the mineralization rate of acetaminophen. This study clearly showed that ACET is readily deactivated through mineralization and formation of bound residues in soil and CBZ is more persistent in soil.

**658 Fate of pharmaceuticals in surface waters downstream of a municipal wastewater treatment plant** S. Bartelt-Hunt, University of Nebraska / Civil Engineering, University of Nebraska-Lincoln / Civil Engineering; D. Brown, G. Hunt, University of Nebraska-Lincoln; D. Snow, University of Nebraska-Lincoln / Water Sciences Laboratory, School of Natural Resources, University of Nebraska. Wastewater treatment plants have been proved to be ineffective in removing pharmaceuticals and as a result, these compounds are frequently detected in municipal wastewater effluents. In this study, the fate of 25 pharmaceuticals including veterinary and human antibiotics and non-prescription drugs was monitored in surface water downstream of a wastewater treatment plant outfall using Polar Organic Chemical Integrative Samplers (POCIS). To quantitatively evaluate pharmaceutical fate in the environment, uptake rates were quantified in the laboratory. Twenty new uptake rates were determined for compounds that had no previously reported literature values. In surface water, select pharmaceuticals were observed to persist for at least 1300 m downstream. Carbamazepine and DEET were persistent with average aqueous in-stream concentrations of 110 and 60 ng/L, respectively. First-order loss rates were determined for 25 pharmaceuticals in receiving waters and pharmaceutical loading rates to the environment were determined.

**659 Occurrence of emerging endocrine active chemicals in wastewater effluents: synthetic steroids and thyroid disruptors** R. Marfil-Vega,

ORISE Postdoc at US EPA / ORISE Research Participant to the National Risk Management, University of Cincinnati, ORISE Postdoctoral Fellow, ORD, US EPA, ORISE Postdoc at US EPA; W. Brashear, PTS; K. Tadele, SSC at US EPA; M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development. Endocrine disruption encompasses the disturbance of various functions of living organisms, including metabolism, growth and development, tissue function, and mood. Affected metabolic pathways include, but are not limited to, steroidogenesis and nuclear receptors for steroid hormones (estrogens, androgens, and progestins) and thyroid homeostasis. Several classes of Endocrine Disrupting Chemicals (EDCs) with estrogenic effects have been extensively monitored during the past decade in wastewater and surface waters by the targeted chemical analysis. More recently, the attention of the scientific community has expanded to (anti)-androgenic compounds. Much less effort has been focused on the presence of progestins, agonists of the progesterone receptor, and thyroid hormones in the environmental waters. A reason for this could be that progesterone (natural progestin) is rapidly degraded during wastewater treatment, but the synthetic progestins are hypothesized to be more recalcitrant. Furthermore, the synthetic progestins are used for oral contraception at a higher amount than estrogens. Therefore, there is an elevated potential risk for progestins to reach the environment from wastewater treatment plant discharges. In regard to the thyroid hormone metabolism, its complexity allows for structurally diverse chemicals to disrupt different biological endpoints. Up to date, very limited information is available on the presence of thyroid disruptors, both from natural and industrial origin, in environmental waters. In the current work, we will be presenting the validation of an analytical method to monitor progestins and selected thyroid disruptors, as part of an on-going multilaboratory and interdisciplinary effort to evaluate the endocrine disrupting potency of wastewater effluents. Selected compounds were analyzed by Solid Phase Extraction followed by UPLC/MS/MS in effluents collected at four wastewater treatment plants during three different sampling campaigns. The data on the occurrence and concentrations will be reported.

**660 The relative contribution of humans, livestock and wildlife to the mass of 17 $\beta$ -estradiol and testosterone released to the environment** C. Hassinger, ARCADIS; P. Anderson, Ohio EPA; E. Osborn, ARCADIS; D. Pfeiffer, ARCADIS / Senior Scientist, Arcadis U.S., Inc. / Senior Scientist; G. Scheef, Intervet Innovation GmbH. The concentrations of hormones in surface water has received much scrutiny in recent research due to widespread detection and demonstrated effects on aquatic species at concentrations on the order of 1 ng/L. Humans and livestock are generally assumed to be the primary sources, depending upon location of study area. Wildlife, fish and plants may also contribute; however, data on the relative contributions of each group are few. To better understand the relative contribution, this study focuses on hormones originating from the excreta of all vertebrates for which there are available data: humans, livestock and representative species of wildlife and fish. The total excreted mass of two endogenously produced hormones, 17 $\beta$ -estradiol (E2) and testosterone (T) were estimated for these groups of vertebrates based on total daily excretion rates. To estimate the total mass of hormones excreted, the per capita total daily excretion mass of each hormone and the estimated total number of humans, livestock and representative species of vertebrate wildlife (fish, terrestrial herbivores, birds) were obtained. Human population statistics were obtained from 2010 U.S. census data and were stratified by sex and cycling/pregnancy status. Livestock population data for cattle, pigs and chickens were obtained from U.S. Department of Agriculture inventory statistics and were each stratified by sex and pregnancy status. The peer-reviewed literature was surveyed for information on E2 and T concentrations in excreta and total daily excretion rates. Hormone data presented as a concentration in excreta rather than a total daily excretion rate were multiplied by the estimated daily excreta production rates to obtain a daily hormone mass excreted. The total mass of E2 and T excreted by humans, livestock and wildlife are compared and the potential implications are discussed.
**661 Transport of Three Veterinary Antimicrobials from Feedlot Pens via Simulated Rainfall Runoff** S. Sura, Agriculture and Agri-Food Canada (AAFC) / Food and Bioproduct Sciences; D. Degenhardt, Alberta Innovates – Technology Futures; A.J. Cessna, National Water Research

Institute / Environment Canada, Environmental Health National Program / Agriculture and Agri-Food Canada; F.J. Larney, A. Olson, T.A. McAllister, Agriculture and Agri-Food Canada (AAFC). Veterinary antimicrobials are used in animal production, therapeutically to treat diseases and sub-therapeutically to prevent diseases and promote growth. There is a growing concern that environmental contamination by these chemicals may result in widespread bacterial resistance to antimicrobials used in human medicine. The majority of administered antimicrobials (up to 80% or more) are excreted in the feces or urine either as parent compounds or their metabolites. These antimicrobials are introduced into the environment mainly due to application of manure as fertilizer to agriculture fields or through leaching or runoff from manure storage locations (stockpiles, windrows, lagoons). Veterinary antimicrobials have been detected in manure, manure-treated soils, and surface and ground water resources near large-scale cattle feeding operations. Runoff and leaching after major precipitation events appear to be major transport pathways by which these veterinary antimicrobials eventually contaminate surface and ground water. A study was conducted at Agriculture and Agri-Food Canada Research Centre, Lethbridge, AB, Canada in spring 2011 to investigate the transport of three antimicrobials commonly used in beef cattle (*Bos taurus*) production. Beef cattle were administered the following antimicrobial treatments in the research feedlot situated on the Research Centre: (1) 44 mg of chlortetracycline kg<sup>-1</sup> feed (dry-weight), (2) 44 mg of chlortetracycline + 44 mg sulfamethazine kg<sup>-1</sup> feed, (3) 11 mg of tylosin kg<sup>-1</sup> feed and (4) no antimicrobials (control). Three pens per treatment were selected and concentrations of antimicrobials (tylosin, chlortetracycline and sulfamethazine) were measured in simulated rainfall runoff from two locations (bedding and floor areas) randomly selected in each feedlot pen. Manure and runoff samples collected from each area were extracted by accelerated solvent extraction and the extracts analyzed for chlortetracycline, sulfamethazine and tylosin using LC/MS/MS analysis. The residue data will be used to investigate the transport of the three antimicrobials in runoff and potentially generate information to support the inclusion of retention ponds in feedlots to capture runoff from feedlot pens, thereby minimizing the risk of contamination of surface and groundwater resources.

**662 Isomer-Specific Oxidation of Surfactant Metabolite Nonylphenol by Potassium Permanganate** Z. Lu; J. Gan, University of California Riverside.

Nonylphenol (NP), the metabolite of non-ionic surfactant nonylphenol ethoxylates, is one of the chemicals of emerging concern. Nonylphenol is frequently detected in soil, water and sediment due to its wide use and it is known as an environmental endocrine disruptor. Traditionally, NP is reported and studied as one compound rather than a mixture of numerous isomers. Recently, studies have shown that different NP isomers may have different estrogenic potencies and biodegradabilities in culture. However, there is no study on its isomer specific behavior during advanced oxidation processes. We investigated the reaction kinetics of 19 NP isomers (including 6 diastereoisomers) and potassium permanganate at pH 5, 7 and 9. At pH 7 with 10 mg/L KMnO<sub>4</sub> and 50  $\mu$ g/L technical nonylphenol, the half lives of 19 isomers ranged from 4.7 to 6.3 min and order of isomers with increasing half lives were: NP 119, NP 35, NP 128, NP 36, NP 37, NP 9, NP X (unknown structure), NP 38, NP 193b, NP 110b, NP 65, NP 111b, NP 110 a, NP 193 a, NP 143, NP 111a, NP 152, NP 112 and NP 194. Therefore, generally, the reaction was faster when the  $\alpha$ -position was less bulky: dimethyl>ethyl-methyl> methyl-(n or iso)-propylpentyl. This study suggested that side chain branching would significantly affect the reactivities and persistence of NP isomers during advanced oxidation processes.

**663 Organic photovoltaics: Are policies for safe disposal and recycling necessary?** Y. Zimmermann, University of Applied Sciences and Arts Northwestern Switzerland (FHNW) / School of Life Sciences; A. Schaeffer, RWTH Aachen University; P.F. Corvini, M. Lenz, University of Applied Sciences and Arts Northwestern Switzerland (FHNW). Organic photovoltaic solar cells (OPVs) are a promising renewable energy technology due to the fact that characteristics such as light-weight, semi-transparency and mechanical flexibility offer novel application possibilities. Substantial progress has been achieved during the last decade increasing power conversion efficiencies towards the crucial 10% threshold. In consideration of the anticipated forthcoming large-scale production, the environmental impact of such OPVs has to be assessed and should be compared to current best available thin film technologies. Various materials present in OPV, such as metal nanoparticles as well as fullerene-derivatives, may potentially have adverse effects in the environment. So far, no studies exist investigating a possible

release of OPV components into the environment under environmentally relevant leaching-scenarios. Whereas some research has already been carried out regarding the ecotoxicity of certain single, pure OPV components (e.g. nanoparticles), other components and/or degradation products/transformation products have not been investigated at all until now. For the first time, this study systematically composes the database about OPV materials and their fate and effects in the environment. Furthermore, priority pollutants are identified. We conclude that so far there is no evidence for an alarming risk deriving from OPVs during use phase (i.e. when intact). However, during end-of-life phase (i.e. when disposed in landfills) an increased release of harmful components seems plausible, which might result in adverse effects of OPVs in the environment. Preliminary results from our lab confirm that some compounds (organic and inorganic origin) are indeed leaching from OPVs under such conditions. By means of a variety of analytical methods such as ICP-MS, accelerated solvent extraction, SEC-HPLC and qTOF, leachates were identified. It was possible to show that inorganic compounds are actually leaching from OPV under harsh environmental conditions when applying end-of-life scenarios. These results have to be introduced into policies for safe disposal and recycling of OPVs.

**664 The influence of natural organic matter and salinity on the toxicity of nanoparticles in zebrafish embryos** G. Goss, University of Alberta / Biological Sciences; R. Clark, University of Alberta / Chemistry; D. Snell, University of Alberta; J. Veinot, University of Alberta / Dept of Chemistry; K.J. Ong, University of Alberta. The biological effects of nanoparticles on aquatic organisms have been well studied in pristine experimental media, but there is a need to determine whether nanoparticles will behave in a similar manner or have comparable toxicity in natural environmental conditions. Using single walled carbon nanotubes, silver, cadmium selenide, and zinc oxide nanomaterials, we characterize the nanoparticles in water containing natural organic matter and in a range of salinities. We find that aquatic exposure to nanoparticles in different environmental conditions can alter the biological effects of the nanoparticles, including effects on zebrafish (*Danio rerio*) embryo survival, hatch, growth, morphological development, and movement over 96 hours post-fertilization. Using both physicochemical characterization and biological effects data, we determine whether these effects are related to size, charge, composition, and/or polydispersity of the nanoparticles in different media. Furthermore, we determine the mechanism by which nanoparticles are inhibiting hatch, and determine whether the presence of humic acid abrogates these effects.

**665 Ceria(III) and ceria(IV) nanoparticles physico-chemistry in algae and daphnia exposure media and biouptake** R. Merrifield, University of Birmingham; J. Lead, University of Birmingham / School of Geography, Earth and Environmental Scien. This presentation will discuss the synthesis, characterisation and ecotoxicological effect (on freshwater algae) of ceria nanoparticles (NPs). The NPs were made in two different oxidation states (PVP-Ce<sub>2</sub>O<sub>3</sub> and PVP-CeO<sub>2</sub>) and were PVP stabilised, with similar hydrodynamic diameters of 7.5±0.6 and 6.5±0.45 nm and core sizes 4.6±0.6 and 4.2±0.8 nm, respectively. The ecotoxicological media (algae media and daphnia media) did not alter the hydrodynamic or core size (measured by STEM, FIFFF and DLS) of any of the NPs over the course of the exposure period. However the zeta potential, oxidation potential and oxidation state altered significantly for the PVP-CeO<sub>2</sub> NPs in algae media compared to no significant change in the other suspensions. The NPs were exposed to environmentally relevant aquatic freshwater algae species *chlamydomonas* using standard OECD procedures. The NPs were found to have penetrated into the algae cells and accumulated in vesicles, even at exposure concentrations of 80ppb.

**666 Role of surface chemistry of Ceria nanoparticles in organic matter interactions and in toxicity to *Caenorhabditis elegans*** B. Collin, E. Oostveen, University of Kentucky / Department of Plant and Soil Sciences; O.V. Tsyusko, University of Kentucky / Department of Plant & Soil Sciences; U. Graham, University of Kentucky / Center for Applied Energy Research; J.M. Unrine, University of Kentucky, University of Kentucky / Department of Plant and Soil Sciences, University of Kentucky / Department of Plant & Soil Sciences, University of Kentucky / Savannah River Ecology Laboratory, University of Kentucky / Department of Plant and Soil Sciences, University of Georgia / Savannah River Ecology Laboratory. Ceria nanoparticles (CeO<sub>2</sub> NPs) are increasingly being used for a variety of applications including fuel catalysts and mechanical planarization media;

however, little is known about their fate, transport and possible toxicity in the environment. To improve stability and prevent aggregation, surface coatings are commonly applied to manufactured nanoparticles but the physicochemical properties of these coatings will influence their behavior in natural systems. Once release in the environment, CeO<sub>2</sub> NPs will interact with abundant organic ligands. The adsorption of natural organic matter (NOM) to the surfaces of NPs is known to strongly influence their surface properties and aggregation behavior. Our objective is to investigate the role of NP surface chemistry and environmental modifications of NP surfaces in determining their aggregation, deposition as well as bioavailability and toxicity to soil dwelling organisms. To reach this objective, we synthesized 4 nm CeO<sub>2</sub> NPs coated with either neutral 10 kDa dextran (Dex-CeO<sub>2</sub>), negatively charged carboxymethyl-dextran (CM-CeO<sub>2</sub>) or positively charged diethylaminoethyl-dextran (DEAE-CeO<sub>2</sub>). We investigated the effects of exposure media (reconstituted moderately hard water; RMHW) and NOM on the point of zero net charge (ZPC) of particles with the various coatings at 100 mg/L. We found that the ZPC of the Dex-CeO<sub>2</sub> was reduced from around pH 7 to pH 6 in RMHW, but the addition of 100 mg/L fulvic or humic acid reduced the ZPC to less than pH 4. Neither the RMHW nor the NOM had much of an effect on the ZPC of the DEAE-CeO<sub>2</sub> particles (around pH 12) under the same conditions. The DEAE coated particles were much more toxic to *Caenorhabditis elegans* than the DEX and CM particles. Synchrotron based x-ray fluorescence imaging indicated that the DEAE particles were accumulated to a greater extent than the DEX particles. Spatially resolved XANES demonstrated that Ce in the particles in the exposure media were mainly in the +IV valence state, but up to 80 % of the Ce associated with the nematodes was in the +III valence state. This suggests that the mechanism of toxicity may involve oxidation of biomolecules coupled with reduction of Ce in the particles. We are currently investigating the role of NOM in altering the bioavailability and toxicity of CeO<sub>2</sub> NPs with various coatings.

**667 Transmission Electron Microscopy Evaluation of quantum dot uptake in fathead minnow ovarian explant cultures** C. Lavelle, Center for Environmental and Human Toxicology, University of Florida; K.J. Kroll, University of Florida / Physiological Sciences; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology, University of Florida / Dept. of Physiological Sciences &. The need for understanding the interactions of nanomaterials (NMs) with biological systems is evident, as their use in a variety of applications including cosmetics, electronics, and biomedicine is increasing. Of specific importance is the biological fate of NMs in aquatic organisms, particularly in fish, for which much is not yet understood. Previous research has shown that particle characteristics such as size and surface chemistry (including plasma protein coatings) influence biological fate and ultimately the overall effects. One class of NMs of interest are quantum dots (QD) which are structurally composed of a semiconductor core and shell that can be modified by the addition of different functional groups. The goal of this study was to determine what particle surface characteristics and physiological conditions allow for uptake of QDs into developing oocytes or their follicle cells *in vitro*. Oocytes were collected from mature female fathead minnows (FHM) and transferred to a 24-well plate with approximately even numbers of oocytes in each well. Media was supplemented with insulin (30ug/mL), hCG (10U/mL), and QDs (10 nM, ± plasma containing 17ug/mL vitellogenin). Oocytes were incubated for 24 hours and some cells were removed for confocal microscopy while the rest were preserved for histology and transmission electron microscopy (TEM). Confocal images of tissues following different treatments suggest that QDs may be taken up into oocytes/follicle cells *in vitro*. TEM analysis was used to confirm the localization of the QDs within the oocytes and follicle cells. Additionally, a separate exposure to primary cultures of follicle cells was conducted to validate QD uptake into those steroidogenic cells. Media from the follicle cell culture was assayed for the effects of QD exposure on 17β-estradiol accumulation. This assay has the potential to be a valuable tool in high-throughput screening of NMs that may cause direct toxicity to the oocyte or perturb the functions of the follicle cells.

**668 Effect of silver nanoparticles on freshwater systems: environmental feedbacks and population cycles** L.M. Stevenson, H. Dickson, University of California, Santa Barbara / Ecology, Evolution and Marine biology; E. McCauley, University of Calgary / Biological Sciences; R. Nisbet, University of California, Santa Barbara / Ecology, Evolution and Marine biology.

Engineered nanoparticles have the potential to interrupt basic ecosystem processes and can have cascading effects on entire communities. Further, ecosystem processes can, in turn, impact rates of aggregation and dissolution of nanoparticles. The availability of organic material, especially dissolved organic carbon (DOC), drastically alters the behavior and toxicity of citrate-coated silver nanoparticles (AgNPs) to freshwater phytoplankton (*Chlamydomonas reinhardtii*) and zooplankton (*Daphnia pulicaria*). In high-density algal batch cultures, greater concentrations of DOC lead to larger particle sizes and mitigate toxicity of AgNPs. Experimental removal of DOC results in disassociated particles and enhanced mortality of algal cells. At certain levels of exposure, initial toxicity to algal cultures is slowly mitigated by DOC over 48-72 hours, which allows for population recovery. Algal cultures that maintain high concentrations of DOC experience a second toxic effect, possibly due to a sustained increase in silver ion concentration. DOC also has a mitigating effect on toxicity to *Daphnia* – 100 µg/L concentrations of AgNPs cause 100% mortality in 48-hour acute tests in synthetic freshwater media but have no effect on *Daphnia* when DOC is added to the media. It is crucial to understand the mitigating effect of DOC on AgNP toxicity to freshwater algae and *Daphnia* considering the natural population dynamics of these two species. In both laboratory mesocosms and in the field, daphnid population growth may be cyclical with pronounced peaks in both *Daphnia* and algal populations. On average, algal population densities are low, but productivity remains high and the rate of DOC production by algae varies during fluctuations in algal abundance. Thus, mitigation of AgNP toxicity for *Daphnia* may be determined by algal population dynamics. To test the effects of AgNPs on interacting populations of *Daphnia* and algae, we developed a flow-through system and will present preliminary results from this design. By starting with experiments on algae and *Daphnia* alone, we are able to tease out direct and indirect effects of these particles in a dynamic system.

#### 669 Aquatic exposure models for nanomaterials based on empirical

**data** J. Quik, Wageningen University / Aquatic Ecology and Water Quality Management Group, RIVM / Laboratory for Ecological Risk Assessment; J. de Klein, Wageningen University / Aquatic Ecology and Water Quality Management Group; J. Spijker, National Institute for Public Health and the Environment (RIVM) / Laboratory for Ecological Risk Assessment (LER); D. van de Meent, Radboud University Nijmegen / Institute of Wetland and Water Research; A. Koelmans, Wageningen University, IMARES / Environment. Exposure modelling is an integral part of risk assessment of chemicals. Recent literature identified several nano-specific fate processes affecting their transformation and transport in the aquatic environment. The main removal processes are related to sedimentation and transformation processes such as changes in coating and heteroaggregation with natural colloids. This interaction with natural colloids is thought to have a dominant effect on the further fate of nanomaterials in aquatic systems. In this study we investigate different modelling approaches for the exposure concentration of nanomaterials in water. This is the first study to relate this to laboratory sedimentation measurements in natural water. In order to find the optimal model for estimating the exposure concentrations of nanomaterials in water we used three different modelling approaches ranging from simple first order removal rate constants to a mechanistical model linking homo and hetero aggregation kinetics based on the von Smoluchowski theory and stokes sedimentation theory. And third we use an empirical model based on laboratory sedimentation measurements of NPs in different natural waters. Preliminary results show that at low initial nanoparticle concentrations heteroaggregation is the main process resulting in removal of nanoparticles from the water phase. This varies with differences in the aggregate density. At low initial nanoparticle concentrations and with assumption that there is a much larger concentration of natural colloids present the removal from the water phase can be adequately modelled using first order removal rate constants. This general observation is in good agreement with the laboratory measurements. Further comparison of the model results to the dataset on CeO<sub>2</sub> nanoparticle sedimentation in natural waters resulted in estimating key parameters such as the attachment efficiency and fractal dimension of aggregates. A derivative of this model was further applied to a known water quality modelling framework, Duflow, to estimate exposure concentrations in a river catchment taking into account emissions from water treatment plants and deposition from land and air.

**670 Rapid settling of nanomaterials due to hetero-aggregation with suspended sediment** I. Velzeboer, Wageningen University; J. Quik, Wageningen University / Aquatic Ecology and Water Quality Management Group, RIVM / Laboratory for Ecological Risk Assessment; B. Koelmans, Wageningen University; D.v. Meent, RIVM. To date, sedimentation of engineered nanoparticles (ENPs) has been studied mainly in artificial media and stagnant systems mimicking natural waters. This neglects the role of turbulence and hetero-aggregation with sediment. This study aims at quantifying the removal rates of selected ENPs (CeO<sub>2</sub>, PVP-Ag and SiO<sub>2</sub>-Ag) in agitated sediment-water systems resembling fresh, estuarine and marine water types. Experimental systems and conditions were designed to mimic low energy and periodically resuspended sediment water systems (14 days), followed by a long term aging (6 months), resuspension and settling phase, as would occur in receiving shallow lakes. ENPs in systems with periodical resuspension of sediment are removed with settling rates as high as those for the sediment particles, e.g., 0.038 – 1.5 m/d, or > 1.5 m/d for marine waters. Higher settling rates of ~ 3 m/d are observed after 6 months of aging in the sediment bed at all salinities, which is explained from ENPs being progressively captured in sediment flocs. The removal rates are 1 – 2 orders of magnitude higher than those reported in recent stagnant aggregation-sedimentation studies. This implies that in dynamic natural waters, hetero-aggregation with suspended sediment is the rate determining step in removal of ENPs from the water column, and that aggregation efficiencies are close to one.

#### 671 Collaborative Monitoring and Data Sharing to Support the Whiting

**Fishery Bycatch** B. Bernstein, Consultant; D. Fraser, Whiting Fishery. In response to concerns about bycatch of four species of rockfish whose populations are severely depressed, the federal groundfish fishery management plan in 2010 implemented far reaching changes to the offshore (or mothership) fishery's management structure. These addressed the need to reduce the bycatch of key rockfish species but allowed the fishery to create its own approach to ensuring accountability at both the individual and fleet-wide levels while also spreading risk across the fishery's participants. The revised management plan, Amendment 21, created an overall total allowable catch (TAC) for the fishery and split this into catch shares assigned to individual participants based on catch history. The plan implemented a cap on the allowable bycatch and assigned a bycatch quota to each participant based on their assigned proportion of the whiting TAC. Because individual rockfish bycatch quotas were often extremely low (a fraction of a fish in many cases), fishermen ran the very real risk that a single unlucky tow could shut them down for the season. Amendment 21 allowed permit holders in the mothership sector to form coops and to create their own strategies for allocating quota and risk. All 37 participants joined a single coop and designed a system that depends on data sharing and collaborative management to spread risk while ensuring individual accountability. By combining all bycatch quota into a single shared pool, the coop created the equivalent of an insurance plan that allows fishermen to draw on the bycatch pool to cover unlucky tows as long as their overall performance is within well-defined limits. In addition to sharing data on whiting catch and rockfish bycatch, experienced skippers in the fleet have shared their combined knowledge to educate the entire fleet on methods for avoiding rockfish bycatch hotspots and understanding the topographic and oceanographic factors associated with increased bycatch risk. The fleet used this knowledge to voluntarily identify nine areas that were closed to whiting fishing. The coop manager has the authority to close areas with high bycatch, using a real time data submission and access system called SeaState. The whiting mothership sector provides a striking example of how performance standards can create the environment and incentives for the grassroots creation of a cooperative management and monitoring system that exceeds the performance of previous command and control management approaches.

#### 672 Development of Interagency Partnerships for Wetland Monitoring and Assessment: Lessons Learned from California

E.D. Stein, Southern California Coastal Water Research Project / Biology department; J. Collins, San Francisco Estuary Institute and Aquatic Science Center. Comprehensive wetland monitoring and assessment must meet the information needs of many agencies at all levels of government that are responsible for wetland protection. The challenges are to identify the common information needs, develop standardized and practicable methods to acquire the needed information, manage it effectively, and know when and why the needs are not being met. Technical challenges focus around development of assessment tools that can be used to readily convey information about function or

condition across a variety of wetland types in an accessible manner. However, even once such tools have been developed, program implementation involves unique challenges. In California, like many states, responsibility for wetland assessment and management is divided among many State and Federal agencies and programs (19 in California). Although the specific mandates and objectives vary among agencies, each requires information on extent and condition to gauge program and project effectiveness. This talk will summarize experiences over the past ten years in developing and maintaining interagency partnerships to facilitate comprehensive wetland monitoring and assessment. Collaborations often begin at the local/watershed level and have evolved to overall statewide partnerships that have been institutionalized through real-life management and regulatory decisions using a variety of formal and informal mechanisms. We will summarize lessons learned in terms of technical tool development, vertical and horizontal coordination, information management, and reporting.

**673 Initiate and Sustain Collaboration by Focusing on the Delivery of Information to the User** J. Marshack, California Water Quality Monitoring Council; K. Larsen, California State Water Resources Control Board. Government agencies, regulated dischargers and others spend millions of dollars annually monitoring California's water quality and aquatic ecosystems. Lacking an agency with over-arching authority to monitor and protect California's water resources, differing mandates have resulted in inconsistent monitoring objectives and methods to collect and assess the data, making it impossible to integrate information from multiple studies. And there is no single user-friendly place to access the information. Pursuant to state legislation and an agreement between the California Environmental Protection and Natural Resources Agencies, the California Water Quality Monitoring Council was established to address these problems. The Council published A Comprehensive Monitoring Program Strategy for California to coordinate the water quality and ecosystem monitoring, assessment, and reporting efforts of organizations both within and outside state government. Goals are to improve collective efficiency and effectiveness and ensure that resulting information is internet-available to decision makers and the public. Rather than focus on technical details, such as methods consistency and standard data formats, the Council presented a new solution – provide a platform for intuitive, streamlined access to information that directly addresses users' questions. Under Council guidance, collaborative theme-specific workgroups were formed, each developing an Internet portal focusing on one high-level question: Is our water safe to drink? Is it safe to swim in our waters? Is it safe to eat fish and shellfish from our waters? Are our aquatic ecosystems healthy? These are accessed from a single website [www.CaWaterQuality.net](http://www.CaWaterQuality.net). Portal development provides the context to effectively evaluate and resolve monitoring design, coordination, and data access problems – highlighting gaps and inconsistencies in monitoring and assessment methods and data management – within and between organizations. But funding and institutional barriers must be overcome. The legislation included no funding mechanism to initiate and sustain collaboration. State budget shortfalls and high agency workloads challenge implementation. While some agencies and organizations embrace the Council's vision, others avoid participation. In spite of the difficulties, a structure has been created to identify and prioritize actions and motivate improvement.

**674 Integrated Watershed Monitoring and Assessment using a Collaborative Approach: An Example from the San Diego Region** D. Gibson, L. Busse, B. Posthumus, San Diego Regional Water Quality Control Board; B. Bernstein, Consultant. The San Diego Regional Water Board is currently restructuring its monitoring and assessment programs from being discharger-oriented towards being waterbody-oriented. In order to successfully make this transition and realize credible and durable results, a collaborative process is often necessary to ensure that the monitoring and assessment programs are informed by a broad range of experience, expertise, and perspectives. Collaboration also helps to build support and buy-in for the monitoring and assessment programs that are ultimately developed and implemented. The goal of the project is to develop an integrated, coordinated and cost-effective watershed monitoring and assessment program for the San Diego River watershed. The integrated watershed monitoring and assessment program described here was based on a collaborative approach and reflects substantial consensus among a broadly representative group of stakeholders in the San Diego River watershed. The effort to develop an integrated watershed-scale assessment, and to improve the coordination and efficiency of monitoring and assessment includes several principles: (1) Shift attention toward

management of watersheds and/or waterbodies and away from management only of individual discharges and discharge types and their compliance with regulations, (2) Develop the ability to assess and describe the condition of beneficial uses and ecosystems rather than focusing only on simple indicators (e.g., concentration of a chemical constituent) or basic measures of management activity (e.g., numbers of inspections or 303(d) listings), (3) Implement the Surface Water Ambient Monitoring Program (SWAMP) Assessment Framework's call for question-driven monitoring that moves through a sequence of questions from impact assessment to source identification and then to evaluating solutions, (4) Ensure that permit-mandated monitoring programs are designed to support watershed scale assessment and management, and (5) Develop and maintain collaborative relationships with other entities and programs conducting related monitoring and assessments in the watershed. It is intended to use the integrative monitoring and assessment program approach in the San Diego River watershed as a prototype for analogous monitoring and assessments in other watersheds and/or water bodies in the region. The San Diego Water Board recently started an integrated monitoring and assessment program for San Diego's coastal wetlands.

**675 Site-specific Water Quality Objectives for Selenium in the Newport Bay Watershed: Habitat, Populations, and Protective Criteria** E. Byron, CH2M Hill / Environmental Services; G. Santolo, H. Ohlendorf, CH2M Hill; T.S. Presser, U.S. Geological Survey / Water Resources Division; S.N. Luoma, University of California Davis / John Muir Institute of the Environment, U.S. Geological Survey, University of California, Davis; J. Skorupa, U.S. Fish & Wildlife Service / Environmental Contaminants Div. Selenium is a naturally occurring element that readily bioaccumulates through the food chain and can cause adverse effects on higher-level aquatic life and wildlife. The Newport Bay watershed, Orange County, California, is an example where ambient concentrations of selenium exceed water quality objectives. Because of the importance of food-chain impacts from selenium, site-specific tissue-based water quality objectives (SSOs) have been proposed for selenium for the watershed and bay to be assessed by bird egg and fish tissue concentrations. The Upper Bay supports five threatened or endangered bird species: brown pelican, light-footed clapper rail, California least tern, Belding's savannah sparrow, and coastal California gnatcatcher. The protection of these listed species drove the selection of food-chain based tissue endpoints for the SSOs. Habitats are highly variable in this urban watershed. Many of the areas with highest concentrations of selenium in surfacing groundwater are low base-flow, channelized drains and often are completely concrete lined. They support almost no fish or bird use. As the drains join into the main channels they become permanently wetted and acquire more habitat of higher value. In several areas of the watershed, ponded water and marshes promote the formation of more bioavailable forms of selenium, with significantly increased ambient tissue concentrations. The lower watershed supports nesting of shorebirds and waterfowl along with reproducing populations of several species of fish. A biodynamic model was developed by USGS researchers to link the SSO tissue concentrations to waterborne concentrations. The model can be run to start with a water column concentration to predict fish and bird tissue concentrations, or, starting with fish or bird concentrations (the SSO tissue target values) to predict waterborne concentrations. Protective tissue concentrations for whole-body fish and bird eggs were chosen based on an extensive literature review and knowledge of the local, Newport Bay ecological receptor communities and habitat types. The Newport Bay watershed tissue targets, unlike standard EPA procedure, are USFWS's best estimates of true no effect values.

**676 Working toward Creative Solutions in Complex Environmental Disputes with Mediation** J.H. Reaves, Law Offices of John H. Reaves, APC. Old models produce prolonged conflicts. A broad range of disputes and claims go to litigation, which is adversarial, costly, and time-consuming. Multi-party contamination cases chew up obscene amounts of money in litigation instead of coordinating and working toward resolving the problem from the start. The developer of a project may be closed-minded to public input, inviting CEQA challenges, delays. An energy facility project may be overly wed to a siting location that sets up battles with the public. A utility may be disinterested in any public input for a large project or rate restructuring. A governmental agency's regulation or Notices of Violation may be uncompromising and tone-deaf to the burdens they cause. Each of these old models produces conflict, damages reputations, and results in great social and economic inefficiencies. What's changing? Mediation has become more

mainstream in business and tort litigation and encouraged by courts. The environmental and land use fields, however, are still rife with examples of expensive, protracted battles that may not be justified from a broader economic or social view. With current models, parties stake out early positions that harden with time, conflict, and expense. Scarce resources demand better use of funds to accomplish goals. We need to develop a more a new, more efficient model. What is mediation? Consensual. Mutual agreement as to role of mediator. Collaborative. Informal. Confidential. A way to keep the parties talking in structured, respectful manner. A way to put a human side, voice, and values to an adversary. It can preserve, restore, or build relationships. It provides close access to a neutral helper. It helps shape an efficient, coordinated game plan when desirable. It helps reassess conflict in terms of values, not positions. It allows a party to tell a mediator privately what hidden concerns exist. It provides parties "reality checks." It helps avoid or break impasses. It allows parties to address issues a court cannot. *90% of cases mediated get resolved.* What are the barriers? Following old models by habit. Assumptions about other party's motives. Negotiation strategy, including fear of appearing weak by being first to make overture. Business model of wearing party down by attrition. Ego, power, money. Regulatory self-image.

**677 Developing and Sustaining Successful Watershed Monitoring Programs: An Example from the San Gabriel and Los Angeles Rivers Watersheds, California** K. Morris, N.L. Steele, Council for Watershed Health;

S. Johnson, Aquatic Bioassay and Consulting Lab; P. Markle, S. Bishop, Los Angeles County Sanitation Districts. The San Gabriel River Regional Monitoring Program (SGRRMP) is the first comprehensive watershed-wide monitoring program in southern California. The SGRRMP was developed in 2004 by a diverse group of stakeholders representing major permittees, regulatory and management agencies, scientific and academic interests, and conservation groups. In 2007, the Los Angeles River Watershed Monitoring Program (LARWMP) was developed in the neighboring Los Angeles River Watershed using the same program design approach. The objectives of these programs are to increase awareness of the importance of issues at the watershed scale and to improve the coordination and integration of monitoring efforts to assess both compliance and ambient conditions. Monitoring commenced in 2005 and 2008 for the SGRRMP and LARWMP, respectively, and the results have already provided valuable information on the condition of surface waters at both the regional and sub-watershed scales. The success of these programs is attributed to the following factors: effective collaboration, leadership competence, stakeholder participation, communication of results, secure funding, and program responsiveness to emerging issues, policy and method developments. This presentation will provide examples of how these factors were incorporated into the design, phased- implementation, and continued operation of the programs.

**678 Undergraduate and Graduate Sampling Extends Blanchard River Watershed Partnership Monitoring** M.T Homsher, University of Findlay

/ Environmental Safety & Occupational Health Dept.; C.D. Norris, The University of Findlay / Chemistry Department; T. Albadran, A. Alghafey, G. Alzaabi, A. Abdulmalik, A. Khanal, S.J. Ramesh, University of Findlay / Environmental Safety & Occupational Health Dept.. Local university students have collaborated with the Blanchard River Watershed Partnership (BRWP) since 2005. Past activities have included Spring and Fall river cleanup by 40-60 students and faculty volunteers coordinated with the Blanchard Watershed Partnership. The Total Maximum Daily Loads (TMDL) of the Clean Water Act requires water quality and physical parameter monitoring. Students from the University of Findlay Environmental Safety and Occupational Health program initiated phosphorus, nitrate/nitrite, temperature, pH, DO, conductivity, barometric pressure, GPS coordinates, depth, width and flow rate determination. In 2011, the Blanchard River and its sub-watersheds were identified as the largest contributors of phosphorus and sediment to the Great Lakes. We responded to this concern in Ohio with harmful algal blooms, by engaging the issue with increased monitoring in Spring, Summer, and Fall 2011 with the support of a GLISTEN grant. Spring 2012 sampling and analysis was supported by The University of Findlay. Our preliminary Spring 2012 samples indicate lower loading of phosphorus, and sediment associated with less frequent rain and fewer inches of rainfall to date. Average phosphorus loadings in Summer 2011 for nine sites was 0.19 mg P/L, however sites adjacent to horse farms and failing septic systems averaged 0.27 mg P/L just below an advisory threshold of 0.30 mg P/L.

**679 Effect of activated carbon amendment and bioturbation on sediment-to-water fluxes of polychlorinated biphenyls and polycyclic aromatic hydrocarbons** D. Kupryianchyk, Wageningen University / Aquatic Ecology and Water Quality Management Group; A. Noori, M. Rakowska, T. Grotenhuis, Wageningen University; A. Koelmans, Wageningen University, IMARES / Environment. Aquatic sediments are recognized to be an ultimate sink for hydrophobic organic contaminants (HOCs) like polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs). Several processes, like diffusive transport, sediment resuspension or bioturbation, cause the release of HOCs from the sediment bed into the overlying water column. This may pose a risk to the aquatic foodweb. The contaminated mass release (flux) from the sediment bed to water interface can be described as a product of the concentration gradient between pore water and overlying water and an aqueous mass transfer coefficient,  $K_L$ . Amendment of contaminated sediment with activated carbon (AC) is meant to reduce HOC sediment-to-water fluxes. The effect of bioturbation and effectiveness of different AC treatments, however, is unknown. Moreover, it is not clear how the effects of bioturbation and AC on sediment-to-water fluxes do interfere. The aim of this study was to estimate mass transfer of PCBs and PAHs from naturally contaminated sediment that was treated in three ways: (i) capping with powdered AC (SAE Super, Norit), (ii) mixing with granular AC (1240W, Norit), and (iii) mixing with granular AC with subsequent removal of granules (sediment "stripping"). Mass transport of HOCs may be affected by biological activity in the sediment, so the effect of bioturbation by *Lumbriculus variegatus* and *Asellus aquaticus* was assessed for all three scenarios. Sediment-to-water fluxes were measured by a flux method using Empore disks as a sink for HOCs in the overlying water. For 19 PCBs studied (logKow 5.18–8.18),  $K_L$  values ranged from 0.04 to 2.5 m/d in non-bioturbated systems. The most effective AC treatment in terms of reducing PCB release from the sediment bed to overlying water was sediment capping with powdered AC, followed by sediment "stripping" with GAC and sediment mixing with GAC. Non-AC amended systems with tubificids showed apparent  $K_L$  values that were a factor of 100–200 higher than those in non-turbated systems. Biological activity of *L. variegatus* had lower effect on  $K_L$  than that of *A. aquaticus*. However, in the presence of PAC and GAC, *L. variegatus* did not cause an increase in mass transfer coefficients. This suggests that sediment amendment with AC reduced mass transfer due to strong binding of PCBs to AC, but at the same time reduced mass transfer of contaminants due to a decrease in bioturbation activity.

**680 Effect of activated carbon amendment for the treatment of parent- and alkylated-PAHs in a petroleum-impacted sediment under stagnant conditions** Y. Choi, Stanford University / Department of Civil

and Environmental Engineering, Stanford University; Y. Cho, R.G. Luthy, Stanford University / Department of Civil and Environmental Engineering. Activated carbon (AC) amendment is a promising in-situ remediation technology for the treatment of sediments contaminated with hydrophobic organic contaminants (HOCs). However, pilot-scale field studies have shown that the AC performance under field conditions may not be as readily apparent as what was observed in laboratory tests under well-mixed conditions. This is mainly because of the limited HOC mass transfer in the field during stagnant AC-sediment contact. The effect of various field conditions on AC efficacy in the field, including initial mechanical mixing, AC distribution in sediment matrices, AC particle size ranges, and pore-water movement remains poorly understood. In this study, we conducted a series of column experiments using a petroleum-impacted sediment to test the effectiveness of AC under stagnant conditions with various AC application scenarios. Our test compounds include not only parent polycyclic aromatic hydrocarbons (PAHs) but also alkylated PAHs, which are of major concern in petroleum impacted sediments. After 1 month of no-flow condition, the sediment columns amended with 75–150  $\mu\text{m}$  AC (5% dry sediment wt) with 2 minutes of initial mixing showed 60% reduction in total PAH uptake in polyethylene (PE) samplers compared to the no-AC control columns. The amount of reduction in the columns was smaller than that in a parallel test under well-mixed condition, which showed 87% reduction in PAH uptake. The observed reduction in the columns was significantly increased to 91% using a smaller AC size fraction (< 45  $\mu\text{m}$ ). When AC was applied as layers with a distance of 2 cm, the AC performance was not evident. This indicates that the distribution of AC into the sediment matrix is an important factor for the treatment performance. As sediment-AC contact time increases, the AC performance was improved. For example, for the no-flow sediment columns with 75–150  $\mu\text{m}$  AC with 2 minute mixing, the reduction increased

from 60% to 81% after 6 months of sediment-AC contact. The effect of pore-water movement was observed only for an initial short time period (i.e., one month), showing that pore-water movement is a minor factor for AC performance and becomes less important as contaminant mass transfer proceeds. The results of this study systematically show the effects of various field conditions on the effectiveness of AC amendment for the treatment of parent and alkylated PAHs.

**681 Reducing PCB bioavailability at a Canadian Brownfield site with biochar and activated carbon** B.A. Zeeb, Royal Military College / Chemistry & Chemical Engineering Dept.; M. Denyes, The Royal Military College of Canada; A. Rutter, Queen's University / School of Environmental Studies. In recent years, studies have focused on the use of activated carbon (AC) to sorb persistent organic pollutants (POPs) in aquatic sediments, and to a lesser extent in terrestrial soils. However, little data exists on the potential of using biochar for this same purpose. A preliminary greenhouse experiment, carried out in contaminated polychlorinated biphenyl (PCB)-contaminated soil (Aroclors 1254/1260), indicated that biochar added at 2.8% (by weight) to soil reduced shoot and root concentration in the known phytoextractor *Curcubita pepo* ssp. *pepo* (pumpkin) by up to 23% and 77%, respectively. Biochar also reduced the PCB concentration in *Eisenia fetida* (redworm) tissue. A subsequent field-scale study was conducted at a Canadian Brownfield site contaminated with >50 µg/g Aroclor 1254/1260 using two types of biochar added at 2.8% (by weight). In this trial, granular AC (GAC) was added at 2.8% to serve as a positive control and compare the efficiency of biochar to GAC in reducing the uptake of PCBs. Results indicate that biochar amendments significantly decreased the bioavailability of PCBs to *C. pepo* at rates comparable to GAC. Biochar also reduced PCB uptake into *E. fetida* tissue at rates not significantly different from GAC. An identical study is currently being carried out at a dichlorodiphenyltrichloroethane (DDT)-contaminated site (10.2 µg/g DDT), and results will be compared between these two contaminants. A complementary greenhouse study was conducted to evaluate the extent to which the type of mixing (i-manual and ii-soil tumbling) influences the reduction in PCB-bioavailability. Preliminary results show that reduced PCB-bioavailability does not depend on the type of mixing when the soil amendment is biochar. However, when mixing GAC into soils, reduction in PCB-bioavailability is less apparent when soil is manually mixed. Overall, these results show that biochar has potential to serve as an amendment to decrease the bioavailability of organic contaminants in the soil, and may serve as a technology for remediating Brownfield sites.

**682 Importance of black carbon on PCB sediment pore water concentrations and soluble sediment release of PCBs from Indiana Harbor and Ship Canal** A. Martinez, University of Iowa / Department of Civil & Environmental Engineering, and IIHR-Hydroscience and Engineering, The University of Iowa / Dept Civil and Environmental Eng.; C. O'Sullivan, The University of Iowa / Dept of Chemical and Biochemical Engineering; D.D. Reible, The University of Texas-Austin, University of Texas / Environmental and Water Resources, The University of Texas at Austin / Dept. of Civil & Environmental Eng.; K.C. Hornbuckle, University of Iowa / Department of Civil & Environmental Engineering, IIHR-Hydroscience and Engineering. In general, freely dissolved sediment pore water concentration of persistent organic pollutants (POPs) have been related to bioavailability, which has been shown to be reduced by adding a strong sorbent into the sediment. Here, we try to address another important aspect of freely dissolved sediment pore water concentration, soluble release of POPs from the sediment to the overlying water and how the black carbon present in the sediment affect the release. Polychlorinated biphenyls (PCBs) in bulk sediment from Indiana Harbor and Ship Canal (IHSC), a tributary of Lake Michigan, are among the highest in the Great Lakes region (median ~11000 ng g<sup>-1</sup> dw). In addition, the system also has very high values of black carbon (~30% of total organic carbon). IHSC will be dredged in the near future, and it is unclear if the dredging could decrease or increase the levels of PCBs in this system, although deeper sediments present higher PCB bulk concentrations. Freely dissolved sediment pore water concentrations of PCBs were measured using SPME PDMS-fiber in two cores and ranged from 9 to 1500 ng L<sup>-1</sup> (sum of 209 congeners as 161 peaks). These values are as 60-fold lower than estimations from organic carbon normalized partition coefficients ( $K_{PCB_i, OC}$ ). Hence, black carbon was included into a dual-carbon model which better predicted the PCB solid-water distribution coefficients. The new dual-carbon model was also used to predict PCB mass transfer coefficients

for the sediment-water flux. Our findings indicate that the release of PCBs from IHSC sediments is likely to increase after dredging but the presence of black carbon has a dampening effect on that increase: the presence of black carbon increases the mass transfer coefficient but lowers the sediment to water concentration gradient.

**684 Assessment of secondary biological responses to activated carbon amendment in Grasse River, NY: benthic community and submerged aquatic vegetation** B. Beckingham, University of Tuebingen / Civil & Environmental Engineering, University of Maryland Baltimore County / Department of Civil & Environmental Engineering, University of Tuebingen / Department of Geoscience, University of Tuebingen / Center for Applied Geoscience; U. Ghosh, University of Maryland Baltimore County / Civil & Environmental Engineering, University of Maryland Baltimore County / Department of Chemical, Biochemical, and Environmental Engineering, University of Maryland Baltimore County / Chemical, Biochemical, and Environmental Engineering. Activated carbon (AC) amendment is an innovative in situ remediation strategy for contaminated soils and sediments. One of the few field studies to date, the lower Grasse River pilot-scale AC amendment study has demonstrated in 3 years of post-application monitoring significantly reduced bioaccumulation in benthic invertebrates, reduced aqueous pore water concentrations and reduced potential for flux to the overlying water column. Importantly, in addition to understanding the variables influencing the effectiveness in reducing contaminant exposures to aquatic ecosystems, it is necessary to evaluate the other potential direct or indirect biological responses to AC amendment before this strategy can be widely adopted for sediment management. Therefore, the objectives of the present study were to assess the potential secondary effects of AC amendment to Grasse River sediments by monitoring changes in benthic community structure at field application sites, and additionally, by laboratory testing for growth effects to a submerged aquatic vegetation species, *Elodea canadensis*. The present study did not find adverse effects to benthic community structure following sediment amendment with AC in the field, yet reduced growth in *E. canadensis* was observed. The results of the test indicate that while the plants continued to grow in sediment freshly amended with AC, the growth rate was slower compared to control sediment at AC dose ≥5% dry weight. Plant growth with amendment of pine wood biochar was also significantly reduced compared to the sediment control at this dose level, which was surprising given that biochar is often cited as having beneficial effects in soil. Also interestingly, growth was reduced to a similar extent with amendment of an inert material, perlite. This demonstrates that sediment volume dilution and reduction in nutritional quality may be a key mechanism for reduced plant growth. Conclusions drawn from other published laboratory toxicity studies or field surveys have been variable and there is a need for further study into the mechanisms and factors influencing potential effects. If activated carbon amendment negatively affects ecosystem health it is clear that these effects would be organism-, system- and site-specific, and that the relative benefit of the amendment would depend on the risks posed by the contaminants present.

**685 Effects of thin-layer capping with carbonaceous materials on benthic macrofaunal communities – The other side of the coin** J. Gunnarsson, Stockholm University / Dept of Systems Ecology; G. Samuelsson, C. Raymond, Stockholm University / Dept of Systems Ecology; M. Schaanning, Norwegian Institute for Water Research / Marine Contaminants; G. Cornelissen, E. Eek, Norwegian Geotechnical Institute / Environmental Engineering. Remediation of contaminated sediments *in situ* using thin-layer capping with carbonaceous materials (CM) such as activated carbon (AC) is a recent technique that has proven successful in reducing the bioavailability and sediment-to-water transfer of hydrophobic organic compounds e.g. PCBs, PAHs and dioxins by several orders of magnitude. Thin-layer capping with CM could thus offer an efficient remediation technique, especially in larger contaminated areas, where conventional capping or dredging is not an option. A prerequisite to any remedial action for a successful environmental management is that its benefits for reducing contaminant fluxes do not concomitantly lead to a worsening of the ecological status of the ecosystem by e.g. having a long-lasting negative impact on the macrobenthic community structure and functioning. Most capping studies with CM have reported no or mild effects on benthic organisms. These studies, however, have generally been done in laboratory conditions or in severely contaminated field sediments with disturbed communities. In our studies we have tested the effects of various CM and mineral capping materials on marine coastal benthic

communities using mesocosms with undisturbed sediments and native fauna, and using field studies in the Trondheim harbour and the Grenland fjord. Structural changes in benthic communities (abundance, diversity, biomass) following capping were studied using a suite of univariate and multivariate techniques. Several biotic indices were also used for comparison of ecological status between capped and uncapped areas. Our studies show that capping with mineral materials only (e.g. clay, sand, limestone) usually have only mild and short-lived effects, whereas capping with AC have a significant negative impact on the benthic communities (ca 50 % reduction in species abundance and diversity). The severity of the effects of activated carbon also increased with time, i.e. two years after amendment. Here we summarize our major results on the effects of thin-layer capping on benthic macrofaunal communities and advocate that further ecological assessment and long-time monitoring of the effects of capping with CM on benthic communities are needed before this technique can be recommended.

**686 Effects of in-situ sorbent amendment on soil microbiology and pollutant biodegradation** D. Werner, Newcastle University / Civil Eng. and Geosciences; P. Meynet, K.M. Bushnaf, Newcastle University; R. Davenport, Newcastle University / School of Civil Engineering and Geosciences. Addition of strong sorbents to polluted soils is a novel remediation approach. To understand the long-term benefits, one needs to consider side-effects on the pollutant biodegradation. We therefore investigated the effects of 2% by weight coal-derived activated carbon (AC) in granular or powdered form (GAC or PAC) or wood-derived biochar on soil microbiology. Our results show that the pollutant biodegradation in soil is a complex function of many variables including the pollutant bioavailability which is reduced by sorbent amendments. However, the pollutant bioavailability is not always the rate-limiting factor. Batch and column studies with volatile petroleum hydrocarbons (VPHs) and sandy soils showed nutrient limited biomass growth on VPHs added as vapour or liquid phase to soil with or without biochar. Biomass yields were reduced by biochar amendment, but CO<sub>2</sub> production was comparable with and without biochar addition. The predominant bacterial community structure derived from denaturing gradient gel electrophoresis (DGGE) showed an abundance of *Pseudomonas* sp. and was differentiated in response to both, VPHs and biochar addition. Biochar amendment impacted soil microbial ecology through compound-specific changes in VPH availability and corresponding shifts in VPH consumption. In contrast, AC markedly reduced the availability of all VPHs, and CO<sub>2</sub> production was still notable, but comparably low in AC amended soil. We also investigated AC effects on the microbial community structure and functioning in outdoor lysimeter trials of polycyclic aromatic hydrocarbon (PAH) polluted soil remediation. In this instance, total microbial cell counts and respiration rates measured after 3 years were highest in GAC amended soil. The predominant bacterial community structure was not greatly affected by PAC or GAC amendment, and taxa with closest affiliations to known PAH degraders (*Mycobacterium* sp., *Rhodococcus jostii* strain RHAI, *Sphingomonas* sp., *Rhodococcus erythropolis*) remained or even increased in abundance in soil following AC amendment. We suggest that these putative PAH degraders were capable of using low concentrations of a variety of carbon substrates for their growth and maintenance, and hence were able to persist in the unamended, GAC and PAC amended soil despite very low PAH availability. The effect of biodegradation on PAH availability was most notable in unamended soil, while the lowest PAH availability overall was measured in PAC amended soil.

**687 Early Warning Program to Detect and Identify Contaminants of Emerging Concern and Their Effects to Fish and Wildlife** Z. Jorgenson, US Fish and Wildlife Service / Aquatic Toxicology Laboratory, U.S. Fish and Wildlife / Environmental Contaminants; J. Berninger, Baylor University / Department of Environmental Science; L.R. Iwanowicz, United States Geological Survey / Leetown Science Center; K. Lee, US Geological Survey; S. Choy, USFWS / Environmental Contaminants; J. Moore, Michigan State University, Wildlife Toxicology Laboratory / Dept. of Animal Science; J. Banda, D. Gefell, U.S. Fish and Wildlife Service; L.M. Thomas, US Fish and Wildlife Service / Mid-Continent Ecology Division; E. Durhan, US EPA / Mid-Continent Ecology Division, US-EPA / Research Chemist; M. Kahl, U.S. EPA / National Health and Environmental Effects Research Laboratory; P. Mazik, West Virginia Cooperative Fish and Wildlife Unit; V. Blazer, National Fish Health Research Laboratory / USGS; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; G.T. Ankley, US EPA / Office of Research and Development,

National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory. The Great Lakes basin provides an opportunity to investigate impacts to fish and wildlife from various natural and anthropogenic influences, particularly within Areas of Concern (AOC). While AOC beneficial use impairments related to chemical pollution largely encompass legacy contaminants (metals, PAHs, PCBs), many AOCs also contend with contaminants of emerging concern (CEC), such as endocrine active compounds and pharmaceuticals, where little is known about concentrations or effects. Our study explores the current concentrations of over 150 select CECs within AOCs and the potential biotic impacts to resident fish populations, naïve laboratory fish caged *in situ*, and *in vitro* bioassays. Surface water, sediment and resident fish samples were collected at multiple sites within seven AOCs. Laboratory reared fathead minnows (*Pimephales promelas*) were exposed *in situ* at five of the AOCs. Water and sediment samples were analyzed for select pharmaceuticals, hormones, and other inorganic and organic wastewater indicators. Resident fish were weighed, measured, bled and necropsied in the field. A suite of bioindicators were assessed to evaluate general and reproductive fish health. Samples from caged fathead minnows were used to both evaluate targeted endpoints associated with reproductive endocrine adverse outcome pathways (AOPs) using several apical measurements and to conduct unsupervised transcriptomic and metabolomic assessments. *In vitro* assays were conducted concurrently with the wild fish collections and the caged fish studies. Results from all analyses will be interpreted based on a variety of factors, including: geographic differences in CEC concentrations and effects in fish, the relationship between the combination of CEC concentrations and effects in fish, and possible sources of contamination. Results will contribute to our understanding of how different landscapes influence varying concentrations and composition of CECs across the Great Lakes basin along with how exposure to these compounds may affect fish and wildlife.

**688 Are endocrine active chemicals present and affecting resident fish in the Great Lakes basin? A reconnaissance study** L.R. Iwanowicz, United States Geological Survey / Leetown Science Center; V. Blazer, USGS; C. Hahn, R. Braham, West Virginia State University; H. Walsh, A. Sperry, West Virginia University Research Corporation. Contaminants of emerging concern (CECs) include endocrine active chemicals (EACs) and are commonly found in aquatic ecosystems at measureable concentrations. A multiagency project is progress in the Great Lakes basin to evaluate the significance of such chemicals. One of the many objectives of this research is to determine if CECs are present and associated with biological effects in resident fish populations. Resident fish species included in this reconnaissance study are the pelagic small- and largemouth bass, and the benthic brown bullhead and white sucker. Physiological and anatomical biomarker metrics indicative of estrogenic EDC exposure including gonadosomatic indices, gonad histology and plasma vitellogenin were evaluated. In addition, next generation sequencing technologies were employed to identify biomarker genes in these non-model species. Expression analysis was conducted to compliment physiological and microscopic pathology data as well as expression analyses of caged fathead minnows performed by others at selected sites. Nuclear receptor bioassays were used to identify the presence of EAC activity at all sample sites. Here we present biological data from the fall of 2010 and spring of 2011 field collections. Measureable vitellogenin was detected in a number of male fishes, and intersex was observed in male smallmouth bass. Nuclear receptor agonist activity was detected in grab water sample extracts from a number of sites as well. The significance of these and other findings will be discussed.

**689 Pathway level impacts of in situ exposure of fathead minnow to effluent mixtures in the Duluth harbor** N. Vinas, Mississippi State University; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; L. Escalon, US Army Engineer Research and Development; T. Habib, BTS; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory; E. Durhan, US EPA / Mid-Continent Ecology Division, US-EPA / Research Chemist; M. Kahl, U.S. EPA / National Health and Environmental Effects Research Laboratory; K. Jensen, US EPA; J. Cavallin, U.S. EPA, ORISE / National Health and Environmental Effects Research Laboratory; J. Berninger, Baylor University / Department of Environmental Science; E.J. Perkins, US Army

Engineering Research & Development / Environmental Laboratory, US Army ERDC / Environmental Processes & Effect Division, US Army Engineering Research & Development / Environmental Genomics and Genetics Team. There is a major effort to characterize the potential adverse effects of effluents released from sewage treatment plants in North America. At many locations pharmaceuticals, endocrine disruptors, and other chemicals of emerging concerns are present in the environment at concentrations capable of altering physiological processes in wildlife. In order to elucidate the effects of sewage treatment plants on wildlife, fathead minnows were caged in situ at several locations at the Duluth (MN) harbor, proximal and distal from the wastewater treatment plant discharge location. Fish were also exposed in the laboratory to 100% of effluent as a positive control. Several endpoints such as steroid hormones, vitellogenin, transcriptomics and metabolomics were analyzed. We applied a pathway level approach to understand the effects of the discharge as well as the potential dilution of the adverse effects at distal locations. Effects on gene expression were very similar for the different locations, with a higher amount of changes for the 100% effluent and the higher intensity for fish exposed to locations closer to the discharge site. Changes in gene expression were involved in pathways related to cytochrome P450s, hypoxia inducible factor, neurological function, or embryonic development among others. While distance from the discharge site decreased the effects on gene expression, pathway analysis was very effective in detecting the potential adverse effects of the discharge.

**690 Taking Metabolomics to the Field: A Pilot Study in a Great Lakes Area of Concern (AOC)** D.R. Ekman, US EPA / National Exposure Research Laboratory; D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; Z. Jorgenson, US FWS; K. Lee, USGS; D. Skelton, Q. Teng, E. Durhan, K. Jensen, M. Kahl, J. Cavallin, G. Ankley, T. Collette, US EPA. Measurement of changes in endogenous metabolites via <sup>1</sup>H-NMR-based metabolomics has shown great potential for assessing organisms exposed to environmental pollutants, and thus could aid the efforts of risk assessors. However, to date, the application of metabolomics to ecological studies (i.e., eco-metabolomics) remains relatively uncommon. Rarer still is the application of eco-metabolomics outside of controlled laboratory settings, such as in the study of wild or cage-deployed organisms. With this in mind, we have been working to apply metabolomics technologies to analyze samples from organisms exposed in the field as a means to assess the health of surface waters receiving effluent from waste water treatment plants (WWTPs). Presented here are the results of a pilot metabolomics study conducted in the St. Louis River AOC, one of 43 Great Lakes AOCs. We report on the impact of exposures on the liver metabolome of caged fathead minnows (*Pimephales promelas*) at various sites, including areas receiving treated effluent from WWTPs within this AOC. These sites are characterized by complex mixtures of anthropogenic chemicals (i.e., multiple stressors) as well as other stressors characteristic of urban influenced surface waters. The impact of exposure on the metabolite profiles of the caged fathead minnows showed what appeared to be a proximity effect in which those deployed more closely to the effluent outflow responded more severely than those deployed more distally. Furthermore, the impact of exposure appeared more drastic for female fish than male fish, highlighting the importance of assessing sex dependent responses. In addition to metabolomics measurements, a variety of other molecular indicators as well as apical, whole organism endpoints have been collected from the deployed fish. Our goal is to integrate these multiple measurements in order to better track/understand fish responses resulting from exposure to the multiple stressors present in these waterways, and ultimately to assess the success of remediation efforts across multiple Great Lakes AOCs.

**691 The effect of temperature on copper kinetics in *Folsomia candida* (Collembola)** D.M. Jevtic, Jagiellonian University / Institute of Environmental Sciences; J.B. Schmidt, Roskilde University / Department of Environmental, Social and Spatial Change; N.T. Hamda, Jagiellonian University / Institute of Environmental Sciences, Jagiellonian University / Environmental Sciences; R. Laskowski, Jagiellonian University / Institute of Environmental Sciences. The importance of temperature in (eco)toxicological tests has been long recognized. Still, ecological risk assessment (ERA) protocols are based on tests conducted in one constant temperature. This approach lacks ecological realism and possibly leads to erroneous conclusions on effects of temperature in natural environments. On the other hand, understanding toxicokinetic processes and applying toxicokinetic models to the analysis of (eco)toxicity data is one of the most useful approaches in

linking the effects of toxicants over different levels of biological organization. In this study individuals of springtail *Folsomia candida* were exposed to copper-spiked OECD soil (500 mg/kg dry wt) under five different temperature regimes – two fluctuating and three constant temperatures. Fluctuating regimes represented daily fluctuations – high (from 9°C to 26.5°C) and moderate (from 15°C to 25°C). Constant temperatures corresponded to 15°C, 19.5°C and 25°C. The constant temperature of 19.5°C was chosen based on equalizing organisms' daily energy budgets with fluctuating regimes, taking into account that metabolic activity does not follow a linear relation with temperature. The time-dependent internal concentration of copper was measured at ten time points during the exposure phase (28 days) and at four time points upon transfer to an uncontaminated soil (14 days). Accumulation ( $k_a$ ) and elimination rate constants ( $k_e$ ) were estimated by fitting the time course of internal concentrations with a one compartment first-order toxicokinetic model. Our results indicate that copper kinetics in fluctuating environments follows the similar pattern compared to the corresponding constant temperature. In addition, accumulation and elimination rates were higher in 25°C compared to other tested temperature regimes, suggesting that ecotoxicological tests conducted in one single temperature may question the relevance of ERA predictions. In order to reduce the uncertainty in current ERA approaches, methods have to be revised – either by measuring toxic effects under naturalistic thermal conditions, or by developing and applying appropriate mechanistic effect models able to accurately predict toxic effects in different temperature regimes.

**692 Use of Microarrays in Linking Biological Pathways with Adverse Outcomes in fathead minnows as a result of multiple stressors across varying Landscapes** J.P. Crago, Great Lakes WATER Institute, University of Wisconsin-Milwaukee, / Student; R. Klaper, University of Wisconsin-Milwaukee / School of Freshwater Sciences, University of Wisconsin-Milwaukee / Great Lakes Water Institute. In the natural environment, fish are continually exposed to a wide variety of contaminants that can exert deleterious effects on egg production through additive or synergistic effects. Although previous studies have used microarrays to obtain expression profiles for streams with varying contaminant loads, there are few studies that tie a change in gene expression profiles to adverse reproductive outcomes, such as egg production, in the field. This study looked at 17 streams that varied in their surrounding landscape conditions and stressors. Impacts of degree of urbanization and contamination were evaluated using reproductive success in fathead minnows as an apical endpoint in conjunction with individual molecular biomarkers and microarray measurements of global gene expression patterns. The goal was to: 1) determine the impacts of multiple stressors from different landscapes on reproductive success and gene expression 2) determine whether individual molecular biomarkers or specific gene expression profiles from microarrays were associated with egg production across streams with varying landscape patterns and contaminant impacts; and 3) determine which specific water- and sediment-quality constituents were associated with the mRNA expression profiles. For the first part of the study, liver vitellogenin mRNA was shown to be useful as a short-term biomarker for egg production but its limits as a biomarker over longer periods. Microarray data revealed that there were 20 transcripts that were significantly differentially expressed in male fathead minnows in rivers where low egg production occurred. Functional analysis indicates that 12 of the 20 differentially expressed transcripts were associated with oxidative stress (8 down-regulated and 4 up-regulated). The eight down-regulated transcripts are associated with the thioredoxin pathway and selenium production. The down-regulation of the thioredoxin pathway is associated with methyl mercury, cadmium and to a lesser extent arsenic exposure. Two of the four up-regulated transcripts were associated with chromatin remodeling and DNA repair in response to cellular oxidative stress. These results indicate that oxidative stress from a variety of heavy metal exposure in these streams could play an important role in reproductive success.

**693 Comparing Effects of Complex Mixtures versus Single PCBs: Functional Outcomes of Exposure in Field and Lab Studies** M. Ottinger, University of Maryland / Department of Animal and Avian Sciences; T. Carro, University of Maryland / Animal Science; M.E. Barton, University of Maryland / Animal and Avian Sciences; L.A. Baltos, University of Maryland; K. Dean, University of Lethbridge / Neuroscience, University of Maryland / post-doctoral research fellow. Environmental exposure to endocrine disrupting chemicals (EDCs) often involves complex mixtures. Most studies have focused on acute effects, with little attention to non-lethal effects. We have

been investigating biological effects of a range of EDCs in laboratory studies on Japanese quail; embryonic exposure to a range of EDCs affected neural systems, immune response, thyroid and reproductive axes, and impaired male reproductive behavior. Recent studies have focused on polychlorinated biphenyls (PCBs) in Japanese quail and tree swallows; treatments included single congeners (PCB 126, PCB 77) and complex PCB mixtures. Eggs were injected with concentrations that bracketed those found in eggs in contaminated regions. Results showed dose dependent lethality for PCB 126 and the complex PCB mixtures. All impacted organ indices and physiological systems. However, PCB 77 did not impact lethality. This suggests that the predictive value of the Toxic Equivalency (TEQ), based on activation of the aryl hydrocarbon receptor (AhR) may not be sufficient for some compounds, such as endocrine disrupting compounds (EDCs). Other approaches have been developed to address inconsistencies in effects and to incorporate diverse data into the potency estimates. Perhaps it is time to develop a more inclusive estimation method for endocrine and neuroendocrine effects. An Endocrine Disruption Index (EDI) would complement other indices, and focus on endocrine disruption with consideration of effects beyond those mediated solely by the AhR for a comparative assessment of non-lethal EDC effects. Initial approaches in developing this index will be discussed. In summary, testing our laboratory findings in field birds has required considerations in methodologies and measurements, including field injections with continued parental incubation, consideration of environmental conditions, and assay of physiological markers of health and fitness. As such, there are some issues that must be considered when interpreting findings from laboratory and field studies, especially relative to biological actions of complex mixtures. The conclusions and opinions presented here are those of the authors, they do not represent the official position of any of the funding agencies, the Hudson River Trustees, or the United States.

**694 The estimation, confirmation, and management of risk at multiple biological scales with multiple stressors for the South River watershed.**

**Virginia USA** W.G. Landis, Western Washington University, Institute of Environmental Toxicology, Western Washington University / Institute of Environmental Tox. & Chem.; K.K. Ayre, Western Washington University; M.G. Cains, A.J. Markiewicz, H.M. Summers, J. Stinson, Western Washington University / Institute of Environmental Toxicology. We have now completed a regional risk assessment using Bayesian networks for the South River, VA. Historic industrial activities in Waynesboro, Virginia from 1929 to 1950 resulted in mercury contamination of the South River. Despite the time that has elapsed from cessation of the mercury release, Hg concentrations remain in the river, fish and wildlife. In addition to the Hg there are also additional stressors such as organic contaminants, suspended solids, nutrients, temperature and pesticides. We have calculated risk to fish, birds, amphibians and water quality from just upstream of Waynesboro to its confluence to form the Shenandoah River. The risks to organisms were calculated using levels of stressors that would affect successful reproduction of the population. The water quality parameters are based on water quality criteria and impacts to ecosystem services such as recreation. The Bayesian networks reflect causal pathways, incorporates the broad array of data and expert judgment available for the site. The networks also represent interactions at a number of biological scales. Our risk calculations demonstrate the importance of including multiple stressors, both chemical and physical and over a number for scales in order to calculate risk. While Hg is important for many endpoints, other factors such as turbidity and temperature are critical to maintaining important populations and ecosystem services. We also demonstrate how our risk assessment predictions can be confirmed by examining the patterns of risk throughout the spatial extent of the watershed and by examining different biological and ecological scales. Our results demonstrate that methods need to be developed that examine shifts in probability distributions, especially as management of toxics and nutrients are applied to the system. Subtle changes to the landscape seem to be more important than drastic alterations to only a few features.

**695 Use of Alkyl Polycyclic Aromatic Hydrocarbon Data in Evaluating the Contribution of Pavement Sealers to Urban Sediments** K. O'Reilly, J. Pietari, P. Boehm, Exponent. Environmental forensic studies have resulted in conflicting conclusions about the relative importance of pavement sealers as a source of polycyclic aromatic hydrocarbons (PAHs) in urban sediments. Published work has been based primarily on the chemistry of the priority pollutant PAHs. This limited number of constituents makes it difficult to separate similarity between sources from actual causation. Inclusion

of an extended list of alkyl PAHs and related hetero-compounds allows for more refined comparisons among sources and between sources and receptors. In this presentation, the results of a forensic investigation of urban sediments based on extended PAH data will be discussed.

**696 Role of Coal Tar-based Sealants in the Source Apportionment of PAHs in Urban Stormwater Pond Sediments** J.L. Crane, Minnesota Pollution Control Agency / Env. Analysis & Outcomes Div.. Municipalities in the Minneapolis—St. Paul, MN (Twin Cities) metropolitan area have discovered high concentrations of PAHs in some of their stormwater pond sediments prior to routine maintenance dredging. This situation can lead to more expensive disposal options when the benzo[a]pyrene (B[a]P) equivalents exceed Minnesota's human health risk-based Tier 2 Soil Reference Value (SRV) of 3 mg/kg. To address this issue, a study of surficial sediments in 15 stormwater ponds from the Twin Cities area was conducted to determine concentrations of 41 parent and carcinogenic PAHs (p-cPAHs) and 34 parent and alkylated PAHs (p-alkPAHs). Environmental forensic techniques were used to determine sources of PAHs in composite sediment samples collected from each pond. The p-alkPAH data set was used to determine mean PAH source categories as follows: 82.6% pyrogenic (combustion-related), 15.0% petrogenic (petroleum-related), and 2.4% diagenic (natural) sources. The U.S. Environmental Protection Agency's (EPA) Contaminant Mass Balance 8.2 (CMB8.2) receptor model was used to apportion sources of PAHs in sediment samples using a common subset of PAHs from the p-alkPAH and p-cPAH data sets, as well as from a separate stormwater pond study from the Twin Cities area (i.e., Met Council data set from Polta et al. 2006). For the p-alkPAHs, the model performance results were exceptionally good, and acceptable results were obtained for the other two data sets as well. The allocation of PAHs was dominated by the sum of coal tar-based sealant dust and scrapings (i.e., CT-sealant sum) for the p-alkPAH, p-cPAH, and Met Council data sets as 70.5, 67.6, and 69.4%, respectively. These results were comparable to Van Metre and Mahler's (2010) result of 72.2% CT-sealant dust from their use of the CMB8.2 model on a Twin Cities area lake. The CMB8.2 model was also run to exclude CT-sealant source profiles to further test whether CT-sealants are an important source of PAHs in Minnesota's stormwater ponds; the model supported their importance. The model results for p-alkPAHs were extrapolated based on all 34 PAHs to show CT-sealants were the most important source of PAHs (58.2%), followed by petrogenic PAHs (15.0%), and vehicle emission sources (14.7%). The p-cPAH data set was used to calculate B[a]P equivalents two ways, including using proposed EPA relative potency factors, and the results were compared to the Tier 1 and 2 SRVs to evaluate disposal options for dredged material from these ponds.

**697 Acute Toxicity of Runoff from Coal-Tar- and Asphalt-Based Pavement Sealants to Two Aquatic Organisms** B. Mahler, U.S. Geological Survey / Water Resources Discipline; P. Van Metre, U. S. Geological Survey; C.G. Ingersoll, USGS / Columbia Environmental Research Center, U.S. Geological Survey / Columbia Environmental Research Center; J.L. Kunz, USGS, US Geological Survey / Department of Toxicology. There are anecdotal reports that runoff from pavement with newly applied coal-tar-based (CT) sealcoat is toxic to aquatic life; no information is available regarding toxicity associated with runoff from pavement with asphalt-based (AS) sealcoat. We measured chemistry and toxicity of runoff collected periodically from 5 hours to 36 days after application of CT and AS sealcoat; runoff from unsealed pavement was collected once. Sites were at the University of Texas, Austin, Texas. Unfiltered runoff was analyzed for 27 polycyclic aromatic hydrocarbons (PAHs). Standard toxicity tests were done with a cladoceran (*Ceriodaphnia dubia*) and fathead minnows (*Pimephales promelas*) using 48-hour exposure to undiluted and diluted (1 part runoff from sealed pavement to 9 parts control water) runoff under ambient laboratory lighting; 24-hour survival of organisms following a 4-hour pulse of ultraviolet radiation (UVR) also was evaluated. Concentrations of PAHs in runoff from CT-sealcoated pavement (CT runoff), on average, were about 10 times higher than those for runoff from AS-sealcoated pavement (AS runoff). Concentrations in runoff from the unsealed pavement were near or less than the detection limit and non-toxic to test organisms. In the CT-runoff treatment, there was 100% mortality (both species) within 24 hours of exposure to undiluted CT runoff collected 4, 12, 24, 48, 72 hours and 7 days following application. There was no mortality with the 10% dilution of CT runoff without UVR, but with UVR there was 100% mortality of *Ceriodaphnia dubia* for as long as 64 days following sealcoat application.

Mortality of organisms exposed to undiluted AS runoff occurred only following the pulse of UVR (to Day 36 for *C. dubia* or 48 hours for *P. promelas*). The results demonstrate that PAH concentrations and toxicity associated with CT runoff greatly exceed those associated with AS runoff, and that toxicity continues at least several weeks following application.

**698 PAH Source Characterization using Q-Mode Eigen Methods** R.W. Chappell, Environmental Science Solutions LLC; R.L. Olsen, CDM

Smith. Forensic investigations to characterize sources of polycyclic aromatic hydrocarbon (PAH) compounds, which may be introduced into the environment through diverse and complex natural and anthropogenic processes and pathways, generally involve identifying and evaluating corresponding multivariate profile patterns. One group of multivariate statistical methods, broadly referred to as Q-mode eigen methods, endeavor to simplify source characterization by mapping PAH profile similarities in reduced multi-dimensional space, thus providing a framework to qualitatively evaluate, distinguish between, and otherwise fingerprint possibly multiple different PAH sources. This paper demonstrates various Q-mode methods and their application to PAH concentrations in soils at a former chemical site in the northeastern United States. At issue was characterizing the degree to which PAH concentrations may be attributed to fugitive site sources versus urban or ambient sources. The paper also discusses important data treatment issues prior to multivariate analysis, such as the handling of missing data and nondetects.

**699 A Risk-Based Remedy for Wood Treating Compounds in Estuarine River and Marsh Sediments adjacent to the Former Gautier Oil Site,**

**Gautier, MS** T. Iannuzzi, J. Beckner, L. Fontenot, ARCADIS; M. Adkins, CSX Transportation, Inc.. The former Gautier Oil Site, Gautier, MS, was used for wood preserving (creosote treated piles, bridge timbers, and cross-ties) operations for more than a century, affecting on-site areas and sediments in adjacent waterways. A remedy was implemented to contain and recover free product wood treating compounds on-site. A risk assessment and feasibility study (FS) were performed for the offsite estuarine areas, including Bayou Pierre (marsh) and the West Pascagoula River. The key issues were contaminated sediments and bioavailability and potential toxicity of polycyclic aromatic hydrocarbons (PAHs). The risk assessment was focused on potential direct and indirect impacts of PAHs to the estuarine food web, and human exposures via direct sediment contact and ingestion of local seafood. A range of sediment and biological monitoring data were collected to support the risk assessment. Human health and wildlife risks (via food web exposure) from PAHs were determined to be *de minimis* based on these data. A sediment quality triad (SQT) assessment was conducted to quantify risk associated with impacted sediments to benthic communities in the in the aquatic/wetland areas immediately adjacent to the site. The SQT, in conjunction with a thorough understanding of the ecology and fate/transport processes at the site, was used to help define potential sediment remediation needs and options. The results suggest that the benthic invertebrate communities in the River and Bayou adjacent to the site are similar in diversity, abundance and structure to those in reference locations, despite variable and elevated levels of PAHs in near-site surface sediments. Site-specific toxicity was limited—an ecological effects range of 216 to 826 mg/kg total PAH was developed for benthic community impacts. This range is comparable to findings from similar studies at other wood treatment facilities. From these data, a conservative remediation goal of 200 mg/kg was selected for surface sediments adjacent to the site. The RI/FS and risk assessment results were used to define the impacted areas to be remediated and to help develop a focused remedy for the sediments at the site that would reduce exposure, and that would foster future attenuation of PAHs in sediments. To mitigate for potential impacts of the remedy on wetlands habitats adjacent to the site, an ecological restoration program was developed and implemented to provide enhanced habitat within the River and Bayou system.

**700 Sediment Contamination in the Gowanus Canal: Establishing the Current Sources of PAHs using Multiple Lines of Evidence** E.A. Garvey,

Louis Berger Group, The Louis Berger Group, Inc. / Site Assessment and Remediation; S. Gbondo-Tugbawa, C. Prabhu, S. McDonald, The Louis Berger Group, Inc.; E. Mahoney, New York City Department of Environmental Protection. The Gowanus Canal in Brooklyn, NY has become a center of environmental interest as the City of New York, the USEPA and the National Grid Corporation evaluate the extensive contamination that lies within its banks. The Gowanus Canal itself is a small, urbanized, largely

commercial waterway with extensively bulkheaded shorelines. Its use for commercial shipping extends back to the late 19<sup>th</sup> century, and parallels the growth and decline of industrial activities in Brooklyn. There are a number of industrial contaminant sources to the canal, in particular, three manufactured gas plants operated along its banks during the first half of the 20<sup>th</sup> century. Additionally, several fuel storage facilities operated along its banks as well. CSO discharges also impact water quality in the Canal. Several investigations conducted by the USEPA and National Grid Corporation provide data to document the extent of contamination in the Canal and the immediate upland areas. Limited data are also available to describe the chemical loading from the CSO discharges. EPA anticipates issuing a ROD in the near future, including a possible ecological PRG for PAHs that may be used as a basis to regulate CSO discharges to the Canal. This presentation will describe the current nature and extent of contamination in the Canal with a focus on PAH contamination. It will also describe the City's working conceptual site model for the site, including the importance of current groundwater loads, the extent of sediment contamination, and the role of CSO discharges in determining PAH levels for both existing conditions and potential future conditions. The historical uses of the Canal have resulted in extensive levels of PAH compounds and oil residues in the sediment. The unique history of industrial discharge and residential groundwater usage in the vicinity of the Canal has led to the migration of PAH-bearing NAPL beyond the estuarine sediments lining the Canal and into the native soils below. An important component in the analysis of current conditions is the use of geochemical evidence to determine an initial solids balance and preliminary estimates of relative contaminant loads to the Canal. The geochemical evidence suggests the dominance of harbor solids in the sediments accumulating within the Canal. Additionally, anticipated improvements resulting from CSO upgrades currently under construction will be described as part of the future conditions.

**701 Effect of phenanthrene and/or pyrene on metabolomic profiles in the Japanese medaka (*Oryzias latipes*)** S. Uno, Kagoshima University / Faculty of Fisheries; K. Nakayama, Ehime University / Center for Marine Environmental Studies; E. KOKUSHI, Kagoshima University / Faculty of Fisheries; A. Shintoyo, K. Ito, Kagoshima University; J. Koyama, Kagoshima University / Faculty of Fisheries. The effects of phenanthrene and/or pyrene on metabolomics profiles in the Japanese medaka (*Oryzias latipes*) were examined using GC/MS. Phenanthrene and pyrene are common polycyclic aromatic hydrocarbons (PAHs) generally release by hydrocarbon combustion or oil spill. Some PAHs are known to cause deformities or growth retardation in fish embryos and juveniles. However, little is known about their combined effects. All exposures were performed on one month old medaka and fish were collected at 0, 24, and 96 hr without feeding. Metabolites with significantly different levels between exposed and control groups were screened by one-way of variance (ANOVA). Principal component analysis (PCA) was then applied to the screened metabolites data, and principal component (PC) scores for each sample obtained. Each individual exposure group of phenanthrene and pyrene clustered at similar place on two dimensional PCA score plots, being separated from control group along the PC1 axis. This result suggests that the effects of individual exposure of phenanthrene and pyrene produced similar metabolite profiles in medaka. In contrast, the group exposed to phenanthrene and pyrene together clustered away from control group along the PC2 axis. This suggests that the combined exposure to both PAHs induced different effects to medaka than induced by exposure to individual PAHs. The differences in metabolite profiles between individual and combined exposure groups were due to variations of amino acids and glucose. All essential amino acids in the individual exposure groups increased from 0 to 24 hr, while those in control were decreased over the same period. These increases in were likely caused by degradation of the proteins in medaka muscle generating essential amino acids needed to provide the excess energy needed to eliminate phenanthrene or pyrene. On the other hand, those in the group exposed to both of phenanthrene and pyrene behaved similarly to the control group from 0 to 24 hr, seemingly unaffected by the combined PAH exposure. However all essential amino acids and glucose in the combined exposure group didn't change between 24 to 96 hr, while amino acids in the control significantly increased over this time period. These results suggest that the combined exposure of phenanthrene and pyrene inhibited protein degradation in medaka muscle and could not generate the excess energy. The effects by combined PAH exposure were unpredictable from the individual exposure.

**702 Fully automated, trace level detection of PAHs in saltwater by online-SPE LC-MSMS: the quest to eliminate sample preparation** C. Ramirez, Florida International University; C. Wang, Florida International University / Department of Chemistry & Biochemistry; P.R. Gardinali, Florida International University / Department of Chemistry & Biochemistry and SERC. Along with volatile aromatic hydrocarbons, PAHs are considered one of the major contributors to the toxicity of crude oils. Following a release of crude oil or petroleum distillates in environmental waters PAHs are often used as markers to determine not only the extent of contamination and fate of the released product but also the potential effects of the spilled oil on natural resources. Therefore, there is a clear need for fast, reproducible and sensitive methods to quantify PAHs in large numbers of samples in a short period of time. GC-MS and HPLC-FLD have been extensively used to isolate and quantify these compounds. GC-MS combines labor-intensive extraction and cleanup steps, and HPLC-FLD lacks the required resolution and selectivity to address coelutions. In order to overcome these challenges, this study uses a dopant-assisted atmospheric pressure photoionization tandem mass spectrometry (APPI-MS/MS) method combined with online SPE followed by UPLC separation to provide a one-step protocol to detect PAHs at low part-per trillion level with very limited sample preparation. Seawater samples were fortified with isotopically labeled PAHs and loaded to a Hypersil Gold-aQ column (20x2.1 mm, 12  $\mu$ m), using an auxiliary pump for sample preconcentration and salt removal. The SPE column was then connected to an UPLC pump and backflushed to a Hypersil Green PAH analytical column (150x2.1 mm, 3  $\mu$ m) where a 20 min gradient separation was performed at a flow rate of 0.600 mL/min. The gas-phase dopant (Chlorobenzene) was delivered directly into the APPI source. Detection was performed by a TSQ-Quantum Access QqQ Mass Spectrometer equipped with a Syagen Photomate source (10.6 eV Kr lamp). The automated system performs the injection, online preconcentration, seawater matrix removal, UPLC separation and selective MS/MS detection in 28 min. SRM was used to detect parent and alkylated PAHs, including all target analytes listed by the USEPA and the EU as priority pollutants. Calibrations were linear ( $R^2 > 0.99$ ) in the ranges tested (5 to 500 ng/L for 10 mL injections), method detection limits (MDLs) ranged from 6 to 21 ng/L in fortified seawater (sample size 10mL), and analysis of standard reference materials yielded recoveries between 85 to 117%. The full method is comparable to traditional GC/MS and, because of the absence of sample preparation, is particularly advantageous for the real time analysis of single compounds during short or long-term toxicological studies.

**703 Applications of Spatially-Explicit Bioaccumulation Modeling** K. von Stackelberg, E Risk Sciences, LLP. Bioaccumulation of sediment-associated contaminants may lead to potential exposures and risks in ecological and human receptors consuming fish. This presentation describes several applications of a spatially-explicit bioaccumulation model, *FishRand*, which offers the ability to incorporate spatial and temporal aspects of exposure by simulating fish migration, foraging area, and site use, which can be important drivers of actual exposures. The probabilistic framework allows for predictions of population distributions for direct estimates of risk to fish. Alternatively, for estimating risks to fish-consuming ecological and human receptors, the model provides additional uncertainty distributions. In addition, the probabilistic framework allows for greater linkages with other models such as economic models that cannot use deterministic results, as well as decision analytic frameworks.

**704 Refinement of pesticide exposure assessment for birds to include spatial and temporal variation: a modeling approach** T. Kulakowski, University of Reading / School of Biological Sciences; K.A. Kulakowska, University of Reading / School of Biological Sciences; R. Sibby, University of Reading. Agent-based population modeling is a promising way to develop ecological risk assessment towards increased ecological realism. Pesticide exposure of wild living animals is heavily influenced by their interactions with changing environment. Incorporation of landscape structure and dynamics as well as species-specific ecology in spatially explicit population models enables better estimation of the risks pesticides pose to wildlife. We have developed a population agent-based framework and implemented models of two bird species: skylark (*Alauda arvensis*) and woodpigeon (*Columba palumbus*). We chose them because of their importance in risk assessment: skylarks nest in arable fields and so are at risk from pesticides throughout the breeding cycle, while woodpigeon are at risk because they eat the leaves and seeds of arable crops. Furthermore, they represent two different groups of

birds: *Alaudidae* and *Columbidae*. This enables more flexibility in analyzing impacts of different behavior on exposure patterns. For both species there is abundant ecological data available for model parameterization and testing. Except of ecological literature we used two extensive long-term studies conducted in the UK. Woodpigeons were observed between 1960 and 2005 and skylarks between 2000 and 2010. The model framework is designed to enable quick implementation of additional bird species with as little effort as possible. The core of birds energetics and breeding, landscape management and data analysis is common for all the species, while specific behavior for each species is an extension to the model. The model simulates realistic landscape using GIS data. Here we briefly present the model design and evaluation. In addition we describe a case study where we compare exposure of modeled populations to different pesticide application scenarios. We compare pesticide application on winter wheat and oilseed rape in two different times in spring corresponding to different stages of breeding cycle of modeled species. We conclude that spatial structure of landscape together with species ecology can affect exposure in a way that is difficult to predict without modeling. In this way we show that including realistic landscape and species specific behavior is important in pesticide exposure assessment.

**705 Application of a spatially explicit exposure model to inform remedial decision-making at a Superfund Site** J. Isanhardt, R. Blackburn, S. Skipper, U.S. Fish and Wildlife Service; D. Wall, USEPA. Ecological risk assessment is a critical and complex component of the Superfund decision-making process. Often ecological scenarios are overly simplified or not evaluated properly due to costs or schedule. Many Superfund sites do not have the budget or schedule to properly assess the complex exposure variables such as receptor life history traits and other ecological processes. The use of a spatially explicit exposure wildlife model provides an additional tool toward a more scientifically defensible decision-making process in ecological risk assessment. Use of the Spatially Explicit Exposure Model (SEEM) incorporates habitat suitability and foraging habits in order to better estimate wildlife exposure at contaminated sites. Also, rather than assess risk for a single representative individual, SEEM tracks the foraging behavior of all individuals in a local population, thereby providing population-level estimates of risk that can be interpreted by natural resource and risk managers. Exposure models employ several site-specific variables (e.g., habitat types, foraging range, population size), which likely improve the assumptions associated with exposure point concentrations used in ecological risk assessment; however the accuracy of model results are not always evaluated. We conducted biological monitoring at Eureka Mills Superfund Site, Eureka, Utah, where lead contamination is an issue, to assess whether breeding songbirds that appear to be most at risk as predicted by SEEM are being exposed to elevated lead levels. To address the potential for adverse effects from lead exposure in breeding songbirds, we compared results of traditional deterministic exposure assessments with a spatial model and compared the results of both with blood-lead concentrations from songbird species at Eureka Mills, a site impacted by historic mining wastes. The results from this study can be used to (1) prioritize areas within the study area for cleanup relative to terrestrial receptor use if adverse effects or the potential for adverse effects are detected; (2) provide a further understanding of the strengths and weaknesses associated with spatially explicit exposure modeling techniques; and (3) clarify interim benchmark concentrations (i.e., potential cleanup and monitoring levels).

**706 Kicking the tires: corroboration of model output with field data of the spatially-explicit exposure model (SEEM)** M. Quinn, US Army Institute for Public Health / Health Effects Research Program, US Army Public Health Command / Health Effects Research Program; M.S. Johnson, US Army, Public Health Command / Health Effects Research Program, US Army Institute of Public Health / Health Effects Research Program, Army Institute of Public Health / Health Effects Research Program, US Army Ctr for Health Promotion & Preventive Med. / Health Effects Research Program; T. Wickwire, Exponent Inc.. Understanding the influence of habitat and contaminants in soil on a spatial scale is critical to predicting exposure patterns. Current practice often simplifies these associations through the use of conservative assumptions that are rarely predictive. We tested the Spatially Explicit Exposure Model (SEEM) at two skeet ranges and investigated risk of lead (Pb) exposure to small mammalian species. Habitat was classified into three general categories (high, medium, and low) as were soil Pb concentrations. Mean daily exposure estimates for populations of small rodents were modeled and compared with the EcoSSL for Pb to calculate a

risk estimate. These estimates were compared with blood Pb concentrations of these species at each site with the resulting risk estimated derived through the use of a tissue-specific toxicity reference value. This effort illustrates the benefits and shortcomings of using SEEM at contaminated sites and provides evidence toward greater use in making informed land-use decisions.

**707 Using spatially explicit data, geochemistry and modeling to inform ecological risk assessment for a proposed pit mine expansion** D.A. Rudnick, L. Williams, Integral Consulting Inc.; J. Ortega, Newmont Mining Corporation; A. Nicholson, M. Aldea, Integral Consulting Inc.. A screening level ecological risk assessment (SLERA) was conducted for a proposed Pit Lake, an expansion of an existing Pit Mine owned and operated by Newmont Mining Corporation in the arid Great Basin ecosystem of north-western Nevada. As is typical for SLERAs, conservative assumptions for both toxicity and exposure to the ecological community were initially used to evaluate the potential for unacceptable risk. As a result, the initial screening approach provided minimal information to refine the list of chemicals of interest needed to focus risk management and reduction strategies. To provide a more complete evaluation of potential risk, spatially explicit modeled and empirical site data was incorporated into the assessment for multiple media including soil and expected future sediment and surface water conditions over multiple time periods. These data were used in conjunction with an expanded list of toxicity values and exposure pathway models to evaluate risks to ecological receptors at the site. Multiple exposure scenarios were used to evaluate both baseline risks. The results of exposure modeling indicated that a handful of metals, including aluminum, antimony, arsenic and mercury, showed potential for risk to some ecological receptors. However, an evaluation of geochemical conditions helped to further inform the risk assessment by showing that expected conditions at the future Pit Lake are likely to limit bioavailability to ecological receptors, reducing the potential for unacceptable risk. Opportunities for risk mitigation were explored by evaluating whether surface materials with lower chemical concentrations could be placed at the site in order to reduce exposure to areas with higher levels of chemicals of interest. The results of this assessment illustrates the importance of a robust, spatially and temporally explicit data set, an in-depth understanding of site-specific geochemistry, and consideration of site management alternatives that may be available, in order to develop an accurate understanding of the potential for unacceptable ecological risk at mining sites.

**708 Expanding the utility of spatially explicit exposure modeling: applications beyond site-specific assessments** C.J. Salice, Texas Tech University / Environmental Toxicology, Texas Tech University / TIEHH, Texas Tech University / Department of Environmental Toxicology. Spatially explicit ecological risk assessments represent a marked improvement in the risk assessment process by moving away from restrictive assumptions about exposure. Generally, spatially explicit modeling is most suited to site-specific assessment. However, the spatially explicit approaches can be applied to a broader range of risk assessment scenarios including national-level assessment for pesticides and for exploring potential management or clean-up scenarios. I use examples from two different assessments in which spatially explicit concepts and models were used to generate improved estimates of risk in the one case and to explore clean-up strategies in another. In the first example, an important assumption in many risk assessments is that receptors occupy contaminated habitats 100% of the time and subsequently consume 100% contaminated diet at an upper-end contamination level level (e.g. 95<sup>th</sup> percentile). Alternatively, incorporating foraging behavior and the variability of residues on food items is an indirect way of accounting for spatial heterogeneity. In the simplest approach, receptors average exposures by foraging over a broad area and, hence, are assumed to receive the mean residue exposure. But because risk endpoints are frequently thresholds, variability in food item residues has important implications for exposure and risk estimates. For birds foraging in pesticide treated fields for example, including spatial variation in residue concentrations on food items results in similar mean exposure levels compared to just assuming birds always consume mean residue food items but some birds will receive a higher maximum exposure and hence, the actual estimates of risk are vastly different. In a second example involving a population-level assessment of mink inhabiting a PCB contaminated river, PCBs were modeled as distributed heterogeneously with hot spots of contamination of varying degrees. Simulations of remediation strategies indicated that a focused clean-up on hot spots proved very effective although the effectiveness was impacted by how quickly clean-up was initiated after contamination and the percentage removal of PCBs. Nonetheless,

the model pointed to the importance of spatially explicit data and management options. These examples illustrate the utility in using spatially explicit approaches for risk assessment and environmental management even under circumstances where site-specific data may be lacking, sparse or non-existent.

**709 Lessons learned by comparing results of spatial models to non-spatial assessments** R.T. Rytí, Neptune and Company, Inc.. Watershed-scale ecological risk assessments for the Los Alamos National Laboratory (LANL) in New Mexico, USA have utilized complex spatial models to assess wildlife exposure. For assessments of individual contaminated sites a simple screening level approach is typically used. In some cases the simple methods are followed by more complex assessments. This paper contrasts the results of the non-spatial assessments with those provided by the ECORISK model, which was developed for use at LANL. ECORISK integrates biological, ecological, and toxicological information using geographic information system interfaces so that model input and output are spatially explicit on the grid system basis. When comparing the spatial and non-spatial model results one should consider what methods were used to calculate representative soil concentrations, the granularity of the assessment based on the model structure, and the spatial boundaries evaluated in the assessments. One advantage of the ECORISK model results is that they can be expressed as probabilities of adverse effects. In contrast the non-spatial assessments simply provide qualitative information on the likelihood of adverse effects. ECORISK model results for an endangered species, the Mexican spotted owl, based on exposure to contaminants in soil and modeled uptake into their prey are used to illustrate these points.

**710 Spatially Explicit Wildlife Exposure Models (PANEL): Moving Toward Their Increased Acceptance and Use** M.S. Johnson, US Army, Public Health Command / Health Effects Research Program, US Army Institute of Public Health / Health Effects Research Program, Army Institute of Public Health / Health Effects Research Program, US Army Ctr for Health Promotion & Preventive Med. / Health Effects Research Program; B. Hope, CH2MHILL; T. Wickwire, Exponent Inc.. Limitations inherent in models currently used in ecological risk assessment have spurred demand for spatially explicit exposure models. These models are scientifically sound and technically innovative tools for more realistically capturing potential wildlife exposures to chemicals in the environment. Currently available spatially explicit exposure models are diverse and powerful tools for expanding analytical capabilities, improving risk estimates, communicating these estimates to a broad audience, and creating more effective risk management outcomes. Their use has thus far been limited by a lack of information about available models and their capabilities, along with few examples of how they may be applied in actual assessments. This current lack of widespread use should not, however, be interpreted as implying that spatially explicit exposure models are not valuable tools in the risk assessment toolbox. The overall objective of this session is to emphasize the value of spatially explicit exposure models, encourage their increased use, and illustrate how they can provide more realistic estimates of risk to mobile ecological receptors. Using case studies when applicable, presentations in this session will identify impediments to use/acceptance of spatially explicit exposure models, how model outputs fit into the classic ecological risk assessment framework, and how these outputs provide value to the risk management process. Finally, a path for moving spatially explicit exposure models into the mainstream of ecological risk assessment will be discussed.

**711 In ovo toxicity of methylmercury in thick-billed murre and arctic terns** B.M. Braune, A.M. Scheuhammer, D. Crump, S. Jones, D. Bond, Environment Canada. Mercury has been increasing in some marine birds in the Canadian Arctic over the past several decades. To evaluate the potential reproductive impact of mercury exposure, eggs of two species of arctic-breeding seabirds, the thick-billed murre and arctic tern, were dosed with graded concentrations of methylmercury and artificially incubated in the laboratory to determine species differences in sensitivity. Based on the dose-response curves, the median lethal concentrations (LC<sub>50</sub>) for thick-billed murre and arctic tern embryos were 0.48 mg g<sup>-1</sup> and 0.95 mg g<sup>-1</sup> mercury on a wet-weight (ww) basis, respectively. Compared with published LC<sub>50</sub> values for other avian species, the murre and terns had a medium sensitivity to methylmercury exposure. LC<sub>50</sub> values were also calculated for the actual mercury concentration measured in the embryos, that is, the maternally-deposited mercury plus the injected methylmercury dose. This increased the LC<sub>50</sub> values to 0.56 mg g<sup>-1</sup> mercury ww in the thick-billed murre and to

1.10 mg g<sup>-1</sup> mercury ww in the arctic tern. The incidence of gross external anatomical deformities was 4.3% in the murre embryos and 3.6% in the tern embryos. However, given that the eggs were taken from wild populations, it is unlikely that the deformities observed in this study were due to methylmercury exposure alone.

#### **712 How much mercury is too much: dosing and field studies on songbirds**

**D.A. Cristol**, College of William & Mary / Professor of Biology, College of William & Mary / Department of Biology, College of William & Mary / Associate Professor, College of William & Mary / Dept. of Biology. Multi-year field studies on tree swallows, Carolina wrens and eastern bluebirds have been combined with a year-long dosing study on zebra finches and European starlings to produce a more comprehensive assessment of the sub-lethal effects of dietary mercury on songbirds. The experimental dosing studies have confirmed the effects of mercury on behavior. Mercury affected singing behavior in both captivity and the field, and in captivity additional cognitive effects were detectable. Effects of dietary mercury on reproductive success were also evident in the field and mercury's causative role was confirmed through dosing studies. Reproductive success was reduced at relatively low levels of mercury, but some birds maintained the capacity to breed successfully at much higher levels of mercury intake than others. The relatively unchallenging life of captive birds allowed them to reproduce successfully at levels of mercury that were predicted to have been catastrophic in the field. Analysis of endocrine endpoints – testosterone, corticosterone and thyroid hormones – have not yet confirmed the results of field studies that suggested endocrine disruption by mercury. However, careful study of the immune system in captive dosed birds, in particular reduced or delayed proliferation of B-cells, was consistent with the finding of immune suppression from field studies. The experimental manipulation possible in captivity provides rigorous evidence that mercury reduces fitness in songbirds while field studies offer guidance as to the levels of mercury that actually cause biological harm under natural conditions.

#### **713 Neurochemical biomarkers to assess mercury risks in wild birds: potential applications, thresholds, and limitations**

**J. Rutkiewicz**, University of Michigan; N. Basu, University of Michigan / Department of Environmental Health Sciences. Mercury (Hg) is a neurotoxic metal known to accumulate in tissues of wild birds. Studies have identified Hg associated brain lesions, behavioral changes, and reproductive impacts in several avian species. These endpoints are vital for risk assessment but their predictive value is limited. Neurochemical biomarkers, biochemical changes that occur prior to overt damage, may represent subclinical markers of early effects and may help overcome some limitations associated with apical endpoints. Here we review studies by us and others aiming to derive Hg-associated neurochemical thresholds and acknowledge pros/cons to this approach. In the field, a study of bald eagles and common loons with high Hg exposure across Canada found associations between brain Hg and muscarinic cholinergic and N-methyl-D-aspartic acid (NMDA) receptor levels. A study of eagles with comparable exposure across the US Great Lakes found similar associations between brain Hg and the NMDA receptor and the enzymes glutamic acid decarboxylase and glutamine synthetase. Conversely, studies of herring gulls and common loons with low Hg exposure found no associations between brain Hg and neurochemical receptors, thus suggesting a threshold (5-10 ppm Hg in brain) for neurological change exists. Relating Hg burdens in wild birds to neurochemistry may help determine toxic thresholds for risk assessment. However, potential drawbacks and limitations to neurochemical biomarker use exist. A study of postmortem stability of several biomarkers reveals that many are stable under various environmental conditions but others are less stable and their utility may be limited to freshly collected samples. Impacts likely vary across developmental stage. Recent Hg air cell egg injection techniques have been applied in an attempt to validate biomarkers and identify thresholds for change in embryos and hatchlings. Despite accumulating high levels of brain Hg, chicken, quail, and murre embryos did not consistently display the Hg associated neurochemical associations seen in wild birds. These studies underscore the great variability of responses between species, age classes, and exposure routes. Nevertheless, neurochemical biomarkers may have useful applications for assessing Hg risks in wildlife and help to expand our overall understanding of the mechanisms of Hg toxicity.

**714 Effect of methylmercury on foraging behavior of larval yellow perch (*Perca flavescens*) and zebrafish (*Danio rerio*): implications for recruitment** **F.X. Mora**, M. Carvan, University of Wisconsin – Milwaukee; C.A. Murphy, A.D. Deardorff, Michigan State University / Department of Fisheries and Wildlife; N. Basu, University of Michigan / Department of Environmental Health Sciences; J.A. Head, National Oceanic and Atmospheric Administration; F.W. Goetz, University of Wisconsin – Milwaukee. Yellow perch (*Perca flavescens*) is a fish species of economic and ecological importance in the Great Lakes. In Lake Michigan, this species has faced difficulties with successful recruitment. Low recruitment has been widely attributed to overfishing, however very few studies have explored the effect of contaminants, specifically methylmercury, on larval yellow perch. Methylmercury is environmentally present in the Great Lakes and its neurotoxicity has been shown to affect foraging behavior in exposed fish, birds and mammals. Since food limitation is thought to be one of the main causes of larval fish mortality, we investigated the effects of acute 20 hour waterborne methylmercury exposure (0.1 µM, 0.3 µM, 1 µM, 3 µM) on feeding behavior of larval yellow perch. A comparative study was also performed on larval zebrafish (*Danio rerio*). Additionally, we analyzed light/dark swimming activity and swimming speeds of both larval fish species; with these experiments we evaluated the putative role of light/dark perception and overall activity in foraging and prey capture success. Both fish species were studied in order to develop behavioral assays that can transfer easily between an ecologically relevant species and a well-studied fish model. We also looked at the same suite of behaviors of larval yellow perch spawned from fish collected from the wild and measured the corresponding mercury levels. We found that low methylmercury concentrations impaired larval behavior and that this effect could have population implications as suggested when we incorporated these effects into an individual-based model to predict the effects on survival and growth of a cohort. Our results suggest that methylmercury could have an impact on yellow perch recruitment in Lake Michigan.

#### **715 Mercury in Terrestrial Songbirds: species, habitats, and locations at risk**

**A. Jackson**, Biodiversity Research Institute, Oregon State University; D.C. Evers, E. Adams, A. Sauer, Biodiversity Research Institute; C. Eagles-Smith, US Geological Survey / FRES. As research continues to expand on the transfer and fate of methylmercury in ecosystems we now understand that invertivores in terrestrial habitats can be at high risk to atmospheric mercury deposition. By compiling a large dataset of blood mercury levels for songbirds in the northeastern U.S. (N = 3126), we are able to model factors that influence methylmercury availability and apply findings to relatively uncharacterized areas in the central and western U.S. In our northeastern U.S. analysis, we identified five variables that are likely to influence mercury exposure and found, by taking into account species and site differences, that there is a significant effect of habitat type and foraging guild. Fresh- and saltwater wetlands showed significantly higher Hg levels than upland forests and invertivores showed significantly higher Hg levels than omnivores. We can use this information to identify species that would be best used as indicators of greatest risk in different habitat types across the U.S. Such information will better inform land managers, decision makers and governmental regulators concerned about mercury in the environment.

#### **716 Ecological risk of dietary methylmercury exposure to piscivorous fish and wildlife in Canada: A screening level assessment**

**D.C. Depew**, Queen's University / School of Environmental Studies, Queen's University; N.M. Burgess, Environment Canada / Science & Technology Branch, Science & Technology Branch / Environment Canada, Canadian Wildlife Services / Environment Canada; L.M. Campbell, Queen's University / School of Environmental Studies. Deposition of mercury (Hg) from the atmosphere into the environment continues to remain the principle source of Hg contamination for most aquatic ecosystems. Inorganic Hg is readily converted to highly toxic methylmercury (MeHg) that bioaccumulates in aquatic food webs and concentrations in prey fish may be sufficiently high as to pose risks to piscivorous fish and wildlife over large portions of Canada. Using a standardized dietary exposure indicator (Hg<sub>PREY</sub>) modeled from over 200,000 observations of fish Hg concentrations at over 1,900 locations across Canada and recently derived dietary exposure screening benchmarks, we conducted a screening level risk assessment to evaluate the extent and presence of risk to top trophic level piscivores; the common loon (*Gavia immer*), walleye (*Sander vitreus*) and northern pike (*Esox lucius*). Concentrations of Hg<sub>PREY</sub> were sufficiently high enough to exceed benchmark thresholds related to impaired productivity and behaviour in loons at 10 and

36 % of sites respectively, and exceeded benchmark thresholds for impaired reproduction and health in fishes at 82 and 64 % respectively. For both the common loon and piscivorous fishes, the majority of sites deemed to be at risk were located in forested ecozones of eastern Canada known to have been affected by anthropogenic acidification. Results of this assessment suggest that common loons and piscivorous fishes would likely benefit from reductions in Hg emissions.

**717 Mercury Toxicity Thresholds for Birds and Implications for Appropriate Exposure Metrics** P.C. Fuchsman, ENVIRON International Corporation, ENVIRON International Corp.; A.K. Gevertz, ENVIRON International Corp. / Zoology, ENVIRON International Corp. / ESM; A. Fogg, ENVIRON International Corporation; E. Perruchon, ENVIRON International Corp.; M. Cisz, Michigan Technological University; M. Henning, ENVIRON International Corporation. We compiled extensive laboratory and field data linking mercury exposures to effects on birds, with a focus on reproductive effects. The available data have expanded substantially in the last five years. The avian effects data set provides a tool for identifying toxicity reference values for use in risk assessment. In addition, it provides an opportunity to compare the utility of multiple exposure metrics in minimizing interspecies variation, thus improving interspecies extrapolations in risk estimation. Such extrapolation remains a necessity for mercury and is even more frequently required for other, less thoroughly studied chemicals. On the basis of mercury concentrations in eggs, toxicity thresholds are relatively consistent among species, likely because uncertainties of dietary exposure modeling are eliminated. However, egg concentrations are not as frequently available as concentrations in avian dietary items. Therefore we also compared the utility of expressing exposure on the basis of dietary concentrations (mg/kg) versus dietary doses normalized to avian species' body weight (mg/kg BW-day). While body weight scaling of toxicity reference values is no longer widely accepted, body weight normalization of dietary doses remains standard practice. However, the mercury toxicity data support the contention that body weight normalization distorts interspecies comparisons due to extreme differences among species in food ingestion rates relative to body weights.

**718 Mercury in Bats from the Northeastern United States** D. Yates, S. Angelo, D.C. Evers, Biodiversity Research Institute; J. Schmerfeld, U.S. Fish and Wildlife Service, Virginia Field Office; M.S. Moore, T.H. Kunz, Boston University / Center for Ecology and Conservation Biology; T. Divoll, S.T. Edmonds, Biodiversity Research Institute; C. Perkins, University of Connecticut / Center for Environmental Sciences and Engineering; N.O. Driscoll, K.C. Irving Environmental Science Centre; R. Taylor, Texas A&M / Trace Element Research Laboratory. Concentrations of mercury (Hg) and methylmercury (MeHg) in biota from the northeastern United States exist because of atmospheric deposition and anthropogenic point sources. When Hg is methylated it becomes particularly toxic in ecosystem and to the wildlife. This paper examines Hg concentrations found in bat tissues over a four year period in the northeastern United States, and assesses differences sampled near point sources and from nonpoint sources. Percentages of MeHg found in total fur Hg were also evaluated to determine the level of toxicity commonly present in bat tissues. As predicted, Hg was significantly higher in bats captured near point sources compared to nonpoint sources. MeHg made up 86% (range = 71-95%) of the total Hg in 20 bats sampled in northeastern North America where several species are facing threats from white-nose syndrome (WNS), wind-power production, habitat loss, and pollution in air and water, MeHg is a widespread pollutant, and thus it is clear from the present study that a better understanding is needed regarding the neurological and behavioral effects of Hg on bats.

**719 Bioanalytical approach for the characterization of endocrine disrupting compounds in wastewater** S. Dagnino, V. Bellet, M. Grimaldi, V. Cavailles, IRCM, Institut de Recherche en Cancérologie de Montpellier, INSERM, U896; H. Fenet, UMR 5569 Hydrosociences, Université Montpellier 1; P. Balaguer, IRCM, Institut de Recherche en Cancérologie de Montpellier, INSERM, U896. Nuclear receptor based *in vitro* bioassays are useful tools for the detection of endocrine disrupting compounds (EDCs) in environmental samples. Thus, the difficulty lies in the identification of the ligands of such receptors responsible for the measured activity. In the present study, bioanalytical tools were used, in combination with reporter cell lines, in order to characterize EDCs activities in wastewater samples. The occurrence of EDCs such as estrogens in raw urban sewage is usually well

documented, whereas the presence of other receptor ligands has been poorly described. We used ER, PXR, AhR and AR bioassays to characterize EDCs activity in dissolved phase, suspended solids and sludge from a wastewater facility. With bioanalytical characterization, we determined that estrogenic activity was carried out by high affinity compounds in dissolved phase and suspended solids and low affinity compounds in sludge. Sludge revealed to be a complex mixture of ER, AhR, PXR activators and AR inhibitors. Using recombinant ER, and PXR purification column, we were able to determine the contribution of common ER, PXR, AhR and AR ligands and suggested a list of possible compounds responsible for these activities to be considered for further identification.

**720 An Australian-wide assessment of endocrine disruption – stage 1** P.D. Scott, Griffith University / School of Environment; H. Coleman, J. McDonald, University of New South Wales / Water Research Centre; R. Lim, University of Technology Sydney; D. Nuggeoda, RMIT University / School of Applied Sciences, RMIT University / Department of Applied Biology & Biotechnology; L.A. Tremblay, Cawthron Institute; V.J. Pettigrove, The University of Melbourne / CAPIM; H.F. Chapman, Griffith University / School of Environment; S. Blockwell, B. Harper, Sydney Water; T. Reitsema, Department of Water; M. Bartkow, Seqwater; F.D. Leusch, Griffith University / School of Environment. This project uses an integrated approach consisting of multiple *in vitro* and *in vivo* bioassays, *in situ* sampling and trace chemical analysis to compare endocrine disruption at 73 sites in mainland Australia. Sample sites were selected to include waterways impacted by a variety of sources such as wastewater discharge, agricultural run-off, industrial effluent, urban drains and pristine reference sites. Duplicate 1 L discrete water samples were taken quarterly over a one-year period. Samples were concentrated using solid-phase extraction (SPE) and split into two aliquots, one for *in vitro* bioassay analysis and the other for chemical analysis. A battery of CALUX assays (estrogen receptor, ER; androgen receptor, AR; progesterone receptor, PR; and glucocorticoid receptor, GR) was used to determine the classes of EDCs present in water extracts. Chemical analysis was used to identify causative compounds as well as for point source confirmation. Preliminary results have identified at least 11 sites that have estrogenic (or anti-androgenic) EDCs. Analysis with the AR-, PR-, and GR-CALUX assays is currently underway. Chemical analysis has confirmed estrogen mimics (such as bisphenol A, t-octylphenol), the pesticide atrazine, an industrial compound tris(2-carboxyethyl)phosphine (TCEP), and numerous pharmaceuticals and personal care products (e.g., atenolol, dilantin, triclosan, carbamazepine, ibuprofen). Hormone analysis is currently underway. Based on *in vitro* and chemical data, several stock solutions representative of a selection of exposure concentrations found in the environment will be created for *in vivo* laboratory fish exposures using a native species (rainbowfish, *Melanotaenia fluviatilis*) and a widespread exotic pest species (mosquitofish, *Gambusia holbrooki*) in stage 2. An estrogenic biomarker (vitellogenin) and an androgenic biomarker (in development) will be used to assess whole organism endocrine disruption. The same endpoints will be utilized with *in situ* techniques by sampling fish from polluted aquatic environments identified in stage 1 to assess the amount of endocrine disruption present in the most impacted natural aquatic environments. Finally, in stage 3, a risk assessment will be generated using *in vitro*, chemical, *in vivo*, and *in situ* data to assess the potential risk to aquatic ecosystem health.

**721 Evaluation of Endocrine Active Compounds in Wastewater Effluents: implementation of a Mode of Action-based tool-box** R. Marfil-Vega, ORISE Postdoc at US EPA / ORISE Research Participant to the National Risk Management, University of Cincinnati, ORISE Postdoctoral Fellow, ORD, US EPA, ORISE Postdoc at US EPA; M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development. Recently researchers have expanded the scope of their work on endocrine disruption to contaminants that may perturb thyroid hormone homeostasis and/or interact with other nuclear steroid receptors (i.e. androgen, progesterone, and glucocorticoid) different from the estrogen one. Concurrently, there has been an increased public awareness and demand of information by citizens and water utilities on the presence of Endocrine Disrupting Chemicals (EDCs) in environmental waters. To properly disseminate the information available and improve the management of the risks associated with the occurrence of EDCs in discharges from wastewater treatment plants (WWTPs), Environmental Sciences (chemistry, and (eco)-toxicology) and Engineering are closely

developing new monitoring strategies. A comprehensive set of tools needs to be implemented in anticipation of Whole Effluent Toxicity requirements of WWTPs to monitor the increasing number of EDCs in wastewater and meet the pertinent regulations. A Mode Of Action-based approach, in which a battery of bioassays and chemical analysis are combined to identify toxic effects and their causing agents, is proposed for this purpose. The current work encompasses a multi-laboratory and interdisciplinary effort to monitor and characterize the endocrine disrupting activity of effluents from WWTPs, and the specific chemicals that may underlie these effects. Outcomes on selected metabolic pathways within the hypothalamus-pituitary-thyroid and hypothalamus-pituitary-gonadal axes are monitored by means of targeted analysis of six groups of chemicals (total 140 target analytes) and a battery of *in vivo*, *ex vivo* and *in vitro* bioassays (12 assays). In this presentation, the occurrence and concentrations of the selected emerging contaminants (steroid and thyroid hormones, perfluorinated chemicals, pharmaceuticals, and alkylphenolic surfactants) during two sampling events, conducted in early spring and summer, in four WWTPs in New England will be reported. Additionally, the comparison between the active samples in the bioassays (i.e. vitellogenin gene expression assay with larvae Fathead Minnows, transgenic amphibian thyroid toxicity assay, thyroid gland explant culture assay, thyroid peroxidase inhibition assay, rat and human pregnane-X, estrogen-, androgen-, progesterone-, glucocorticoid-cell-based nuclear receptor reporter assays, and aromatase inhibition and steroidogenesis assays) and the concentrations of chemicals determined will be discussed.

**722 In Vitro Assessment of Estrogenic Activity in Source and Treated Drinking Water Extracts from 25 U.S Drinking Water Treatment Plants.** V.S. Wilson, US EPA, ORD, NHEERL, TAD / Reproductive Toxicology Branch; N. Evans, US EPA, ORD, NHEERL, Toxicity Assessment Division; K. Schenck, US EPA / NRMRL; H. Mash, U.S. EPA / Office of Research and Development, NRMRL; L. Rosenblum, Shaw Environmental and Infrastructure; S.T. Glassmeyer, U.S. EPA / Office of Research and Development, U.S. EPA / NERL/MCEARD/CERB; E.T. Furlong, U.S. Geological Survey / National Water Quality Laboratory; D. Kolpin, USGS. The presence of estrogenic compounds in environmental water samples and their potential impact on fish, wildlife and human reproductive health has been an ongoing concern. *In vitro* assays have been successfully used to screen for estrogenic activity in many types of water samples including effluents from waste water treatment and cattle, dairy, swine and poultry operations. Few studies, however, have applied *in vitro* assays to evaluate possible estrogenic activity in source and treated drinking water samples. Scientists from the U.S. Environmental Protection Agency (EPA) and U.S. Geological Survey (USGS) are collaborating on a research study to determine the concentrations of contaminants of emerging concern in source and treated drinking waters collected from up to 25 drinking water treatment plants (DWTP) using various treatment processes from across the United States. For this study untreated source and treated drinking water samples from each plant were assessed for cumulative estrogenic activity using T47D-KBluc cells, an estrogen receptor-mediated transcriptional activation (ER-TA) assay. Extracts of each DWTP sample were prepared targeting steroid hormone enrichment. Aliquots of each extract were also retained for analytical chemistry analysis. Spiked (target = 3 pM EEQ in the assay) and unspiked field blank extracts were prepared concurrently with each DWTP extract. Responses for the spiked samples appropriately ranged from 2.8 to 4.7 pM with a mean of 3.6 pM adding confidence in the predictive ability of the assay. Testing of the source and treated water extracts in the ER-TA assay is ongoing. To date low level estrogenic activity has been detected in eight of the source water extracts but post-treatment extracts from the same plant contained either no detectable or significantly reduced estrogenic activity. ER-TA results will be compared to expected estrogenic activity based on analytical chemistry results. Overall this validated, sensitive cell line can be used for screening individual chemicals, mixtures, animal feedlot effluent and drinking water samples. The results allow the prediction of potentially adverse effects in aquatic systems and estimation of potential effects in humans. Disclaimer: This abstract does not necessarily reflect U.S. EPA policy.

**723 Application of an integrated strategy for monitoring of contaminants, including endocrine active chemicals, in Great Lakes Areas of Concern** D.L. Villeneuve, U.S. EPA / National Health and Environmental Effects Research Laboratory, U.S. EPA; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National

Health and Environmental Effects Research Laboratory; J. Berninger, Baylor University / Department of Environmental Science; J. Cavallin, U.S. EPA, ORISE / National Health and Environmental Effects Research Laboratory; E. Durhan, US EPA / Mid-Continent Ecology Division, US-EPA / Research Chemist; K. Jensen, U.S. EPA / National Health and Environmental Effects Research Laboratory; Z. Jorgenson, US Fish and Wildlife Service / Aquatic Toxicology Laboratory, U.S. Fish and Wildlife / Environmental Contaminants; M. Kahl, U.S. EPA / National Health and Environmental Effects Research Laboratory; K. Lee, US Geological Survey; L.M. Thomas, US Fish and Wildlife Service / Mid-Continent Ecology Division. Chemical monitoring strategies are most effective for those chemicals whose hazards are well understood and for which sensitive and cost effective analytical methods are available. Unfortunately, such chemicals represent a minor fraction of those that may currently occur in the environment and impact biological systems. However, in cases such as endocrine disruption, where specific types of biological perturbation have been plausibly and/or empirically-linked to adverse outcomes (i.e., adverse outcome pathways have been characterized), effects-based monitoring approaches can serve as a powerful complement to analytical environmental chemistry for exposure monitoring and diagnostic risk assessments. This presentation describes an integrated research strategy that was employed in five different Great Lakes Areas of Concern (AOCs). The strategy used a combination of four day *in situ* exposures with fathead minnows (*Pimephales promelas*), *in vitro* bioassay-based screening of surface water samples, and analytical quantification of over 150 analytes in surface water and sediment samples to characterize contamination at selected sites within the five AOCs. Biological effects monitoring focused on endpoints associated with reproductive endocrine adverse outcome pathways as well as xenobiotic and steroid metabolism. *In vitro* screening with the MDA-kb2 cell bioassay detected weak androgenic activity at several sites within the lower Fox River and Green Bay AOC. Hepatic cytochrome p4501a1 mRNA induction was observed in fish exposed *in situ* at most sites examined within the St. Louis River, Detroit River, and Maumee River AOCs. In contrast, hepatic vitellogenin mRNA concentrations were rarely elevated in male fathead minnows exposed *in situ*. Ovarian expression of steroidogenesis-related genes was largely un-impacted by *in situ* exposure within the St. Louis River AOC, despite detection of a variety of known endocrine active chemicals and pharmaceuticals in surface waters collected during the period of exposure. On-going research includes the application of unsupervised analyses (e.g., transcriptomics) as well as construction of chemical-gene interaction networks as a means to aid selection of biological endpoints for future effects-based monitoring at these sites. The contents of this abstract neither constitute nor reflect official US EPA policy.

**724 A methodological approach to weight of evidence in ecotoxicological risk assessment** K. Solomon, University of Guelph / School of Environmental Sciences, University of Guelph / Centre for Toxicology, School of Environmental Sciences; M. Hanson, University of Manitoba / Department of Environment and Geography, University of Manitoba / Faculty of Environment; A. Hosmer, Syngenta Crop Protection, LLC., Syngenta Crop Protection, Inc.; W. Kloas, IGB; G. Van Der Kraak, University of Guelph / Department of Integrative Biology. The term "weight of evidence" (WoE) is widely used in human and ecological risk assessment but is seldom applied properly. Most of the literature uses the term metaphorically. WoE is not a simple vote-counting exercise but is an interpretative methodology for systematically assessing studies using quality pre-determined criteria for: 1) the relevance of a response to a specific endpoint and, 2) the strength of the methods used in the study from which the data were derived. We developed a process for WoE that encompasses all available evidence, rather than some arbitrarily selected subset, and assesses this in a quantitative way. We developed numerical criteria to characterize adverse outcomes(s) in terms of biological relevance of the response and strength of methods used to measure the response. Relevance was characterized quantitatively using criteria based on statistical significance, response to concentration, consequences for survival, growth, development, and reproduction, and mechanistic understanding of mode of action. Strength of the study was then characterized using procedures recommended for assessing studies for inclusion in databases such as IUCLID, the use of GLP and QA/QC, numbers of concentrations used, and the inclusion of realistic and upper-bound values in the range of concentrations tested. The means of the scores of these two assessments were then used to summarize and weigh the evidence in terms of adverse outcomes and the strength of the methods used to derive these data. To derive a weight of evidence that was

easily interpreted visually, these scores were plotted on the X- and Y-axes of a graph. The locations of the plotting points allow all of the studies that reported a particular response to be visually displayed for summary evaluation. Clustering of the studies in a particular part of the graphic is indicative of consistency between observations across studies. Obvious outliers or exceptions can easily be identified and, if necessary, addressed in a narrative. This process will be illustrated using atrazine as a case compound.

**725 Use of an In Vitro Nuclear Receptor Assay Panel to Characterize the Endocrine-Disrupting Activity Load of Wastewater Treatment Plant Effluent Extracts** K.B. Paul, The Hamner Institutes for Health Sciences / Institute for Chemical Safety Sciences, Integrated Systems Toxicology Division / NHEERL, ORD, US EPA, ORISE Postdoctoral Fellow, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL; R. Marfil-Vega, ORISE Postdoc at US EPA / ORISE Research Participant to the National Risk Management, University of Cincinnati, ORISE Postdoctoral Fellow, ORD, US EPA, ORISE Postdoc at US EPA; M.A. Mills, U.S. EPA, U.S. EPA / National Risk Management Research Laboratory, ORD, US EPA / Remediation and Pollution Control Division, NRMRL, U.S. EPA / Office of Research & Development; S.O. Simmons, ORD, U.S. EPA / Integrated Systems Toxicology Division, NHEERL; V.S. Wilson, US EPA, ORD, NHEERL, TAD / Reproductive Toxicology Branch, U.S. EPA / Office of Research and Development, ORD, US EPA / Toxicity Assessment Division, NHEERL, U.S. EPA, ORD, NHEERL / Toxicity Assessment Division; K.M. Crofton, ORD, US EPA / Integrated Systems Toxicology Division, NHEERL. The objective of this multi-laboratory project is to characterize the potential endocrine-disrupting activity of wastewater treatment plant (WWTP) effluent extracts from the Assabet River (Boston, MA) using bioassays and analytical chemistry. We tested the hypothesis that estrogen receptor (ER), androgen receptor (AR), and pregnane-X receptor (PXR) assays would provide a sensitive screen for the potential estrogenic, androgenic, and thyroid-disrupting load of samples obtained from WWTP effluents and aid prioritization of further analytical and biological testing of these effluent extracts. Effluent samples from 4 WWTP sampling sites and a blank were extracted using 6 different protocols, each targeting specific chemical groupings. In order of descending potency, extracts enriched for thyroid hormones, pharmaceuticals, aromatase inhibitors, steroids, and alkylphenols tested positive for estrogenic activity (4-10 ng/L estradiol equivalents, EEQs), and with greater efficacy than the perfluorinated chemicals extracts (> 1 ng/L EEQ). The potency of ER activation by each extract type was WWTP site-dependent. Several extracts demonstrated modest AR agonist activity, generally coincident with extracts from the site that demonstrated the highest ER activation. Significant AR antagonism was not observed for any extract. Preliminary data obtained with a PXR activity assay suggests that the pharmaceutical extract method may be most appropriate for subsequent assays of potential thyroid-disruptors that up-regulate hepatic catabolism of thyroid hormones. This was consistent with previous work that demonstrated PXR activation 3-fold over vehicle control with whole freeze-dried effluents at environmental concentrations. Continuing work will relate activation of ER, AR, and PXR to identify possible potency relationships between these activities in the effluent extracts. Extracts will also be tested in additional bioassays, including a thyroid peroxidase inhibition assay, to assess another thyroid disruption target using an emerging medium-throughput technology. These data inform an integrated bioassay and analytical approach to understanding the potential endocrine-disrupting activity of effluents and potential strategies for monitoring EDC activities following changes in treatment technologies. This abstract does not necessarily reflect the policy of the US EPA.

**726 How reliable monitoring tool can be the estrogenic in vitro assay** ? B. Jarosova, Masaryk University, Research Centre for Toxic Compounds in the Environment / RECETOX, Masaryk University / Faculty of Science, RECETOX; K. Hilscherova, Masaryk University, Research Centre for Toxic Compounds in the Environment / RECETOX; R. Loos, B. Gawlik, EC JRC Ispra, Italy; J.P. Giesy, University of Saskatchewan / Biomedical Veterinary Sciences & Toxicology Centre, Michigan State University / Department of Animal Science, University of Saskatchewan / Toxicology Centre; L. Blaha, Masaryk University, RECETOX / RECETOX, Masaryk University, Research Centre for Toxic Compounds in the Environment / RECETOX, Masaryk University / RECETOX. Although the presence of estrogenic compounds in the environment has been extensively studied in the last decades, many questions related to their risk have not been fully

resolved yet. E.g. instrumental analyses of steroidal estrogens, which appear to be primarily responsible for at least some adverse effects observed in fish downstream of Waste Water Treatment Plants (WWTPs), often fail in detection of their actual concentrations in complex environmental matrices and/or their costs are burdening. In 2010, FATE-SEES pan-European monitoring campaign coordinated by the European Commission's Joint Research Centre (JRC) in Ispra, Italy, was conducted. Samples from 90 European Waste Water Treatment Plant (WWTP) effluents were collected and analyzed for more than 150 polar organic and 20 inorganic compounds to obtain an overview on many so far only locally investigated compound classes. Steroidal estrogens were not detected in any of these samples above the detection limit of 10 ng/L. However, the effect-based monitoring approach (MVLN *in vitro* assay) showed significant estrogenic activity of 27 out of 75 samples with E2 equivalent ranging 0.53 to 17.9 ng/L. The greatest activities have been detected in WWTPs at some of the major European cities indicating the importance of this contamination source. The results were further combined with upgraded literature review of typical concentrations of individual major estrogens in European municipal waste water effluents and their *in vitro* and *in vivo* relative potency to E2 to evaluate usefulness of the *in vitro* assay for environmental monitoring and to answer the question; how they can be interpreted in relation to potential *in vivo* adverse affects.

**727 Area use, site fidelity, and rate of movement of white croaker (*Genyonemus lineatus*) within the Los Angeles and Long Beach Harbor** B. Ahr, M. Farris, C.G. Lowe, California State University Long Beach / Department of Biological Sciences. The Los Angeles (LA) and Long Beach (LB) Harbor in southern California is known to be an area of contaminant accumulation, both from industrial/agricultural and residential sources. This study employs acoustic telemetry techniques to gain insight into the short-term and long-term movements of white croaker (*Genyonemus lineatus*), a well known indicator species. To characterize longer-term, more course-scale movements, the harbors were divided into four areas; inner LA, outer LA, inner LB, and outer LB, and 15 individuals were tagged in each section. Their movements between sections was monitored using 12 acoustic receivers spread throughout the harbors. Short-term, fine-scale movements are studied using active acoustic tracking, where fish are followed over multiple 24 hr periods. Individuals actively tracked use an avg. daily area of 90,600 m<sup>2</sup> ± 57,740 m<sup>2</sup> (± SD). So far, no significant difference has been observed in area use during day time (50,887 m<sup>2</sup> ± 38,315 m<sup>2</sup>) and night time (48,340 m<sup>2</sup> ± 38,394 m<sup>2</sup>) (p = 0.798). Longer-term, course-scale monitoring has indicated that *G. lineatus* tagged in the inner LA area exhibited highest site fidelity, remaining in the area in which they were tagged for 29.46% ± 11.31% (± SD) of the days at liberty during the study period. The lowest site fidelity observed so far was in the outer LB area, where tagged fish remained present for 10.82% ± 11.88% of the days at liberty during the study. Differences in site fidelity were found to be highly significant (p = 0.00038). The average number of detections per fish, was highest (16,518) at Station 6, located in an area of the inner LA Harbor known as the Consolidated Slip. This receiver station has also logged the highest number of total detections from all fish at 611,154 so far. These preliminary results point to the Consolidated Slip as a highly utilized area by *G. lineatus* in the Harbor. This area is also known to contain the highest concentrations of DDT and PCBs in sediments throughout the entire Harbor.

**728 Dominguez Channel and Greater Los Angeles and Long Beach Harbor Waters Toxic Pollutants TMDL, a Summary of the Regulatory and Environmental Overview** M. Arms, Port of Long Beach / Environmental Management Division; A. Jirik, K. Curtis, Port of Los Angeles.

Total Maximum Daily Loads (TMDLs) are regulatory tools that have been successfully applied in many instances across the nation with the end result of a cleaner environment. TMDLs were developed to address point source contamination, but are challenging to implement for non-point source or legacy contamination situations. TMDL development in the Los Angeles area has been driven by a consent decree signed between the United States Environmental Protection Agency (USEPA), Heal the Bay, Inc. and Santa Monica BayKeeper, Inc. in 1999 that required all 1998 Clean Water Act Section 303(d) listed waterbodies to have TMDLs completed within 13 years of the consent decree. The TMDL for Toxic Pollutants in Dominguez Channel and Greater Los Angeles and Long Beach Harbor Waters is one of the 92 TMDLs under the consent decree. This TMDL is complicated by the number of environmental matrices (water, sediment, and tissue), number of stakeholders, presence of legacy pollutants, questions regarding

the bioaccumulation and human health risk of the pollutants, and questions regarding any current inputs of the TMDL pollutants into the system. Because of the complexities of the TMDL, many questions were not completely answered prior to adoption of the TMDL. The purpose of this talk is to summarize the final TMDL, effective March 2012 (with a 20-year implementation), as well as outline the remaining questions and the proposed scientific studies that need to be conducted in order to better inform the TMDL.

**729 Estimating Fish Tissue Concentrations from Sediment-Associated Contaminants: Incorporating Fish Behavior** K. von Stackelberg, E Risk Sciences, LLP. It is important to understand the spatial distribution of non-point sources to sediments and how that influences exposure and potential trophic transfer of contaminants. Aquatic food web exposures to sediment-associated contaminants depend on contaminant concentrations but also the foraging strategies of the fish species. These foraging and migration strategies can lead to differential exposures that are not captured through the use of simple exposure statistics such as means or SWACs. This presentation describes the use of spatially explicit modeling approaches to simulate the effect of fish foraging strategies and habitat use on predicted tissue concentrations. A range of scenarios are explored to highlight the quantitative influence of including fish behavior and capturing spatially-explicit exposures when considering TMDLs.

**730 Modeling Bioaccumulation of Contaminants in Puget Sound: An Analysis of Site-Specific Parameters** G. Lowery, Western Washington University / Huxley College of the Environment, Western Washington University; E. Patmont, Western Washington University / Huxley College of the Environment; R.M. Sofield, Western Washington University / Huxley College of Environment. The industrial activity in the Puget Sound region necessitates understanding the bioaccumulation of contaminants to achieve protective levels for aquatic life and safe fish consumption. Considerable progress has been made in modeling the bioaccumulation of contaminants in aquatic organisms; because of this, there are improved theory and methods to assess the contributing parameters and identify data gaps. In the current study, the extensive data for Puget Sound biological and environmental characteristics were compiled from the Washington State Department of Ecology's Environmental Information Management System (myEIM) for input parameters. The AQUAWEB model of Gobas and Arnot was built in STELLA (ISEE Systems, Inc., Lebanon, New Hampshire; www.iseesystems.com). As a preliminary modeling step, the distribution of each input parameter was determined using Oracle Crystal Ball. The median of each parameter was used in the STELLA® model. STELLA was also used to run a sensitivity analysis. The results are a predicted sum PCB concentration of 155 ng chemical/g of organism in *Mytilus edulis* for three common PCB mixtures of Aroclor 1242, 1254, and 1260. The model was substantially more sensitive to percent sediment organic carbon (a site-specific value) while organism parameters such as mussel weight and lipid content, and other site-specific environmental parameters including water temperature, particulate organic matter, dissolved organic matter, and the concentration of suspended solids had virtually no impact on the model output. To further characterize what concentrations of PCBs are likely to bioaccumulate in *M. edulis* from Puget Sound, a Monte Carlo analysis will be completed using the parameter distributions. Model calibration will be included using measured bioaccumulation in a subset of the Puget Sound dataset.

**731 Overview of Monitoring Conducted in Support of the Los Angeles and Long Beach Harbors Toxics TMDL** A. Jirik, K. Curtis, Port of Los Angeles; M. Arms, Port of Long Beach; A. Crumpacker, D. Moore, Weston Solutions, Inc. The recently adopted Los Angeles and Long Beach Harbors Toxic Total Maximum Daily Load (TMDL) requires that special studies, including harbor-specific sediment and fish tissue linkage studies, will be developed and implemented within the Harbor Complex. These studies are crucial to determine allowable sediment contamination levels in the Harbor Complex which will result in compliance with fish tissue numeric targets. Compliance with the TMDL will likely be based on sediment quality objectives (SQOs), which were adopted by the California State Water Resources Control Board in 2009 to assess the direct effects of pollution in sediments on benthic communities. The direct effect SQOs use a multiple lines of evidence approach and include sediment chemistry, sediment toxicity, and benthic community assessments. Currently, Phase 2 of the SQOs is under

development, and focuses on the indirect effects of sediment contamination. Critical to TMDL implementation is that the SQO Phase 2 decision support tool focuses on prediction of the proportion of fish tissue contamination from sediment pollution. Within the Harbor Complex, it is not currently known how much of the observed fish tissue contamination can be linked to local contaminated sediments. This makes compliance with the TMDL, which requires clean-up of contaminated sediments to levels which will result in fish tissue numeric target compliance, difficult. The Ports of Los Angeles and Long Beach have devoted significant resources to the development of a hydrodynamic, water quality and sediment transport model, fish tracking studies, and sediment collection, analysis and reporting in support of the TMDL. In 2011, fish tissue, sediment, and overlying water samples were collected for the purpose of developing a sediment and fish tissue linkage analysis. This dataset represents the first major effort in the State focused on collecting data for the purpose of developing sediment and fish tissue linkage. This presentation focuses on initial linkage evaluations between sediments and observed fish tissue concentrations as well as a comparison of the 2011 results to Palos Verdes shelf studies. Final results of these analyses will be important for the development of the TMDL monitoring and implementation plans, as well as to calculate revised sediment numeric targets.

**732 Sediment Transport: The Key to Understanding Contaminants in Sediments for TMDL Applications** Y. Poon, S. Ueoka, Everest International Consultants; A. Jirik, Port of Los Angeles; K. Curtis, Port of Los Angeles / Environmental Management Division; M. Arms, Port of Long Beach / Environmental Management Division. The Dominguez Channel and Greater Los Angeles and Long Beach Harbor Waters (Harbor) Toxic Pollutants Total Maximum Daily Loads (TMDLs) will limit the discharge of pollutants into San Pedro Bay with the goal of meeting water quality standards. Impairments are attributed to heavy metal and organic pollutant concentrations in existing sediments and organic pollutant levels in fish tissue. Fundamentally, the Harbor TMDLs were developed based on the concept that pollutant concentrations in the sediment bed are the result of depositing sediment and contaminants, and there is a direct linkage between the contaminants in the sediment bed to the fish tissue. Hence, an understanding of the sediment loadings to the harbor from watersheds and storm water runoffs, as well as the erosion and migration of the resuspended sediment from existing harbor bed, is important for the interpretation and implementation of the Harbor Toxic TMDL. This paper provides a summary of recent studies conducted by the Port of Los Angeles and the Port of Long Beach (Ports) and the others to understand the loading, erosion and transport of sediments in the Harbor. These studies include field works and the development of a three-dimension (3-D) hydrodynamic, sediment and contaminant transport for the Harbor. The field studies include: (i) an ongoing sediment tracer study to assess the erosion of the sediment bed in the Dominguez Channel and Consolidated Slip; the study aims at understanding erosion of bed sediments and the transport of contaminants associated with the eroded bed sediments into the Harbor using synthetic tracers to mimic the sediment properties and tracking the erosion and migration of the tracers into the Harbor under both dry and wet weather conditions; (ii) a sediment tracer study to assess deposition of sediments in the Harbor from the Los Angeles River and San Gabriel River during rain events; and (iii) a study to understand the dispersion of sediment plumes due to dredging activities in the Harbor. The data collected from these field studies were also used to calibrate the 3-D hydrodynamic and sediment transport model.

**733 Tracking, Identifying, and Abating Non Point Source Pollution, the Big Question for TMDL Compliance** G. Williams, D. Renfrew, Weston Solutions, Inc. Agencies and municipalities facing Total Maximum Daily Load (TMDL) implementation and compliance are required to develop implementation plans that identify sources and provide solutions to abate point and non-point pollutant sources. Requirements to abate or reduce sources are set on an implementation timeline as part of the TMDL and require coordination among stakeholders. Non-point sources of pollution are some of the most difficult to control, because of the complexities required to identify, quantify, and abate them. In the case of air deposition and stormwater runoff, multiple jurisdictions, regulatory agencies, and potential pollutant sources must all be considered during TMDL implementation planning. The load allocations for air deposition of pollutants included in the TMDL for Toxic Pollutants in Dominguez Channel and Greater Los Angeles and Long Beach Harbor Waters (Toxics TMDL) is greater than the

load allocation from sediments for some pollutants included in the TMDL. No reductions of air deposition are required within the TMDL. A similar situation can be found for the Chollas Creek Dissolved Metals TMDL, which is located in the City of San Diego. To address the uncertainty of air deposition, and its importance as a non-point source contributing to elevated dissolved copper levels in the Creek, the City of San Diego conducted a multiple phased aerial deposition and pollutant source identification study to better understand surface water pollutant source contributions in the Chollas Creek Watershed. Findings from the study demonstrated numerous air deposition sources from industries, transportation, facilities and architectural building materials. These aerial sources can be collectively considered non-point sources even though they originated from a given location and were transported through an alternative transport mechanism (air deposition versus stormwater runoff). The study showed that 49% of the copper load found in urban runoff from Chollas Creek was attributable to automobile brake pad wear from the overall watershed while 51% of the copper load was attributable to specific *permitted* industrial source emissions. Because atmospheric deposition can be a significant contribution to TMDL loads, both directly and indirectly through stormwater runoff, mechanisms to quantify, identify sources, and abate these sources are necessary for successful TMDL implementation and ultimately, compliance.

**734 Root pore size as a potential mechanism of exclusion for gold nanoparticle uptake in aquatic vascular plants** B. Glenn, Clemson University / Clemson Institute of Environmental Toxicology (CU-Entox), Clemson Institute of Environmental Toxicology / graduate student; J. Hudson, Advanced Materials Research Laboratories (AMRL); S.J. Klaine, Clemson University / Institute of Environmental Toxicology (CU-ENTOX), Clemson Institute of Environmental Toxicology / Institute of Environmental Toxicology (ENTOX), Clemson University / Institute of Environmental Toxicology (ENTOX). The three aquatic plants *Egeria densa*, *Myriophyllum simulans*, and *Azolla caroliniana* have been found to bioconcentrate spherical, citrate capped gold nanoparticles (AuNPs) in suspension. The bioconcentration factor of AuNPs was found to be dependent on size of AuNP and species of aquatic plant. The AuNP treatments used in this study had an average size of 4, 18 and 30 nanometers (nm). To determine a possible mechanism of exclusion, the roots of each species were further investigated. The root structure was investigated using a published solute exclusion technique to estimate root pore size. Based off of size of solute, and principles of diffusion, the change in root cell shape can be linked to the cellular wall pore size. This estimation of pore size was then confirmed using high-resolution transmission electron microscopy (TEM) to visualize the pore structure in the roots of each species. Based on previous research, exposure to AuNPs in well water at a nominal concentration of 250 µg/L showed highest bioconcentration of small AuNPs and the least bioconcentration of the large AuNPs in each species. *Azolla caroliniana* showed the highest tissue concentrations of the species tested. Results indicated that pore size plays an important role in AuNP uptake, excluding the larger particles. While root pore size was important in initial AuNP uptake, results also indicated that plant physiology played an important role in concentration of AuNPs into the plant tissue. Aquatic plants with a transpiration stream tended to show higher bioconcentration factors than those that were fully submerged.

**735 Impact of Cerium Oxide Nanoparticles on Cilantro (*Coriandrum sativum*)** M.I. Morales, A.C. Barrios, C.M. Rico, J.R. Peralta-Videa, J.L. Gardea-Torresdey, The University of Texas at El Paso / Department of Chemistry. The impact of engineered nanoparticles (ENPs) on edible plants is currently a theme of great concern. Studies have reported that CeO<sub>2</sub> NPs are stored in plant tissues without modification. Thus, these NPs could be distributed in the food chain through edible plants, posing a threat for human health. Cilantro (*Coriandrum sativum*) is a very important culinary and medicinal plant worldwide. It is consumed either as a fresh herb or as a spice. In this research cilantro plants were germinated and grown in organic soil treated with CeO<sub>2</sub> NPs at concentrations varying from 0 to 500 mg kg<sup>-1</sup>. Spectroscopic techniques were used to analyze the plants treated with CeO<sub>2</sub> NPs. The data showed a significant difference in the uptake of the CeO<sub>2</sub> NPs at 250 and 500 mg kg<sup>-1</sup> compared to 62.5 and 125 mg kg<sup>-1</sup>. In addition, plants treated with 125 and 250 mg Kg<sup>-1</sup> of CeO<sub>2</sub> NPs were significantly longer compared with controls and plants treated with 62.5 and 500 mg kg<sup>-1</sup> CeO<sub>2</sub> NPs.

**736 Impact of functionalized and non-functionalized multiwalled carbon nanotubes on arsenic hyperaccumulation in Chinese brake fern (*Pteris vittata*)** B. Shrestha, Texas Tech University / Department of Environmental Toxicology, Texas Tech University; P. Payton, USDA-ARS; J. Canas, Texas Tech University / Department of Environmental Toxicol. Arsenic (As) is a widely distributed and highly toxic contaminant in the environment. Carbon nanotubes (CNTs) are considered a good adsorbent for inorganic and organic ions. Surface modified, raw and functionalized CNTs have been found to adsorb anionic heavy metals like As and chromium. Hence, the presence of CNTs in soil may modify the bioavailability of anionic As, which may ultimately affect As hyperaccumulation in plants, including food crops, from soil. Considering the potential release of CNTs into the environment, it is important to understand their effect on the fate of contaminants, like As. In addition, evaluation of potential application of CNTs in green technology, such as phytoextraction of cationic and anionic heavy metals from soil and groundwater, is innovative for environmental remediation. This study aimed to evaluate the effects of functionalized and non-functionalized multiwalled carbon nanotubes (MWNT) on As hyperaccumulation in Chinese brake fern (*Pteris vittata*, an As hyperaccumulator). Clean field soil was spiked with potassium arsenate monobasic and aged for four weeks at 60% water holding capacity. Soil samples were taken to determine initial total As concentrations. Arsenic-spiked soil was spiked with functionalized and non-functionalized MWNT at four concentrations (0-, 25-, 50-, 100 mg/kg). Chinese brake fern (four to five frond stage) was planted in a pot containing the As-MWNT mixture and grown for 4 weeks in a greenhouse at 16:8 hours light:dark at 60% water holding capacity. Fern were harvested after 4 weeks and dried at 65°C for 48 h. Fern roots and fronds were digested and analyzed using EPA Method 3050B. Translocation and bioaccumulation factors for As in the fern was calculated based on the ratio of total As concentration in fronds to roots and plants to soils, respectively. This research will provide valuable information on the effects of MWNT on As bioavailability in soil as well as on the potential application of MWNT in green technology for environmental remediation.

**737 Hg bioaccumulation in shoots of the macrophyte *Elodea nuttallii*: an opportunity for phytoremediation?** N. Regier, University of Geneva; C. Cosio, Geneva University, Geneva University / Forel Institute. Previous studies suggest that macrophytes might participate in bioaccumulation and biomagnification of toxic mercury (Hg) in aquatic environment. Hg bioaccumulation and uptake mechanisms in macrophytes need therefore to be studied. Amongst several macrophytes collected in an Hg contaminated reservoir in Romania, *Elodea nuttallii* showed a high organic and inorganic Hg accumulation and was then further studied in the laboratory. *Elodea nuttallii* is a rooted submerged aquatic macrophyte native to North America, which occurs as aggressive invader worldwide. It is often found in metal contaminated sites. Hg tolerance and accumulation of this plant was also high in the microcosm. Basipetal transport of inorganic Hg was predominant, whereas acropetal transport of methyl-Hg was observed with apparently negligible methylation or demethylation *in planta*. Hg concentrations were higher in roots>leaves>stems and in top>middle>bottom of shoots. In shoots, more than 60% Hg was found intracellularly where it is believed to be highly available to predators. Accumulation of inorganic and methyl-Hg in shoots was highly reduced by cold, death and by competition with Cu<sup>2+</sup> for inorganic Hg. Hg in *E. nuttallii* shoots seems to mainly originate from the water column, but methyl-Hg can also be remobilized from the sediments and might drive in part its entry in the food web. At the cellular level, uptake of Hg into the cell sap of shoots was linked to the metabolism, in particular to copper transporters. In summary, our results revealed that shoots of *E. nuttallii* are extremely tolerant to Hg and show huge bioaccumulation ability. Both might be interesting for phytoremediation of contaminated water. Based on densities previously reported in the field by other authors (350-2800 g DW m<sup>-3</sup>) and concentration of Hg found in Babeni reservoir, it can be estimated that 0.7 to 5.6 mg Hg m<sup>-3</sup> could be removed with these plants. This amount is likely to return to water and sediments at the end of the growing season when plants decay. Moreover, the Hg uptake by shoots might be an important pathway of Hg from the water to organisms feeding on the macrophytes. In conclusion, these plants should probably be removed in contaminated sites.

**738 Plant uptake, translocation and bioaccumulation of PPCPs in vegetables** X. Wu, J.L. Conkle, J. Gan, University of California, Riverside / Dept. of Environmental Sciences. In arid and semi-arid regions (e.g.,

American Southwest), municipal treated wastewater is becoming an important water source to augment agricultural irrigation. An emerging threshold issue to this reuse, however, is the potential accumulation of trace contaminants such as pharmaceutical and personal care products (PPCPs) from the recycled water to edible plant tissues. At present very few studies have considered the uptake of PPCPs by plants, and our knowledge of plant accumulation, especially in vegetables, is essentially nonexistent. In this study, we evaluated the uptake and translocation of 19 PPCPs which were frequently detected in treated wastewater by four common vegetables (iceberg lettuce, spinach, cucumber and pepper) that were grown in spiked nutrient solutions under greenhouse conditions. The spiked concentrations were 500 ng/L and 5 µg/L, with the lower treatment level close to those in real treated wastewater. The result showed that many PPCPs could be accumulated by vegetables via root uptake. Fluoxetine accumulated in both leaves and roots, while triclocarban and triclosan tended to accumulate in roots. Some PPCPs like caffeine, meprobamate, diuron, carbamazepine, were more likely to accumulate in leaves. The accumulation potential and the translocation tendency from roots to leaves were further evaluated by correlating with the properties of PPCPs, e.g., log  $K_{ow}$ .

**739 Uptake of pharmaceutical and personal care products by cabbage (*Brassica campestris*) from fortified and biosolids-amended soils** C. Holling, Colorado State University-Pueblo / Biology; J.L. Bailey, Colorado State University-Pueblo / Chemistry; B. Vanden Heuvel, Colorado State University-Pueblo / Biology; C.A. Kinney, Eastern Washington University / Chemistry & Biochemistry, Colorado State University-Pueblo / Chemistry. Pharmaceuticals and personal care products (PPCPs) are commonly present in wastewater biosolids and subsequently present in soil amended with biosolids. To measure the potential for PPCPs to accumulate in crops, two sets of greenhouse experiments to study the accumulation of PPCPs in soils or biosolids by Chinese cabbage (*Brassica campestris*) were. In the first set of experiments the soil was fortified with four pharmaceuticals to environmentally relevant concentrations based on typical biosolids application rates. This resulted in final soil concentrations of 2.6 ng g<sup>-1</sup> carbamazepine, 3.1 ng g<sup>-1</sup> sulfamethoxazole, 5.4 ng g<sup>-1</sup> salbutamol, and 0.5 ng g<sup>-1</sup> trimethoprim. In the second set of experiments cabbage was grown in soil amended with an agronomic rate of biosolids from a local wastewater treatment plant. The concentration of PPCPs in the biosolids-amended soil was 93.1 ng g<sup>-1</sup> carbamazepine, 67.4 ng g<sup>-1</sup> sulfamethoxazole, 30.3 ng g<sup>-1</sup> salbutamol, 433.7 ng g<sup>-1</sup> triclosan and 24.7 ng g<sup>-1</sup> trimethoprim. After growing to maturity the plants in each study were harvested and the arials were separated from roots for individual analysis. All four of the human pharmaceuticals in the fortified soil were detected in both the aerial and root tissues of the cabbage. The median concentrations of pharmaceuticals in the cabbage tissues were: 255.4 ng g<sup>-1</sup> arials and 272.9 ng g<sup>-1</sup> roots carbamazepine; 110.8 ng g<sup>-1</sup> arials and 226.7 ng g<sup>-1</sup> roots sulfamethoxazole; 47.6 ng g<sup>-1</sup> arials and 91.6 ng g<sup>-1</sup> roots salbutamol; and 7.6 ng g<sup>-1</sup> arials and 53.7 ng g<sup>-1</sup> roots trimethoprim. Although all study compounds were present in the biosolids-amended planting soil, only carbamazepine (317.6 ng g<sup>-1</sup> arials and 416.2 ng g<sup>-1</sup>), salbutamol (21.2 ng g<sup>-1</sup> arials and 187.6 ng g<sup>-1</sup>), and triclosan (22.9 ng g<sup>-1</sup> arials and 1220.1 ng g<sup>-1</sup> roots) were detected in the arials and roots of the cabbage. Sulfamethoxazole was also detected in the roots of one of the plants grown in the biosolid-amended soil. The results of this study demonstrate that plants exposed to environmentally relevant concentrations of the PPCPs can accumulate these compounds including in the edible portion of the plant.

**740 Evaluation of Extraction Methods on the Characterization of Antibiotic Uptake in Lettuce** J.B. Sallach, University of Nebraska-Lincoln / Department of Civil Engineering; S. Bartelt-Hunt, University of Nebraska / Civil Engineering, University of Nebraska-Lincoln / Civil Engineering; D. Snow, University of Nebraska-Lincoln / Water Sciences Laboratory, School of Natural Resources, University of Nebraska / Associate Professor; X. Li, University of Nebraska-Lincoln / Civil Engineering; L. Hodges, University of Nebraska-Lincoln / Agronomy and Horticulture. Global water scarcity necessitates the reuse of municipal or agricultural wastewater for irrigation. Typically, municipal and agricultural wastewater can contain low levels of antibiotics and these compounds can be introduced to plants after irrigation with recycled wastewater. In addition, there is little information on the optimal methods for extraction of antibiotics from complex cellulosic matrices, such as plant tissues. In this study, the potential uptake of four antibiotics originating in irrigation water was evaluated. The recovery of four antibiotics (sulfamethoxazole, oxytetracycline, lincomycin, and ciprofloxacin)

was optimized by comparing four extraction techniques: freeze and thaw, mechanical maceration, ultrasonication, and microwave assisted solvent extraction (MASE). To evaluate the extraction techniques, lettuce samples were spiked with a known quantity of each antibiotic and corresponding internal standards. Extracts were analyzed by electrospray ionization LC-MS/MS and method detection limits (MDL) and percent recoveries were determined. Initial results show MASE having the least efficient extraction, perhaps resulting from increased temperatures. Ultrasonication resulted in the lowest MDLs and highest percent recovery for the target antibiotics, followed by the freeze and thaw method. After development of the extraction approach, the presence of antibiotics in lettuce grown in a potting soil was monitored after subirrigation for 6 weeks with a simulated wastewater containing 1 mg/L of ciprofloxacin, lincomycin, oxytetracycline, and sulfamethoxazole. Initial results indicate that antibiotics from recycled wastewater can be transferred to plant tissue. The relative quantities of antibiotics in lettuce shoots and rhizosomal soil will be reported. Preliminary results indicate potential antibiotic uptake on the order of 10<sup>-10</sup> ng/g of plant material.

**741 Investigating differences in the root to shoot transfer of organic compounds between zucchini, squash and soybean using a pressure chamber method** W.J. Doucette, N. Orito, Utah State University / Utah Water Research Laboratory. Transpiration Stream Concentration Factors (TSCF) for 14C-caffeine (log K<sub>ow</sub> = -0.07), 14C-triclocarban (log K<sub>ow</sub> = 4.9) and 14C-endosulfan (log K<sub>ow</sub> = 3.83), relative to titrated water, were determined using a pressure chamber method for soybean (*glycine max L.*), zucchini (*cucurbita pepo ssp pepo*), and squash (*cucurbita pepo ssp ovifera*). TSCF values for caffeine (TSCF = 0.8), endosulfan (TSCF = 0.2) and triclocarban (TSCF = 0.05) were statistically equivalent for squash and soybean. For zucchini, the TSCF for caffeine was the same as for squash and soybean. However, for the more hydrophobic endosulfan and triclocarban, the TSCF values were 0.6 and 0.4, or about 3 and 10 times greater, respectively, than the soybean and squash. The greater difference in TSCF with increasing log K<sub>ow</sub> suggested a solubility enhancement in the zucchini xylem sap. To test this hypothesis, the solubility of caffeine and triclocarban in soybean and zucchini xylem sap was determined and compared to deionized water using a modified shake flask method. Caffeine solubility in the xylem saps of soybean and zucchini was equal to deionized water (22000 mg/L) triclocarban solubility in the zucchini xylem sap was double (20.6 mg/L) that of the soybean xylem sap (10.6 mg/L) and deionized water (11.2 mg/L). This indicates that the enhanced root to shoot transfer of hydrophobic organics reported for zucchini may be partly due to increased solubility in the xylem sap. Further xylem sap characterization is needed to determine the mechanism of solubility enhancement.

**MP001 A comparison of food web magnification factors for mercury transfer through communities within two estuaries of Southwest Florida** D. Rumbold, Florida Gulf Coast University / Associate Prof of Marine Science, Florida Gulf Coast University / Professor of Marine Science; T. Lange, D. Richards, Florida Fish and Wildlife Conservation Commission; H. Benedict, Florida Gulf Coast University. We are assessing mercury (Hg) trophic transfer within different ecosystems of southwest Florida using stable isotope analysis (SIA) and the food web magnification factor (FWMF; also known as trophic magnification factor) approach. Viewed as an average biomagnification factor through a community, FWMFs for Hg can differ between systems as a result of variation in food web dynamics (e.g., length, linkage strength, etc.) or methylation potential and basal concentration of Hg entering the food web. Here we compare  $\delta^{15}\text{N}$ -derived slopes and FWMF for the Shark River and Caloosahatchee River estuaries that have watersheds with very different land uses. Although the hydrology of both has been altered, the former has relatively pristine habitats and comprises the major water flow pathway through southern Everglades National Park (ENP), whereas the later watershed is dominated by agriculture upstream and dense urban development downstream. The results of this study will be compared to findings from a similar investigation recently completed in the coastal waters off southwest Florida and  $\delta^{15}\text{N}$ -derived slopes or FWMF reported in the published literature for other marine systems.

**MP002 An evidence of temporal increase of mercury level in offshore region of Japan using archived open sea cetaceans** T. Irai, Ehime University / Center for Marine Environmental Studies (CMES); T. Isobe, Ehime University / Senior Research Fellow Center, Ehime University / Senior Research Fellow, Ehime University / Center for Marine Environmental Studies; Y. Yasuda, S. Urakami, Ehime University; S. Tanabe, Ehime University / Center for Marine Environmental Studies; S.H. Horai, Tottori University / Department of Regional Environment, Tottori University / Associate Professor; T. Yamada, Y. Tajima, National Museum of Nature and Science, Japan. Mercury cycling in the Pacific Ocean has gained significant attention in recent years, especially with regard to raising mercury emissions from Asia. Recent global modeling suggested potential increasing trend of Hg in North Pacific Intermediate Water (NPIW) due to lateral transport of Hg-rich water masses originated from western Pacific. Uncertainty exists concerning whether increases in anthropogenic emissions over time might have caused increased mercury bioaccumulation in the biota in this region. Marine mammals have the highest potential to accumulate Hg, because of their long life span and higher trophic positions in marine food chains. In this study, we examined accumulation features and temporal trends of trace element levels in the liver and brain of striped dolphin (*Stenella coeruleoalba*) and Melon-headed whale (*Peponocephala electra*) which migrate in the range of temperate and tropical regions by the influence of the warm Kuroshio Current. Stranded or bycaught species have been collected from coastal regions of Japan since 1977 to 2011. These samples after collection were stored under  $-25\text{ }^{\circ}\text{C}$  in the environmental specimen Bank (es-Bank), Ehime University. Forty eight striped dolphin (1977 to 2004) and 69 Melon-headed whale (1982 to 2011) specimens were used for chemical analysis. Hepatic Hg levels ranged from  $6.5 - 1100$  and  $12 - 1240\text{ }\mu\text{g g}^{-1}$  (DW) in striped dolphin and Melon-headed whale, respectively. These Hg levels varied depending on the size of individuals but sex dependence was not found. Multiple linear regression analysis which aimed to correct effect of body size indicated significant increase of total Hg level in striped dolphin ( $p < 0.01$ ) and organic Hg level in Melon-headed whale ( $p < 0.05$ ). This result implied temporal increase of Hg level in offshore regions of Japan. Mercury in the brain of striped dolphin and Melon-headed whale correlated positively with hepatic Hg level, and ranged from  $1.4 - 84$  and  $4.3 - 81\text{ }\mu\text{g g}^{-1}$  (DW), respectively. These levels are comparable to the concentrations that were found to cause various toxic effects in animal experiments suggesting that increasing Hg level in open ocean will possibly induce ecotoxicological effects on cetaceans.

**MP003 Assessing the fate of mercury in animal inoculations: Simultaneous determination of ethylmercury and methylmercury in pig livers and kidneys** J.E. Creswell, Brooks Rand Labs; A. Carter, Brooks Rand Labs / Mercury Group Lead; M. Briscoe, M. Kennard-Mayer, Brooks Rand Labs. There has been significant controversy over the use of the ethylmercury-based preservative thimerosal and, as a precautionary measure, it has been phased out of most childhood vaccines used in the United States and the European Union. In the United States, all new vaccines licensed since 1999

are free of thimerosal as a preservative. The preservative is still common in many vaccines used outside North America and Europe. The mechanism of mercury toxicity is not completely understood. There is still significant interest in better understanding the metabolism and accumulation of mercury in different animal species and in evaluating the safety of thimerosal in currently approved vaccines. Tissue deposition of ethylmercury differs from that of more widely-studied methylmercury, emphasizing the importance of measuring ethylmercury in a variety of species. Because of the toxicity of ethylmercury to humans, it is especially important to measure it in food producing animals, such as livestock and fish, raised for human consumption, including those which may have been injected with thimerosal-containing inoculations. We applied a method of simultaneous determination of ethylmercury and methylmercury to cryogenically-ground pig livers and kidneys by derivatization, purge & trap, gas chromatographic separation, pyrolytic decomposition, and atomic fluorescence spectrometry. Liver and kidney samples were selected as these are organs known to accumulate large percentages of the total mercury burden resulting from thimerosal-containing inoculations. This method quantifies the most prevalent organomercurial species in these organs with a single preparation and analytical run, making it simple and relatively low-cost to perform. We validated the performance of the method by analyzing NIST Standard Reference Material 955c: Toxic Elements in Caprine Blood, as well as matrix spikes into the pig liver and kidney tissues. To evaluate the applicability of the method to other animal species, we also analyzed spiked and unspiked freeze-dried fish tissue samples. We report ethylmercury, methylmercury, and inorganic mercury data from the livers and kidneys of pigs and from freeze-dried fish tissue samples.

**MP004 Biomagnification of mercury in a small polynya Arctic food web** L. Arsenault, Acadia University; N.J. O'Driscoll, Acadia University, Acadia University / Department of Earth & Environmental Sciences; M. Mallory, Acadia University / Canadian Wildlife Service; K. Kidd, University of New Brunswick. Mercury is a contaminant of ongoing concern in the Arctic due to its persistence and impacts on the health and reproduction of biota. Polynyas are productive systems that are critical to the feeding, reproduction, and migration of marine birds and mammals. Small polynyas are common in the Arctic; however, the biomagnification of mercury in these systems has not been studied. We examined the biomagnification of mercury in a small polynya located near Nasaruaalik Island in the Canadian High Arctic. Food web samples including kelp, zooplankton, fish, and chicks were analyzed for methylmercury, total mercury and stable isotopes. Methylmercury was highest in Arctic tern (*Sterna paradisaea*) chicks (liver:  $1.17 \pm 0.90\text{ }\mu\text{g/g}$ , muscle:  $0.69 \pm 0.73\text{ }\mu\text{g/g}$ ), Common eider (*Somateria mollissima borealis*) chicks (liver:  $0.69\text{ }\mu\text{g/g}$ , muscle:  $0.90\text{ }\mu\text{g/g}$ ), and Long-tailed duck (*Clangula hyemalis*) chicks (liver:  $0.48 \pm 0.12\text{ }\mu\text{g/g}$ , muscle:  $0.36 \pm 0.07\text{ }\mu\text{g/g}$ ). Copepods (*Calanus hyperboreus*) had the smallest concentration of methylmercury ( $0.01\text{ }\mu\text{g/g}$ ). Arctic cod (*Boreogadus saida*) and Arctic alligatorfish (*Ulcina olrikii*) had log bioaccumulation factors of 6.09 and 6.29 respectively.

**MP005 Bricks that Breathe: Residential mercury contamination in Huancavelica, Peru** N. Hagan, University of North Carolina at Chapel Hill / Environmental Sciences and Engineering; N. Robins, North Carolina State University / Department of History; H. Hsu-Kim, Duke University / Civil & Environmental Engineering; S. Halabi, Duke University / Department of Biostatistics and Bioinformatics; R. Espinoza Gonzales, Environmental Health Council; D. Richter, Duke University / Nicholas School of the Environment; J. Vandenberg, U.S. Environmental Protection Agency / National Center for Environmental Assessment. Between 1564 and 1810, nearly 17,000 metric tons of mercury (Hg) vapor were released from cinnabar smelting into the atmosphere in Huancavelica, Peru. Following atmospheric transport and transformation, Hg deposited in and contaminated the local community. Ambient soil Hg concentrations are among the highest levels in surface soil in the world, ranging up to  $1200\text{ }\mu\text{g/g}$ . Because residents in Huancavelica have built their modest adobe brick homes using this contaminated soil, concern exists for residential Hg exposure. Problems arise because the interior walls and floors are often unsealed and uncovered, which allows Hg to emanate in both particulate and vapor form. Homes in Huancavelica were sampled for Hg in different media, including adobe bricks, dirt floors, surface dust, and air. Interior adobe brick samples had Hg concentrations as high as  $1670\text{ }\mu\text{g/g}$ , while dirt floor samples ranged up to  $2040\text{ }\mu\text{g/g}$ . Surface dust, likely deposited from resuspended adobe brick and dirt floor particles, contained Hg measuring up to  $660\text{ }\mu\text{g/g}$ . Elemental

Hg vapor concentrations in indoor air were measured up to  $5.51 \mu\text{g}/\text{m}^3$ . The results suggest that there is potentially a significant health risk to the residents of Huancavelica, especially women and children who spend a majority of their time in their homes. Inhalation of particulates and Hg vapor and ingestion of settled particles on food and surfaces potentially cause serious neurological and other health problems. The results of this study will provide a detailed understanding of the relationship of Hg between different sources of Hg within the home, as well as the spatial distribution of Hg across the entire community. A comprehensive analysis of residential Hg contamination and exposure in Huancavelica will guide the development and implementation of mitigation and remediation strategies in the community to reduce health risks from residential Hg exposure. Disclaimer: The information in this abstract has been funded in part by the U.S. Environmental Protection Agency and in part by the EPA/UNC Toxicology Training Agreement CR-83515201-0, with the Curriculum in Toxicology, University of North Carolina at Chapel Hill. It has been subjected to review by the National Center for Environmental Assessment and approved for submission. The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

**MP006 Comparison of Methods Implemented for Quantifying Groundwater Seepage and Mercury Loading into River Surface Water** S. Jelen, V. Onwueme, T. Glover, M. Bystedt, AMEC Environment & Infrastructure. Surface water and groundwater investigations are usually conducted separately when characterizing chemical impacts to water resources during remedial investigations. Hydraulic interconnectivity between groundwater and surface water may be discussed in qualitative terms; however, the locations and amounts of groundwater entering into the river system are rarely quantified *in situ*. The locations and quantities of groundwater seepage into a river system can provide valuable information if groundwater has the potential to serve as an ongoing source of contamination to surface water. In this study, several methods were used to investigate groundwater-surface water interactions along a focused area of a river. The local geology is composed of fractured bedrock, which introduces difficulty in creating accurate mapping of groundwater infiltration using traditional methods, such as seepage meters. The methods selected for this investigation included: 1) infrared imagery along the river bank to identify colder groundwater locations that may be mixing with the warmer surface water, and 2) a real-time specific conductivity survey. Additionally, tracers were added to the river surface water upstream of the study area, and the concentrations of these tracers were measured at defined distances along the study site. The observed changes in tracer concentrations were used to calculate the estimated amount of dilution (i.e., groundwater infiltration) occurring within the study area. The amount of dilution determined from the tracer studies not only provided information on the volume of groundwater entering the river system, but also provided an estimate of chemical loading that was occurring through the combination of tracer data and analytical data for mercury concentrations in groundwater and surface water.

**MP007 Determining rate constants for photochemical reduction of mercury in Arctic snow – Method development and testing** E. Mann, Memorial University of Newfoundland / Environmental Science, University of Toronto Scarborough / Chemistry; N. O'Driscoll, M. Mallory, Acadia University; A. Qureshi, Harvard University; T. Avery, Acadia University; J. Dalziel, R. Tordon, Environment Canada; S. Ziegler, Memorial University of Newfoundland. Photochemical reduction and subsequent volatilization is the primary mechanism for mercury losses from snow prior to the melting. The arctic is a region sensitive to mercury inputs and snow melt may represent an important way for mercury to move into Arctic aquatic ecosystems. To date, the few studies investigating mercury photochemical reduction in snow have been field based and subject to many uncontrolled variables, like temperature and irradiation intensity. The goal of this work was to develop a controlled method to study mercury photochemical reduction in snow, and examine the effects of irradiation intensity. The system consists of a small quartz chamber placed inside a Luzchem photoreaction chamber held at  $-10^\circ\text{C}$ . The Luzchem photoreactor produces UV irradiation intensities similar to early spring and early summer Arctic and temperate natural insolation ( $1.26 - 5.78$  and  $2.44 - 4.99 \text{ W}/\text{m}^2$  in for  $\lambda = 280 - 400 \text{ nm}$ , for the photoreactor and Arctic spring, respectively). Over a 24 hour period mercury-free air effectively strips the sample of  $\text{Hg}(0)$  which is analyzed by cold vapour atomic fluorescence spectroscopy (Tekran 2537A), with a 5 min

resolution. Mercury reduction data were found to fit well with a pseudo first order reaction rate model which was used to quantify reaction rate constants ( $R^2 > 0.98$ ). Triplicate analyses were performed for each radiation intensity, and reduction rate constants were generally within 10% of each other. Using gas phase mercury from a Tekran model 2505 and a Hamilton gas-tight digital syringe, multiple injections into a clean quartz chamber in the Luzchem yielded recoveries of  $98 \pm 2\%$ . With a small sample volume ( $175 - 200 \text{ mL}$  of snow), replicates can be analysed, allowing the generation of confidence limits for the produced reduction rate data. In addition, irradiation conditions can be continually monitored and adjusted to suit the needs of the experiment, allowing for a range of test conditions that are also strictly controlled, which is often not possible with *in situ* studies. This methodology should allow us to generate a diverse set of mercury reduction rate constants that are lacking in the present literature and sorely needed for mercury fate modeling pursuits in polar and temperate regions.

**MP008 Does EPA Method 7471 Accurately Measure Mercury Concentrations in Fish?** T. Ellis, A. Carter, M.S. Um, J. Creswell, M. Briscoe, B. Thorsness, Brooks Rand Labs. We compared the extraction efficiencies of the sample preparation methods described in EPA Methods 7471 and 1631 Appendix for total mercury in fish samples. Many labs use EPA 7471 – “Mercury in Solid or Semisolid Waste (Manual Cold-Vapor Technique)” – for the determination of mercury in biological samples, although it is only approved for “soils, sediments, bottom deposits, and sludge-type materials.” EPA 1631 – “Mercury in Water by Oxidation, Purge and Trap, and Cold Vapor Atomic Fluorescence Spectrometry (CVAFS)” – is approved for the analysis of water samples, and has an appendix – “Total Mercury in Tissue, Sludge, Sediment, and Soil by Acid Digestion and  $\text{BrCl}$  Oxidation” – that extends the method to tissue analysis. In a side-by-side analytical comparison on fish samples, we observed that the preparation method from EPA 7471 resulted in mercury concentrations 20% lower than the method from EPA 1631 Appendix, when all sample digestates were analyzed by the same CVAFS technique. The sample preparation procedures described in EPA Methods 7471 and 1631 differ in the oxidation reagent used and the digestion parameters. We hypothesized that incomplete digestion, incomplete mercury oxidation, or a combination of both are the cause of the low recoveries associated with EPA 7471. EPA 7471 specifies a digestion time of 30 minutes and potassium permanganate oxidation, while EPA 1631 Appendix specifies a digestion time of at least four hours and bromine monochloride oxidation. To test for incomplete digestion, we prepared a set of samples and CRMs following the digestion protocol in EPA 7471, but with increased digestion times. To test for incomplete mercury oxidation, we prepared a parallel set of samples and CRMs following EPA 1631 Appendix, but using potassium permanganate as the oxidizing reagent instead of bromine monochloride. We conclude that EPA Method 7471 poses a risk of low-biased data for total mercury in biological tissues.

**MP009 Effect of Natural Water Constituents on the Photo-Decomposition of Methylmercury** M. Kim, Y. Choi, Seoul National University; K. Zoh, Seoul National University, Seoul National University / Department of Environmental Health, School of Public Health. Methylmercury ( $\text{MeHg}$ ) is a highly toxic form of the mercury ( $\text{Hg}$ ) species, and can be accumulated into aquatic food chain. It is reported that  $\text{MeHg}$  in natural water is controlled by biotic and abiotic factors. Although numerous studies have demonstrated that  $\text{MeHg}$  decomposition can be microbially mediated in water and sediment, the photo-induced decomposition of  $\text{MeHg}$  in natural water is known as the another significant pathway to reduce  $\text{MeHg}$  accumulation in water environment. In this study, we investigated the effect of natural water constituents such as  $\text{NO}_3^-$ ,  $\text{Fe}^{3+}$ ,  $\text{HCO}_3^-$ , and dissolved organic matter (DOM) such as humic acid and fulvic acid on the kinetics of  $\text{MeHg}$  photo-decomposition under UVA irradiation ( $\lambda = 365 \text{ nm}$ ). The concentrations of  $\text{NO}_3^-$ ,  $\text{Fe(III)}$ ,  $\text{HCO}_3^-$ , humic acid, and fulvic acid used in the experiment were in the similar ranges found in surface water environment. Photodegradation of  $\text{MeHg}$  under UVA irradiation followed the pseudo-first-order reaction kinetics. Approximately 63% of  $\text{MeHg}$  was decomposed after 90 min during UV photolysis only reaction. Half-life of  $\text{MeHg}$  varied from 3 to 63 min depending on the UVA intensity which ranged from  $0.3$  to  $3.0 \text{ mW cm}^{-2}$ . Interestingly, the photodecomposition rate of  $\text{MeHg}$  increased in the presence of  $\text{NO}_3^-$ ,  $\text{Fe(III)}$ , and fulvic acid due to their photosensitization effect, whereas humic acid and  $\text{HCO}_3^-$  ion inhibited the demethylation rate due to the reduction of light penetration and OH radical scavenging effect. This result clearly support that  $\text{MeHg}$  decomposition

in surface water is induced by UV irradiation and OH radical is a critical factor in the photo-decomposition of MeHg. Also, our result implies that the level of MeHg in natural water can be affected the variation of natural water constituents such as  $\text{NO}_3^-$ ,  $\text{Fe}^{3+}$ ,  $\text{HCO}_3^-$ , humic acid, and fulvic acid concentration along with sunlight intensity.

**MP010 Effect of Organic Matters on the Abiotic Photo-production of Methylmercury in Water** M. Kim, Y. Choi, Seoul National University; K. Zoh, Seoul National University, Seoul National University / Department of Environmental Health, School of Public Health. Mercury is a toxic element found in a variety of natural water systems. Numerous experiments by microbiologists suggest that biotic sediments are major sites for methylation of inorganic mercury and that sulfate-reducing bacteria contribute considerably to methylmercury. However, these processes cannot account for all of the methyl mercury that is formed naturally. Purely chemical methylation of mercury is possible only if suitable methyl donors are present. Chemical reagents thought to cause abiotic methyl mercury formation include small organic molecules such as formate, acetate, malonate and larger organic components of dissolved organic matter such as fulvic and humic acids. In this study, we investigated the abiotic photochemical reaction of Hg(II) with various small organics such as formate, acetate, malonate, and large organics such as fulvic and humic acid in the absence and presence of UVA light. The result showed that the production of MeHg from of (Hg(II)) was proceeded via complexes between Hg(II) and organic matter. The production of MeHg was significantly enhanced by the presence of UVA light compared to dark condition. MeHg production rate with the irradiation of UVA when acetate is present was highest among the organics. MeHg production rate in the presence of UVA increased as the increase in acetate concentration, whereas MeHg production decreased as the increase of acetate concentration in the dark condition. The production of MeHg from Hg(II) with acetate was much higher than that by Hg(II) with formate, and malonate, indicating acetate is a suitable methyl donor. The presence of fulvic and humic acid also production MeHg from Hg(II) ion in the presence of UVA light, but the MeHg productions were small compared to when small organics were present. Our result implies that abiotic MeHg production can be mediated by sunlight in the presence of Hg(II) and suitable organic matters as methyl donors in natural water.

**MP011 EPA's Assessment of Mercury in Fish from U.S. Rivers** L.L. Stahl, J.B. Wathen, US EPA, Office of Water / Office of Science and Technology; A.R. Olsen, U.S. EPA, Office of Research and Development / Western Ecology Division, National Health and Environmental Effects Laboratory; B.D. Snyder, Tetra Tech, Inc. / Center for Ecological Sciences; H.B. McCarty, CSC. Elevated mercury concentrations in fish are the leading cause of fish consumption advisories. In a continuing effort to characterize the extent of mercury contamination in the Nation's waters, EPA's Office of Water and Office of Research and Development collaborated to conduct the first statistically-based survey of mercury in fish from U.S. rivers. This national fish survey was conducted under the framework of EPA's National Rivers and Streams Assessment (NRSA), a probability-based survey designed to assess the condition of the Nation's streams and rivers. In 2008 and 2009, field teams applied consistent methods nationwide to collect samples of fish commonly consumed by humans at 566 randomly selected river locations ( $\geq 5$ th order based on 1:100,000-scale Strahler order) in the lower 48 states during June through October. They collected one fish composite sample at every sampling location, and each composite sample consisted of five similarly-sized adult fish of the same species. Largemouth and smallmouth bass were the primary species collected for the study, accounting for 34% and 24% of all fish composites, respectively. Fillets from the fish composite samples were analyzed for total mercury using a Direct Mercury Analyzer. Study data show that mercury was detected at quantifiable levels in every fish sample collected for the study (quantitation limits ranged from 0.5-1.5 ng/g or ppb). Based on results from this probabilistic study, the mean concentration of mercury in fish from U. S rivers is 231 ppb, and the maximum mercury concentration measured for the fillet samples is 1,419 ppb. Nearly 26% (or 17,775 river miles) of the total 69,432 river miles included in this survey had mercury fish tissue concentrations exceeded EPA's 300 ppb human health screening value.

**MP012 Experimental Control of Methylmercury in Rice Wetlands using Alternative Rice Harvest Practices** C. Eagles-Smith, US Geological Survey / FRESC; J.T. Ackerman, USGS-WERC; J. Fleck, L. Windham-Myers,

US Geological Survey; H. McQuillen, Bureau of Land Management; W. Heim, Moss Landing Marine Laboratory; M. Stephenson, California Department of Fish and Game. Mercury (Hg) threatens ecosystem health at a global scale, yet Hg risk can differ substantially among habitat types because of habitat-specific variations in the biogeochemical, hydrological, and ecological factors that regulate the production and bioaccumulation of methylmercury (MeHg). Wetlands often are associated with elevated MeHg concentrations, and agricultural wetlands such as rice fields may support particularly high MeHg production. Rice fields are characterized by a series of extreme wetting and drying cycles, sulfate-containing fertilizers, and high levels of labile organic carbon, which are all key components to the Hg cycle. Importantly, rice fields comprise approximately one-fifth of freshwater habitats and 11% of cultivated land area globally, they provide critical wildlife habitat, and offer substantial economic, human health, and ecosystem benefits. Thus, there is strong impetus to better understand the drivers of Hg cycling in rice fields and develop useful management approaches to mitigate Hg risk associated with rice without compromising productivity. We employed a series of replicated post-harvest experiments at a production-agriculture scale to test the applicability of implementing low-cost management techniques to alter carbon cycling as a way to control MeHg cycling. Specifically, after harvest (and prior to post-harvest flooding) we either: (1) tilled residual rice straw (carbon) into the soil, (2) bailed rice straw and removed bails from fields, or (3) followed standard practices of leaving straw in the fields for natural decomposition. We measured the response to our treatments at the inlets and outlets of each wetland during the following winter and subsequent growing season using an integrated suite of indicators. We employed caged fish as bioindicators to evaluate MeHg bioaccumulation over discrete timeframes, and monitored temporal fluctuations in aqueous carbon and MeHg dynamics at the same locations. Our preliminary results indicate that both caged fish and aqueous Hg concentrations were elevated in rice fields relative to non-agricultural wetlands with similar hydrological management. However, our management techniques resulted in a wide gradient in available carbon across rice fields. Moreover, we found that aqueous MeHg concentrations were positively correlated with the biomass of surface litter across rice fields, suggesting that that carbon management may influence MeHg cycling in these managed systems.

**MP013 Factors Limiting Mercury Bioaccumulation in Contaminated Estuarine Systems** B. Henry, Exponent; D. Glaser, Anchor QEA, LLC; S. Brown, Rohm and Haas Chemicals LLC / Department of Toxicology, The Dow Chemical Company / Global Remediation. Salt marshes are considered potential sources of methylmercury to the coastal pelagic zone and to marsh biota. Methylation rates and methylmercury concentrations in pore water have been reported as negatively correlated with pore water sulfide and positively correlated with some measures of dissolved organic matter. Extrapolation of this conceptual model of mercury behavior to marshes in which total mercury levels are elevated due to local sources, however, is problematic. Marshes with elevated total mercury in sediments do not necessarily exhibit proportionally elevated concentrations of methylmercury in sediment pore water and resident biota. Based on literature review, we have developed a conceptual model to explain the disconnect or lack of correlation sometimes observed between elevated total mercury and methylmercury in tidal marshes subject to local sources of mercury, and thus the relative insensitivity of some estuarine systems to mercury contamination. Key factors potentially include 1) food webs with strong ties to the water column; 2) a large volume of tidal exchange that reduces mercury concentrations in surface water, 3) high concentrations of sulfide that limit methylation in sediment, 4) high organic carbon content that results in sequestration of mercury and reduced availability of inorganic mercury for methylation, and 4) extensive movement of crabs and larger fish throughout estuaries, which limits local exposure. These factors may interact to limit mercury bioaccumulation in contaminated estuarine systems (i.e., compared to that expected based on total mercury concentrations in sediment). The lack of correlation between total mercury in sediment and methylmercury exposure to biota has important implications for risk assessment and the determination of remedial approaches. Data from a contaminated tidal marsh system will be used to illustrate the model.

**MP014 Impact of salt marsh reclamation on mercury fate and biogeochemistry** A. Godfrey, Acadia University / Earth and Environmental Sciences; T. Sizmur, Iowa State University / Cademartini Lab; N.J. O'Driscoll, Acadia University, Acadia University / Department of Earth

& Environmental Sciences. Much of the world's coastline has been dyked to increase the area of arable farmland and eliminate seawater inundation. Efforts are now being made in some areas to intentionally breach these dykes and restore the land and re-create the original salt marsh habitat. Salt marshes accumulate sediments over time and build up natural levees that protect the coastline against storm surges and, potentially, against sea level rise. We investigated one such reclamation site (Beaubassin, New Brunswick, Canada) that was breached in October of 2010. Sediment cores were taken from (i) behind a dyke ten months after it was intentionally breached, (ii) a neighbouring salt marsh, and (iii) the mudflats on the seaward side of the dyke. These samples were compared with cores collected the previous summer, before the dyke had been breached. Cores were sectioned, dried, and the solids analyzed for both total mercury (THg; using thermal degradation AAS) and methyl mercury (MeHg; using ethylation, tenax trap, and GC-AFS). Total mercury concentrations in the post-breach cores were approximately double the concentrations in the pre-breach cores, throughout the depth profile. All cores showed THg decreasing with depth, except the salt marsh which revealed similar THg concentrations down the profile. Mean THg sediment concentrations in the upper 2 cm of the cores were  $10.64 \pm 0.48 \text{ ng g}^{-1}$  (pre-breach),  $12.35 \pm 2.67 \text{ ng g}^{-1}$  (mudflat),  $20.23 \pm 1.68 \text{ ng g}^{-1}$  (post-breach), and  $20.28 \pm 3.92 \text{ ng g}^{-1}$  (salt marsh). The post-breach cores contained the greatest concentrations of MeHg in the upper 2 cm of sediment ( $0.57 \pm 0.14 \text{ ng g}^{-1}$ ), decreasing with depth. Pre-breach cores showed the opposite trend with the lowest concentrations in the upper core ( $0.36 \pm 0.02 \text{ ng g}^{-1}$ ) and an increase with depth. As a percentage of THg however, the MeHg concentration was lower pre-breach (3.41%) than post-breach (2.79%). Methylmercury in the post-breach cores and the salt marsh cores were similarly distributed as they both contained elevated MeHg in the upper core. The mudflat cores contained the lowest MeHg concentrations. Salt marsh restoration may increase the availability of THg, and possibly MeHg, to coastal ecosystems.

**MP015 Investigating mercury fractionation in water, sediments, and fish from the Husky Lakes, Northwest Territories, Canada** N. Gantner, University of Victoria / Department of Geography; S. McFadyen, University of Victoria; J. Gareis, Aurora Research Institute; J. Reist, Freshwater Institute, Fisheries and Oceans Canada; H. Hintelmann, Trent University / Chemistry. Mercury can accumulate in apex-predator fish muscle to concentrations exceeding those considered safe for subsistence consumption by humans. Fish species such as Lake trout are typical apex-predators of Arctic lakes and can be a significant source of food for local indigenous peoples. The influence of abiotic factors and biological parameters on Hg accumulation in apex-predators are not well understood. Further, a good understanding of sources of Hg to and processes within water column and food webs is still lacking. Our study aims to investigate the interactions of water column, food webs and Hg transfer in four freshwater systems in the Inuvialuit Settlement Region (Canada). The selected Big, Yaya, Noell, and Husky Lakes systems represent a range of water column and ecological characteristics, as well as Hg delivery (marine-, riverine- or freshwater-derived). We investigate how those characteristics affect Hg transfer and fractionation. All lakes are frequented by the Inuvialuit communities Inuvik and Tuktoyaktuk for subsistence fishing. Sampling includes surface water, benthic and pelagic invertebrates, tissues from harvested fishes, and non-target fishes. Biological parameters of fishes (age, length, weight, diet) are recorded and invertebrates separated by species. Sample analysis includes total Hg (THg), monomethyl Hg (MeHg), and stable isotopes of carbon ( $\delta^{13}\text{C}$ ), nitrogen ( $\delta^{15}\text{N}$ ), and Hg ( $\delta^x\text{Hg}$ ) and otolith microchemistry. Hg IRs are analyzed by multi-collector inductively coupled plasma mass spectrometry (MC-ICP/MS). Hg mass independent fractionation (MIF;  $\Delta^{199}\text{Hg}$ ) and mass dependent fractionation (MDF;  $\delta^{202}\text{Hg}$ ) will be calculated and evaluated against conditions in the water column, food web transfer and the potentially difference in Hg delivery. [THg] detected in harvested fishes will be compared to consumption guidelines. We will present an overview of this multidisciplinary study and discuss our preliminary findings with particular focus on implications for future research efforts in a changing Arctic environment.

**MP016 Investigation of mercury methylation pathways in biofilm versus planktonic cultures of *Desulfovibrio desulfuricans*** T. Lin, UCLA / Civil and Environmental Engineering; R. Kampalath, C. Lin, M. Zhang, K. Chavarria, J. Lacson, J. Jay, UCLA. Biofilms can methylate mercury at higher rates than unattached bacteria and are increasingly recognized as important mercury methylation sites in the environment. Our previous

study showed that methylation rates in biofilm cultures were up to an order of magnitude greater than those in planktonic cultures of a sulfate-reducing bacterium. To probe whether the differential methylation rates resulted from metabolic differences between these two cultures, mercury methylation assays following molybdate or chloroform inhibition (a specific inhibitor of the acetyl-CoA pathway) were conducted on biofilm and planktonic cultures of *Desulfovibrio desulfuricans* strains M8 and ND132. Molybdate was as effective in inhibiting mercury methylation in both planktonic and biofilm cultures as in inhibiting growth. Unlike planktonic cultures, addition of chloroform only impacted mercury methylation in biofilm cultures, indicating a role for the acetyl-CoA pathway. Expression of the *cooS* gene, encoding for carbon monoxide dehydrogenase, a key enzyme in this pathway, was compared in biofilm and planktonic cultures of ND132. Biofilm cultures showed up to 4 times higher expression of *cooS* than planktonic cultures. Although planktonic cultures of *D. desulfuricans* did not methylate mercury as significantly via the acetyl-CoA pathway, in biofilm cultures the acetyl Co-A pathway was expressed at a higher rate and appeared to be employed in mercury methylation in biofilm cultures. This observation has important implications, particularly in developing reliable models to predict mercury methylation rates in different environments and perhaps eventually in being able to control this undesirable chemical transformation.

**MP017 Mercury in breeding common loons, lake sediments and prey fish, and potential effects on health of loons in Quebec, Canada** L. Champoux, Environment Canada / SCIENCE AND TECHNOLOGY BRANCH; D. Masse, La Mauricie National Park, Parks Canada; A. Scheuhammer, Environment Canada / SCIENCE AND TECHNOLOGY BRANCH. As part of a national program assessing the ecological risks of mercury to freshwater fish and wildlife across Canada, a study was conducted to determine environmental and biological factors that best explain variability in Hg levels in fish and loons across study sites in Quebec, Canada. We also assessed Hg concentrations in fish and loons in respect to Hg toxicity. In Quebec, from 2008 to 2010, loon reproductive success was assessed on 15 lakes. Blood and feathers were collected for total mercury and various biomarkers were assessed. Sediments and prey fish samples were also collected for Hg analysis. Stable N and C isotopes were measured in loon blood, fish muscle and benthos in order to take into account the food source and trophic position across lakes. Small fish from some lakes had Hg concentrations sufficiently high to pose a health risk to common loons or other fish-eating wildlife; 17% of the loons sampled (23% of the adults and 12% of the juveniles) had blood Hg concentrations sufficiently high to pose a risk to health. Relationships between levels of thyroid hormones, steroid hormones and cholinesterase and Hg concentrations were determined.

**MP018 Mercury in Mecon river and Foster Bay (Deception Island, Antarctica)** J. Canario, IPMA IP / Aquatic Environment Department, IPMA I.P. / Aquatic Environment and Biodiversity, INRB IP/IPIMAR / Aquatic Environment and Biodiversity; A. Mao de Ferro, A. Mota, Instituto Superior Técnico. Mercury (Hg) is pollutant of great environmental concern mainly due to the well known toxicity of its compounds, particularly its methylated form. Atmospheric transport is the main dispersion mechanism for mercury and is the reason why this contaminant is often found in relatively high concentrations far from emission sources. These are the case of the Polar Regions where relatively high levels of mercury compounds were found in sediments, water and particularly biota. While in the Arctic very much is known about the biogeochemical cycle of Hg, in the Antarctic the behaviour of Hg is less understood. In December 2011 a field work took place in Deception Island, a volcanic island in the South Shetland Archipelago, Antarctica. Sediments, ice, water and suspended particulate matter were collected in Mecon River and in the Foster Bay during 8 consecutive days. All samples were analysed for total mercury (particulate -  $\text{Hg}_p$  - and dissolved  $\text{Hg}_d$ ), methylmercury (MeHg) and other interpretative physico-chemical parameters. Total mercury concentrations in the upstream stations of Mecon River were lower compared to the downstream ones and Foster Bay. Dissolved Hg levels varied from 0.54 ng/L in station #3 to 2.36 ng/L in the Bay and particulate Hg concentrations from 0.012  $\mu\text{g/g}$  to 1.60  $\mu\text{g/g}$  at the same sample sites. In sediments, concentrations were similar in the River ( $0.096 \pm 0.022 \mu\text{g/g}$ ) sites but much higher in Foster Bay ( $0.845 \pm 0.422 \mu\text{g/g}$ ). Methylmercury concentrations were below DL in the river and account less than 2.5% of total Hg in the Foster Bay. Time course evolution showed that Foster Bay is the main source of Hg to the downstream river waters. This aspect was particularly evident during flood tide. Moreover, Hg levels

determined during this campaign in active volcanic vents near the bay suggest that these active volcanic sites could be the main Hg source to this ecosystem.

**MP019 Mercury speciation and bioaccessibility from adobe bricks and dirt floors in Huancavelica, Peru** N. Hagan, University of North Carolina at Chapel Hill / Environmental Sciences and Engineering; N. Robins, North Carolina State University / Department of History; H. Hsu-Kim, Duke University / Department of Civil and Environmental Engineering; J. Vandenberg, U.S. Environmental Protection Agency / National Center for Environmental Assessment; D. Leith, University of North Carolina at Chapel Hill / Environmental Sciences and Engineering. Huancavelica is located in the poorest district of Peru where its residents are faced with living with over 400 years of mercury (Hg) contamination. Many of the residents are not aware of the high levels of Hg contamination throughout the city, and those who are informed lack the resources to alleviate the problem. Ambient soil concentrations of total Hg in Huancavelica range up to 1200 µg/g, among the highest concentrations measured in surface soil in the world. Because the residents of Huancavelica continue to build their modest homes from adobe brick formed from this contaminated soil, concern exists for residential Hg exposure. Concentrations of total Hg in adobe bricks and dirt floors have been measured up to 1670 µg/g and 2040 µg/g, respectively. Sequential selective extractions were used to quantify the amount of Hg in the sample that is water soluble, human stomach acid soluble, organo-chelated, elemental Hg, and mercuric sulfide. Simulated gastric fluid and phagolysosomal fluid extractions were used to estimate the bioaccessibility of Hg from ingestion or inhalation of Hg-contaminated particles within the home. The results of this study will provide a detailed understanding of the potential risks from exposure to Hg in adobe bricks and dirt floors in homes in Huancavelica, and will yield the fundamental knowledge to identify and evaluate effective mitigation strategies to seal adobe brick walls and dirt floors in homes where the greatest risk of exposure to Hg is present. The application of the sealant may ultimately reduce residential exposure to Hg contamination in Huancavelica, Peru. Disclaimer: The information in this abstract has been funded in part by the U.S. Environmental Protection Agency and in part by the EPA/UNC Toxicology Training Agreement CR-83515201-0, with the Curriculum in Toxicology, University of North Carolina at Chapel Hill. It has been subjected to review by the National Center for Environmental Assessment and approved for submission. The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

**MP021 Quantifying Mercury Biomagnification Using Trophic Magnification Factors** J. Williams, TerraGraphics Environmental Engineering. Trophic magnification factors (TMFs) are frequently used to quantify mercury biomagnification rates in aquatic food webs. TMFs are typically calculated as the slope of a regression between organism Hg and  $\delta^{15}N$  or trophic level ( $\log_{10}Hg = a + b\delta^{15}N$ , where  $TMF=10^b$ ). Mercury TMFs are often noted to be remarkably constant across studies, but variation in study design can affect the comparability of TMFs. A literature review was performed to assess the comparability of TMF studies and identify trends in TMF data across systems. 178 reported mercury TMFs were identified among 47 studies. TMFs were reported for freshwater lentic (52% of TMFs), freshwater lotic (20%) and marine systems (28%) and values of  $b$  ranged from 0.08 to 0.53 for  $CH_3Hg$  TMFs and -0.28 to 0.66 for total Hg TMFs. The comparability of TMFs will be described with respect to study design and methodology. The types of organisms included in TMF regressions (whole food web or only fish), use of stable isotope mixing space screening, use of  $CH_3Hg$  or total Hg data, use of wet or dry weight mercury data, and other factors can affect the representativeness and comparability of TMFs. Patterns in TMF data associated with study design, ecosystem type, food chain length, and mercury concentrations at the base of the food web will be detailed.

**MP022 Seasonal variation of mercury diffusive fluxes in the sediment/water interface in the Tagus Estuary (Portugal)** R. Cesario, INRB-IPIMAR National Institute of Biological Resources / Department of Environmental and Biodiversity; J. Canario, IPMA IP / Aquatic Environment Department, IPMA I.P. / Aquatic Environment and Biodiversity, INRB IP/IPIMAR / Aquatic Environment and Biodiversity; A. Mota, Instituto Superior Técnico; M. Caetano, IPMA I.P.; C. Monteiro, Instituto Superior Técnico; M. Nogueira, C. Vale, IPMA I.P. Mercury (Hg) in the

environment constitutes a threat to aquatic life and human health, especially in its methylated form (MeHg). Among other transport mechanisms molecular diffusion play an important role being responsible for the increase of mercury concentrations in the water column due to the Hg concentrations gradient in pore- and over-lying waters. In this work we hypothesize that mercury and methylmercury diffusive fluxes may vary seasonally due to the well known seasonal variation of methylmercury concentrations in surface sediments of the Tagus Estuary. In order to confirm this hypothesis sediment cores and overlying waters were collected in summer of 2010 and winter of 2010/2011. Sediments were sliced in 1-2 cm and pore-waters were separated. Solid sediments were analyzed for Hg, MeHg. Dissolved reactive and total mercury ( $Hg_R$  and  $Hg_T$ ) as well as MeHg were quantified in pore- and overlying waters. No significant differences were observed for total mercury concentrations in solid sediments in both periods. Otherwise, in summer MeHg levels increase significantly (up 23 times) in both dissolved and solid fractions. These results may be explained by the increase of available  $Hg_R$ , dissolved organic carbon and bacterial activity and the lower redox potential. Inorganic mercury ( $Hg-Cl_x^{n-}$ ), Hg-Natural Organic matter and MeHg molecular diffusive fluxes were estimated using pore- and overlying-water Hg gradients. Downward (from water to sediment) inorganic mercury fluxes were found in #ALCX and #CN in summer and in #BRR at winter period. A different pattern was observed for MeHg with downward fluxes in summer period and upward fluxes in winter period, in all sites. The opposite trend found between summer and winter fluxes could be explained by different extension of MeHg demethylation in the water column.

**MP023 Graphical Excellence: Considerations when Presenting Data** W. Swanson, Neptune and Company, Inc, Neptune & Company, Inc.. There is more than one way to make a plot. When presenting data in a scientific report or journal, the objective should be to use plots that make interpretation easy, without distortion. "Graphical excellence consists of complex ideas communicated with clarity, precision and efficiency. (It conveys to) the viewer the greatest number of ideas in the shortest time with the least ink in the smallest space." (Tufte, 1983). What is best way to summarize data results from soils-related studies? How can the environmental fate and effect of soil contaminants be presented in plots in a risk assessment? Some general plot types are presented and examples provided to demonstrate which presentation style is most appropriate for a given situation. The choice of plot will depend on the type and complexity of the data and the nature of the summary or relationship to be portrayed. A plot that works for one data set may be a bad choice for another data set. Examples of good plots and bad plots are taken from literature and soils-related consulting projects to illustrate the basic ideas.

**MP024 A Novel Approach for Estimating Soil Exposure Point Concentrations in Ecological Risk Assessment** B. Anthony, W. Stiteler, M. Erickson, ARCADIS U.S., Inc; G. Griffith, Georgia-Pacific LLC. One of the primary uncertainties with exposure modeling in Ecological Risk Assessment is estimating the appropriate spatial scale for developing exposure point concentrations (EPCs) for the identified receptors. Terrestrial exposure areas within a given site can be estimated based on receptor foraging ranges by assuming that ranges are adjacent and do not overlap. However, this is often not consistent with receptor behavior and the specific location of any given foraging range within a larger site is unknown. An alternative approach is to calculate an average EPC for the total site area, even when it is larger than the estimated foraging range for an individual, as a means to address potential population-level risks. Both approaches are subject to considerable uncertainty with respect to individual receptor exposure and population-level risks. To address these uncertainties at a site with PCB-impacted floodplain soils, a "moving window" method was used in conjunction with spatially interpolated surface soil PCB concentrations in a terrestrial Baseline Ecological Risk Assessment (BERA) conducted for the Kalamazoo River Superfund Site in Michigan. Spatial-interpolation provided a means to incorporate a large number of biased sample points together with unbiased samples. Based on the suite of receptors evaluated in the BERA, 1-acre, 2-acre and 11-acre circular moving windows were evaluated on a one-foot grid over the spatially interpolated surface. This resulted in the EPC surface being represented by an exposure value at 1-foot grid points across the entire floodplain, supporting expression of the BERA hazard quotient results as a percent of foraging ranges potentially affected. This type of output may allow for better-informed risk management decisions for protection of local populations of receptors.

**MP025 Impact of initial concentration of diesel oil on the microbial adaptive responses to phenanthrene and benzo[a]pyrene mineralization**

O.O. Igunnugbemi, K.T. Semple, Lancaster University / Lancaster Environment Centre. The impact of initial diesel oil concentration on microbial adaptive responses to further pollution incidents occurring in previously exposed soil was investigated by monitoring the development of indigenous catabolism of a model low molecular weight polycyclic aromatic hydrocarbon (LMW PAH – phenanthrene) or high molecular weight polycyclic aromatic hydrocarbon (HMW PAH – benzo[a]pyrene). Radiorespiratory assay was used to assess  $^{14}\text{C}$ -PHE or  $^{14}\text{C}$ -BaP catabolism in four UK soils with distinct physicochemical characteristics. Soils previously exposed to diesel oil at 500 or 5000 mg kg<sup>-1</sup> for 30 or 150 d were further amended with diesel oil at 500 mg kg<sup>-1</sup> and microbial degradation of PHE and BaP monitored until  $^{14}\text{CO}_2$  evolution plateaued. The initial concentration of diesel oil significantly affected dissipation of HMW PAHs upon further exposure to diesel oil, but did not have appreciable effect on LMW PAHs. However, multivariate analysis indicated that soil organic C contents and residence time played major role in development of BaP catabolism in the soils pre-exposed to low concentration of diesel oil. We propose that induction of BaP biodegradation is a function of (i) an initial moderate concentration of diesel oil, (ii) duration of exposure before recontamination and (iii) soil physical-chemical characteristics. These findings indicate that the impact of initial concentration of diesel oil on the development of HMW PAH catabolic induction could be influenced by soil organic matter and duration of exposure.

**MP026 Preliminary Ecotoxicological Assessment of Plant Based Biodiesels Compared to Diesel**

I. Bamgbose, Texas Tech University / The Institute of Environmental and Human Health (Department of Environmental Toxicology), Texas Tech University; T.A. Anderson, Texas Tech University / Environmental Toxicology. There has been an increased interest in the use of biodiesel as a potential fuel and a feasible alternative to Diesel fuel. Biodiesels are clean burning alternative fuels produced from livestock feeds and various vegetable oils. In theory, these animal/plant derived materials should have less environmental impact in soil based on their simplified composition relative to Diesel. However, like Diesel fuel, biodiesel fuel could accidentally be spilled into aquatic and terrestrial environments. Consequently, their potential impacts on organisms should be evaluated. In this study, the effects of soil contaminated with Diesel and two plant-derived Biodiesels (safflower methyl-ester and castor ethyl-ester) were evaluated using several ecotoxicological tests including, an earthworm (*Eisenia fetida*) 14 day lethality and reproduction assay, an earthworm filter paper contact test, and seed germination assays. In the seed germination assays, four plant species were used in order to investigate germination and survive in a gradient of fuel-contaminated soil: alfalfa (*Medicago sativa*), lettuce (*Lactuca sativa*), radish (*Raphanus sativus*) and wheatgrass (*Triticum aestivum*). Of the plants tested, lettuce seeds showed the most sensitivity to Diesel, Castor biodiesel, and Safflower biodiesel contaminated soils (silt and sandy loam); most of the lowest germination rates were for lettuce seeds. Like lettuce, wheatgrass was also sensitive to the three fuels with the most sensitivity to Diesel-contaminated soils. Radish seeds, which typically germinated very rapidly (within 4 days), showed the least sensitivity to all three fuels in both soil types. Alfalfa also showed some germination inhibition; however, the interaction between the fuel and soil appeared to be a factor in alfalfa germination success. Both Castor ethyl ester and Safflower methyl ester can have effects on the germination of crop plants. These results are some of the only data available on biodiesel effects on soil systems in general and seed germination in particular.

**MP027 Risk Assessment of petroleum hydrocarbon contamination in soil. I. Migration of conventional and renewable fuels in accidental spill scenarios**

V. Malk, University of Helsinki / Palmenia Centre for Continuing Education; E. Barreto Tejera, Autonomous University of Madrid / Department of Biology; S. Simpanen, University of Helsinki / Department of Environmental Sciences; J. Hakkinen, University of Turku / Centre for Maritime Studies; R. Makela, A. Kiiski, University of Helsinki / Palmenia Centre for Continuing Education; O. Penttinen, University of Helsinki / Department of Environmental Sciences. Frequent disasters in aquatic and terrestrial environments have caused researchers and authorities to realize the potential ecotoxicological threat that chemical accidents can pose to the environment. Most common chemical spills concern oil products, such as diesel oil or gasoline. When a PHC spill occurs in soil, there are many chemical specific, biogeochemical, and temporal variables that dictate how

contaminant moves through environment. Oils typically migrate in soil as non-aqueous phase liquids (NAPL). Computer models and calculations are widely used in risk assessment to estimate distribution of chemicals in contaminated sites, but calculated values should always be carefully used to interpret the real nature. In this study migration of conventional gasoline and diesel and their most attractive substitutes in Finland, renewable diesel NExBTL and ethanol blended gasoline RE85 were investigated on a laboratory scale by dyeing fuels and monitoring their migration in dry and wet quartz sand in a transparent tank. Results from laboratory experiment were compared to values calculated with commonly used analytical equations. Furthermore the real accident case data was compared to values modeled with Hazardous Materials Transportation Environmental Consequence Model (HMTECM). Calculated maximum migration depths of different fuels in dry soil were 120 to 180 % from experimental depths determined in the laboratory experiment. In the real accident case migration depth modeled with HMTECM model was 80-150 % from the measured migration depth. Results showed that calculations can give suggestive estimation about the migration of fuels in the NAPL phase in worst case accident scenario. There was no significant difference in migration of conventional diesel and NExBTL in the laboratory experiment, but RE85 migrated 50 % slower in sand as NAPL phase than normal gasoline.

**MP028 Assessment of the Effects of Phenanthrene and its Nitrogen Heterocyclic Analogues on Microbial Activity in Soil**

I.N. Anyanwu, / Lancaster Environment Centre; K.T. Semple, University Lancaster / Lancaster Environment Centre. The effects of phenanthrene and its nitrogen heterocyclic aromatic (NHAs) analogues on soil microbial respiration were evaluated to assess the toxicity of the chemicals in soil using substrate induced respiration (SIR). Soil samples were amended with phenanthrene and its nitrogen containing analogues and respiration rates were measured over time. The results showed that inhibition of PAH amended soil plateaued after 30 days, while the nitrogen containing analogues showed a pattern of respiration inhibition/stress with increased concentration and aging. The time dependent percentage inhibition/stress was more than 25% which portrays NHAs toxicity. Also, ANOVA results showed significant and strong positive correlation between mean  $\text{CO}_2$  evolved and incubation days (aging). The estimated LOEC was 10 mg/kg based on the concentrations used. This suggests that soil micro-organisms might be more sensitive to NHAs in soil than the homologues PAHs.

**MP029 Do metal impacts in soil alter mammalian bioavailability of polycyclic aromatic hydrocarbons (PAH) in incidentally ingested soil?**

K. James, University of Saskatchewan / Soil Science, University of Saskatchewan / Toxicology Centre; S.D. Siciliano, University of Saskatchewan / Toxicology Group; M. Cave, British Geological Survey; P. Mayer, Aarhus University / National Environmental Research Institute, Aarhus University / Department of Environmental Science, National Environmental Research Inst. / Environmental Chemistry & Microbiology; R. Peters, University of Saskatchewan / Department of Soil Science. The majority of contaminated sites contain elevated levels of metals and hydrocarbons. Yet, risk assessments of either metals or hydrocarbons typically do not consider how these two classes of pollutants may influence exposure to human or ecological receptors. Here, we evaluated the hypothesis that metal concentrations in soil altered mammalian PAH bioavailability. Twenty different contaminated soils with elevated PAH concentrations from North America and Europe, from a variety of sites were used. Using the juvenile swine model, we assessed PAH blood concentrations over a 48 hour time period in six replicate swine which had ingested a 5 g bolus dose of contaminated soil. Using Area Under the Curve analysis, we calculated bioavailability of this ingested soil and compared the bioavailability of these ingested soils to the oral bioavailability of pure PAHs. As expected absolute bioavailability of PAHs in soil was much lower than the current default of 100%. Despite this low bioavailability, we were able to monitor PAH time courses in juvenile swine across soil types. Preliminary evidence suggests that specific metals are influencing mammalian bioavailability. The impact of this on how to assess and derive standards for co-contaminated sites will be discussed.

**MP030 Simulated Earthworm Gut Assessment of Multi-Metal Bioavailability in Petroleum Impacted Soils**

R. Nhan, S.D. Siciliano, University of Saskatchewan / Toxicology Group. Existing technologies assessing the toxicity of contaminated soils that require live organisms are both time and resource intensive. However, this testing is essential in the field of risk

assessment in order to determine client's liability for soil pollution and potential remediation costs. The novel development of an in-vitro laboratory testing technique called the Simulated Earthworm Gut (SEG) has many potential benefits over current methods of determining contamination levels. The SEG is based on the digestive processes of earthworms, where a synthetic earthworm digestive fluid is prepared and undergo testing methods that replicate the digestion and gut content transit time of earthworms. Ultimately resulting in samples used to determine the amount of contaminant absorbed into the organism by advanced laboratory analytical techniques. When this data is used in conjunction with current methods, faster, more cost effective and accurate data can be obtained so less weight can be put on expensive, time consuming live organism tests. Earthworm tests are an important indicator of ecological risks and overall soil quality as they are one of the pioneer soil organisms that create an environment where other vital soil organisms can thrive. Currently, the most effective formulations of the SEG fluid have not been determined. Ongoing work has resulted in promising data in both petroleum hydrocarbon (PHC) and heavy metal contaminant bioavailability but with two different solutions. The goal is to refine and produce a realistic and reliable SEG formulation to test for a wider variety of contaminants. In this pilot study, the formulation used in past PHC experiments will be tested for efficacy in heavy metal contamination. The new SEG formulation accurately predicted metal uptake by earthworms and also allows one to assess hydrocarbon uptake into earthworms. Next steps are to correlate metal toxicity with invertebrate toxicity tests run on these same soils.

**MP031 Evaluating the impact of soil type, ageing, and Zn form on toxicity to *Eisenia fetida* using ZnCl<sub>2</sub>, ZnO bulk powder and ZnO nanoparticles** M. Schulze, Towson University / Urban Environmental Biogeochemistry Laboratory; R. Casey, D.R. Ownby, Towson University / Urban Environmental Biogeochemistry Laboratory, Towson University / Department of Chemistry; S.M. Lev, Towson University / Urban Environmental Biogeochemistry Laboratory, Towson University / Professor. The increasing use of zinc oxide nanoparticles (ZnO NPs) in consumer products and the fate of these particles once they enter the wastewater system requires a risk assessment of these particles in aquatic and terrestrial systems. Of critical importance is an understanding of how ZnO nanoparticles behave once introduced into the soil environment, their potential to induce toxic effects and bioaccumulate in soil dwelling organisms enabling trophic transfer. To date, there is limited information on the long-term behavior of NPs in terrestrial systems. Earthworms are an ideal organism to evaluate the fate and effects of NPs in a terrestrial system since they directly process soil through their digestive system making them susceptible to changes in the chemistry of the soil environment. As they are an important food source for other terrestrial organisms, earthworms may represent a critical entry point into the food web for trace metal pollutants, including NPs, in terrestrial systems. This investigation is part of a larger study to determine the uptake and elimination rates of isotopically-enriched (<sup>68</sup>Zn) ZnO NPs, bulk ZnO powder and ZnCl<sub>2</sub> by *Eisenia fetida* over the course of a 21 day uptake and 21 day elimination period. Earthworms were exposed to two different clean experimental soils (OECD and Potting Soil) for 42 days to evaluate survivability under experimental conditions. Earthworms exhibited weight loss (-0.03 +/- 0.02 g/worm) and lower survival rates (67%) in OECD soil as compared to weight gain (+0.13 +/- 0.07 g/worm) and higher survival (83%) in the commercial potting soil. The potting soil was amended with three forms of Zn (ZnCl<sub>2</sub>, ZnO bulk powder, ZnO NP) over a range of Zn concentrations to establish an EC<sub>10</sub> and EC<sub>50</sub> for *Eisenia fetida*. A split of the experimental soils was aged under constant temperature and moisture conditions for 28 days and the exposure experiment was repeated to assess the impact of ageing on the effect concentrations.

**MP033 Incorporating Invertebrate Community Data and Bioaccessibility Estimates into an Ecological Risk Assessment of a Shooting Range** S.R. Bowman, The Ohio State University / Evolution, Ecology, and Organismal Biology, The Ohio State University / Department of Evolution, Ecology, and Organismal Biology, The Ohio State University; J.L. Bryant, The Ohio State University / Entomology; R. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology. Our study is an attempt to incorporate invertebrate community data and bioaccessibility into the site-specific ecological risk assessment of a shooting range. The study site is a private shooting range located in central Ohio. Areas of interest for this study include the main shotfall area that receives spent

ammunition from a trap and skeet range (2899 ± 1228 mg/kg soil Pb), an area where Pb pellets were excavated (Fall 2009; 628 ± 44 mg/kg soil Pb), and a reference area (1356 ± 86 mg/kg soil Pb) with less total Pb. Ground beetles were collected from 2008 to 2012 using pitfall traps in shotfall, reference, and lead extracted areas. Forty-five species were collected during the first two years. Overall species richness did not differ between sites; however, an indicator species analysis suggested that six species were indicators of the reference site, while one species was an indicator of the shotfall site. We hope that continued beetle and invertebrate sampling will contribute to our understanding of indicator species at the shooting range. We estimated Pb bioaccessibility to shrews (*Blarina brevicauda*) using a modified *in vitro* gastrointestinal method based on shrew digestive physiology. Field soils and earthworms were analyzed for bioaccessible Pb. Using this method, bioaccessible Pb was 5-10% of the total Pb in the tested soils. For earthworms exposed to field soils for 28 days, bioaccessible Pb ranged from < 1% - 4% of the total earthworm Pb. In the future, we hope to collect earthworms and shrews from the shooting range for the determination of Pb concentrations in their tissues. If a correlation is established between field Pb levels in shrews and the relative bioaccessibility, then these modified methods may be a useful tool for Pb exposure estimates for site-specific ecological risk assessment.

**MP034 Assessment of health risks associated with arsenic exposure from rice contamination near abandoned metalliferous mines** W. KIM, J. LEE, M. PAIK, A. KUNHIKRISHNAN, J. YOO, J. KIM, D. KIM, National Academy of Agricultural Science / Chemical Safety Division. To assess the ecotoxicological effects of arsenic (As) in agricultural environment and to give us a basic information for adequate management of As contaminated fields, As was analyzed in soils, irrigation water, and rice collected grown the paddy soils near abandoned metalliferous mines in Korea. The cancer risk probability (R) via rice intake grown near abandoned mines in each age-gender population exceeded the acceptable cancer risk of 10<sup>-6</sup> ~ 10<sup>-4</sup> for regulatory purpose. Particularly, cancer risk probability for children less than six years old was estimated to be high at 5.75 × 10<sup>-4</sup> compared to other age groups. Besides, hazard quotient (HQ) values for all age-gender categories did not exceed 1.0, implying that potential non-cancer toxic effect may not be caused by long-term exposure via As-enriched rice consumption. Human HaCaT cell viability, total antioxidants, and activities of antioxidant enzymes were also estimated on As contaminated polished rice grown adjacent to abandoned mines. The HaCaT cell viability in the As contaminated polished rice was inhibited in a time-dependent manner, ranging from 5-25%. Likewise, time-dependent total antioxidants were significantly decreased to 13-22 mM at 72 h post-incubation than in control. Enzyme activities of scavenging reactive oxygen species (ROS), were 2-5 folds induced compared to control. It demonstrates that mine-impacted polished rice induced HaCaT cell toxicity associated with oxidative stress.

**MP035 Nonlinear Estimation of Mineralization Half-Life by <sup>14</sup>CO<sub>2</sub> Production from MGA, Spectinomycin, Lincomycin, and Ceftiofur in Aerobically Incubated Soil** W. Smolenski, Pfizer Animal Health / Metabolism & Safety; R. Greening, Pfizer Animal Health; B. Hummel, Pfizer Animal Health; S. Lesman, Pfizer Animal Health; J. Robinson, Pfizer Animal Health / Veterinary Medicine Pharmaceuticals. Veterinary drug residues excreted by livestock typically enter soil systems. If the residue persists, the possibility of environmental effects (i.e. bioaccumulation, antibiotic resistance development, toxicity) may increase. Rapid degradation may reduce the likelihood of detrimental environmental effects. Environmental modeling applications typically use half-life (DT<sub>50</sub>) to predict environmental concentrations. If transformation data are not available, conservative DT<sub>50</sub> estimates based on mineralization to CO<sub>2</sub> may be used. Some countries regulatory authorities use the time to reach 50% mineralization (TR50%) as an estimate of DT<sub>50</sub>. When xenobiotics are transformed in soil, not all of the carbon in the molecule becomes CO<sub>2</sub>. Some carbon will bind to the soil or be incorporated into cellular components. Therefore, using the time to reach 50% mineralization is a poor estimate of DT<sub>50</sub>. To calculate half-life based on mineralization (M½), CO<sub>2</sub> production data were fit to a first-order or a sigmoidal logistic nonlinear model that estimated the maximum CO<sub>2</sub> produced at infinity and then determined the time at which mineralization would be at half of this maximum. In these studies each <sup>14</sup>C-radiolabeled drug was amended to 3-4 soils with different physical properties and incubated aerobically for up to 120 days. <sup>14</sup>CO<sub>2</sub> was collected in NaOH and scintillation counted. Soils were periodically extracted and analyzed

for parent and metabolites. All four drugs were transformed in soil and ultimately mineralized to CO<sub>2</sub>. The mean parent compound DT<sub>50</sub> in soil for ceftiofur, MGA and lincomycin were 0.04, 12.5 and 5.8 days and the mean mineralization M<sub>1/2</sub> values for CO<sub>2</sub> production were 13.4, 80.6 and 56.4 days, respectively. For the antibiotic spectinomycin, parent compound disappearance data were not available. The mean M<sub>1/2</sub> of spectinomycin in soil was 33 days based on CO<sub>2</sub> production. Predicting estimates of mineralization half-life from a model that estimates the maximum CO<sub>2</sub> produced is more appropriate than using the time to reach 50% mineralization, but is still conservative. Also, when obtaining an adequate amount of radiolabels drug is prohibitive or toxic at higher concentrations to soil bacteria, and parent compound loss cannot be followed because of analytical reasons, M<sub>1/2</sub> may be substituted as a conservative estimate of half-life.

**MP036 Acute toxicity analysis of urban septic tank sludge** P.B.

Miqueletto, R. Chagas, C. Veronesi, C. Soprani, S. Cassini, R. Franchi, University of Espírito Santo. The objective of this work was to evaluate toxic effects of sludge samples collected from urban septic tanks and upflow anaerobic sludge blanket (UASB) from a wastewater treatment plant located in the University of Espírito Santo. The method employed was the acute toxicity test Microtox based on the bioluminescence inhibition of the marine photobacterium *Vibrio fischeri*. It consists in a widespread methodology with many advantages such as ecological relevance, sensitivity, reproducibility, standardization and simple execution. A series of physical-chemical parameters were also analyzed based on Standard Methods for Examination of Water and Wastewater 20<sup>th</sup> (APHA – 1998). Sludge from four septic tanks was used in the study. From each tank four samples were collected, each aliquot representing a distinct depth, being classified as: 1. scum; 2. liquid waste, 3. superficial sludge; 4. bottom sludge and 5. mixture from all the previous. From the UASB equivalent fractions were also sampled. The tests were executed according to the Microtox User's Guide Manual and results were expressed in EC<sub>50</sub> (Effective Concentration), that represents the sample concentration in which 50% of the bacterial luminescence is inhibited. Only in one of the septic tanks, located in a public building, toxic effects could be verified in the upper layers "scum" and "liquid waste". All samples from the bottom fractions presented higher toxic effects (EC<sub>50</sub>= 9.4%) when compared to the fractions above. The average EC<sub>50</sub> for fraction 3 was 12.6% and 17% for the mixture, meaning even lower toxicity, possibly due to the influence of upper fractions that are stored in great volumes inside the tanks. The sludge from UASB presented higher toxic effects on top side (EC<sub>50</sub>= 5.5%) in comparison to the bottom (EC<sub>50</sub>= 8%), but lower toxicity when compared to tanks samples, since it was analyzed in a dilution of 50 parts in 200, while septic tank samples were diluted in one part in 200. All samples presented elevated levels of TKN, P and COD and were considered as stabilized sludge samples, since the relation VS/TS (volatile solids/total solids) was below 65%. Although many studies have applied the *Vibrio fischeri* test to a range of environmental samples, the analysis of sludge from septic tank represents a new approach, essential to evaluate the risk of releasing this residue in the environment or even ensure the quality required for its application in other activities.

**MP037 Correlating Environmental and Biological Monitoring using GCMS: Commuters' Exposure to Volatile Organic Compounds in the Greater Houston Area** S.L. Tarver, Texas Southern University / Environmental Science and Technology.

The general population is exposed to a large number of pollutants continuously emitted into the environment. Urban air pollution caused by automobile and industrial sources can aggravate many respiratory conditions, and lead to additional acute and chronic health effects. Exposure to volatile organic compounds (VOCs), specifically benzene, toluene, ethylbenzene, and the isomers of xylene (BTEX) is ubiquitous since two common sources are vehicular traffic and tobacco smoke. Bio-monitoring of human specimens is one approach to evaluating the toxicological effects of the compounds and their risks to human health. In past studies, the analysis of non-occupational exposure of VOCs has been conducted using blood specimens, or exhaled breath also referred to as "expired air". Few studies have undertaken urine analysis as a viable option for evaluation of non-occupational exposure to VOCs. The evaluation of environmental exposures to VOCs has been conducted by means of solvent extraction and headspace techniques. Solid-phase microextraction (SPME) has proved to be an excellent method for the analysis of semi-volatile and most volatile organic compounds, but purge and trap (PT) remains the technique of choice for the sample prep and analysis for VOCs. The proposed

plan is to examine the viability of purge and trap gas chromatographic (GC) determination of VOCs in urine with mass spectrometric (MS) detection. The aim of this study is to provide data that supports the use of urine analysis as a biomarker in non-occupational VOC exposure. Air quality inside the vehicles of volunteers without occupational exposure will be monitored for 1-hr and 24-hour sampling periods. Urine samples will be collected from the volunteers and analyzed for detectable concentrations of the VOCs to assess human exposure to them.

**MP038 Development of Dried Blood Spot Reference Material** J.L. Rein-

et al. / Environmental Health Sciences, NIST / Analytical Chemistry Division; S. Long, C. Bryan, M. Schantz, NIST. The practice of collecting human blood on filter paper and using it for population screening dates back to the early 1960s when an assay was developed to measure phenylalanine in dried blood spots (DBS). Though this innovated approach was developed for determination of metabolic diseases, some studies now report the use of DBS for the quantification of organic contaminants and elements. Two NIST Standard Reference Material (SRM) 1958 Organic Contaminants in Fortified Human Serum and SRM 955c Caprine Blood, Level 4 were applied to DBS cards. Initially, measurements of perfluorooctane sulfonate (PFOS) and mercury (Hg) were made on the DBS. Preliminary results show that PFOS and Hg are measurable and the reproducibility of the measurements is good. Future work will include the measurement of additional organic and inorganic compounds. Three other marker organic compounds have been chosen to analyze in the blood spot material. 4,4'-DDE was chosen as a marker compound for organochlorine pesticides. The polychlorinated biphenyl (PCB) congener 153 was chosen as a marker compound for PCBs. Polybrominated diphenyl ether (PBDE) 47 will be used as a marker compound for PBDE exposure. Measurements of arsenic, iodine, and lead in the DBS are planned. With improvements in analytical instrument sensitivity, there is expected to be a surge in the use of DBS as a resource for chemical measurements. In anticipation of the surge, we aim to develop a reference material that will help to determine the recoverability and stability of different analytes from blood spots.

**MP039 Evaluating Dietary Consumption Advisories in Reducing Human Exposure to Persistent Organic Pollutants** M. Binnington,

University of Toronto Scarborough / Dept. of Physical & Enviro. Science, UTSC – Dept. Physical & Environmental Sciences; C. Quinn, F. Wania, University of Toronto Scarborough / Physical & Environmental Sciences. Human exposure to persistent organic pollutants, including polychlorinated biphenyls (PCBs), mainly occurs through dietary intake of contaminated food. Thus, regulatory bodies issue dietary consumption advisories to describe safe intake levels for food items of concern, particularly piscivorous fish. Our study goal was to estimate the effectiveness of published fish advisories in reducing contaminant exposure among susceptible subpopulations, namely children and women of childbearing age. We used the time-variant mechanistic model CoZMoMAN to calculate human bioaccumulation of PCBs under different scenarios of guideline adherence for both hypothetical constant and realistic time-variant chemical emissions. Specifically, we have compared prenatal, postnatal, and childhood contaminant body burdens under different fish consumption advisory scenarios. We also calculated exposure reduction potential for a range of theoretical chemicals varying in phase partitioning and degradability to identify for which chemicals guidelines are most/least effective. We found the most significant predictors of advisory effectiveness to be degree of compliance with specified advisories, and the rate of human contaminant metabolism. More specifically, our model suggests eliminating or reducing fish consumption only during the 1.5-year period of pregnancy and breastfeeding is ineffective in reducing prenatal and postnatal exposures of offspring compared to maternal default fish consumption. Also, advisories proved most effective in reducing measured exposures during periods of increasing, as opposed to decreasing, contaminant emissions. In summary, dietary advisory effectiveness depends mainly on length of compliance period, *in vivo* contaminant half-life, and time from peak emissions. Greatest success in exposure reduction is achieved during long-term dietary adjustment for chemicals readily degraded by humans, during increasing chemical emissions. This clarification of variables critical in predicting guideline success may lead to improved advisories for persistent organics in the future.

**MP040 F2-isoprostanes Determination by Solid Phase Extraction and Liquid Chromatography with Tandem Mass Spectrometry in Human Blood Samples** W. Guo, S.E. Petropoulou, California Department of Toxic Substances Control; N. Holland, School of Public Health, University of California at Berkeley; M. Petreas, California Department of Toxic Substances Control, DTSC; J. Park, California Environmental Protection Agency / Department of Toxic Substances Control, California Environmental Protection Agency / Department of Toxic Substances Control, Environmental Chemistry Laboratory, California Environmental Protection Agency / Research Scientist. Isoprostanes (iPs) are prostaglandin like products formed in vivo by free radical-catalyzed nonenzymatic peroxidation of arachidonic acid. Several F2-iPs are established sensitive and reliable protein markers for oxidative stress. However, it's still a challenge to measure F2-iPs in human blood due to their relatively low quantities. In the past, GC-MS/MS and immunological approaches were used for isoprostane analysis. Although they are sensitive methods, they have complicated sample preparation involving derivatization steps in GC method and lack of specificity in immunoassay. We present a novel LC-MS/MS method using isotope dilution to simultaneously determine six F2-iPs isomers (8-iso-PGF2 $\alpha$ , 8-iso-15(R)-PGF2 $\alpha$ , 15(R)-PGF2 $\alpha$ , PGF2 $\alpha$ , 11 $\beta$ -PGF2 $\alpha$ , 5-iPF2 $\alpha$ -VI) in a single human blood sample (500 $\mu$ L). F2-iPs were detected using an AB Sciex 5500 QTrap mass spectrometer, coupled with a Shimadzu 20AC LC system. Ionization was achieved using electrospray in the negative ESI mode. Each analyte was optimized in several solvent combinations in order to achieve maximum ionization. The most abundant daughter ion was used for quantitation and the secondary ion was used as a confirmation ion. For the separation of the F2-iPs, a base deactivated silica C8 column was used and the total run time was 27 min. We also tested different SPE sorbents to minimize matrix-related suppression effects. Validation of this most robust and accurate SPE protocol is currently underway. To our knowledge, this is the first method using LC-MS/MS for the determination of six F2-iPs in human serum samples in one injection. The finalized method will be incorporated in large biomonitoring and molecular epidemiology studies to measure oxidative stress induced by chemical exposures, or other factors. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

**MP041 Measurement of Hydroxy and Parent-PAHs in Urine and Atmospheric Particulate Matter** O. Motorykin, Oregon State University / Department of Chemistry; S. Simonich, Oregon State University / Depts. of Chemistry and Environmental & Molecular Toxicology; J.E. Schlau, Oregon State University / Chemistry. Humans are exposed to Polycyclic Aromatic Hydrocarbons (PAHs) through polluted air and diet. Broiled, smoked or grilled food contain higher amounts of PAHs compared to uncooked or boiled food. In air, PAHs are emitted from incomplete combustion of fuels and are adsorbed on fine particulate matter, which can be deposited in lungs, causing adverse health effects and cancer. When in the human body, parent-PAHs are metabolized to hydroxy-PAHs and excreted via urine. By comparing the parent PAH composition of particulate matter (PM) and the hydroxy-PAH composition of urine, the metabolic pathways of PAHs can be studied. An analytical method was developed to simultaneously measure 33 hydroxy-PAHs and 19 parent PAHs in urine and particulate matter using gas chromatography/mass spectrometry (GC/MS). Urine samples were deglucuronized with  $\beta$ -glucuronidase/aryl sulfotase and solid phase extracted (SPE) with the combination of C18 and Plexa stationary phases. PM was extracted from filters with the use of Accelerated Solvent Extraction (ASE). The urine extracts and aliquots of PM extracts were mixed with an internal standard and derivitized with *N*-methyl-*N*-tert-butyldimethylsilyl-trifluoroacetamide (MTBSTFA). The derivitized samples were analyzed in electron impact ionization mode with GC/MS. Stable isotope labeled surrogates were used to account for loss throughout the analytical method. Recovery experiments were conducted using a combination of C18 and Plexa SPE columns and elution with a 1:1 mixture of dichloromethane:ethylacetate. Most of the recoveries from urine ranged from 80 to 120%. PM recovery showed that dichloromethane should be used to extract the analytes when using ASE. Intra- and inter-day variability of the measurements and stability of the derivitized product were also investigated. Results showed that the 33 OH-PAH formed stable products over a two week storage period. The stability of OH-PAHs in frozen urine was also studied. Results showed that many OH-PAH were stable in frozen urine for a one week period. However, the dihydroxynaphthalenes were not stable in frozen urine for a one week period.

**MP042 Occurrence and Profiles of Phthalates in Foodstuffs from China and their Implications for Human Exposure** Y. GUO, Wadsworth Center, New York State Department of Health; Z. Zhang, L. Liu, Y. Li, N. Ren, International Joint Research Center for Persistent Toxic Substances (IJRC-PTS), State Key Laboratory of Urban Water Resource and Environment, Harbin Institute of Technology; K. Kannan, Wadsworth Center, New York State Department of Health. Phthalate esters are used in a wide variety of consumer products, and human exposure to this class of compounds is widespread. Nevertheless, studies on dietary exposure of humans to phthalates are limited. In this study, nine phthalate esters were analyzed in eight categories of foodstuffs ( $n = 78$ ) collected from Harbin and Shanghai, China, in 2011. Dimethyl phthalate (DMP), diethyl phthalate (DEP), dibutyl phthalate (DBP), di-*iso*-butyl phthalate (DIBP), butyl benzyl phthalate (BzBP), and diethylhexyl phthalate (DEHP) were frequently detected in food samples. DEHP was the major compound found in most of the food samples, with concentrations that ranged from below the limit of quantification (LOQ) to 762 ng/g wet weight (wt). The concentrations of phthalates in food samples from China were comparable to concentrations reported for several other countries, but the profiles were different; DMP was found more frequently in Chinese foods than in foods from other countries. The estimated daily dietary intake of phthalates (EDIDie) was calculated based on the concentrations measured and the daily ingestion rates of food items. The EDIDie values for DMP, DEP, DIBP, DBP, BzBP, and DEHP (based on mean concentrations) were 166, 70.7, 906, 1100, 481, and 2440 ng/kg-bw/d, respectively, for Chinese adults. The EDIDie values calculated for phthalates were below the reference doses suggested by the United States Environmental Protection Agency (EPA). Comparison of total daily intakes, reported previously based on an urinary biomonitoring study in China, with the current dietary intake estimates suggests that diet is the main source of DEHP exposure in China. Nevertheless, diet accounted for only < 10% of the total exposure to DMP, DEP, DBP, and DIBP, which suggested the existence of other sources of exposure to these phthalates.

**MP043 Optimization of speciation conditions for Arsenic in human urine using isocratic HPLC-ICP-MS** I. Sen, W. Zou, R. Gajek, California Department of Public Health; J. She, Environmental Health Lab / CA Department of Public Health. Arsenic is toxic and carcinogenic in humans depending on the chemical nature and oxidation states of the compounds. In order to determine the extent of toxic exposures to human and to identify the contribution of inorganic and seafood related Arsenic exposure, it is very important to ascertain the measurements of total Arsenic along with the quantification of each different species of Arsenic present in human urine. In the body, Arsenic is metabolized to several different inorganic and organic species, including trivalent Arsenic (As-III) and pentavalent Arsenic (As-V), and the methylated species such as Monomethylarsonic acid (MMA), and Dimethylarsinic acid (DMA), in addition to Arsenobetaine (AsB) and Arsenocholine (AsC) which stays unaffected in the body. Conventionally HPLC gradient pump is used in combination of different mobile phase composition to optimize the baseline separation of each Arsenic species as well as reduce the total elution time. In this study we used HPLC isocratic pump with single mobile phase composition and pH conditions to optimize the baseline separation of each Arsenic species with the shortest possible elution time. The separation was performed with Hamilton PRP-X100 $\text{\textcircled{R}}$  anion exchange column using Agilent 1200 HPLC isocratic pump along with Agilent 7700 inductively coupled plasma mass spectrometry as a detector. The results showed that each of the six Arsenic species was well separated and LOD of each of the species is approximately 1 ppb. The baseline resolved separation of Arsenobetaine (AsB) with As-III is critical since in real urine sample AsB could present in 100 ppb range with very low As-III (1-2 ppb) concentration. Besides, As-III tends to oxidize at room temperature to As-V during the course of long analyses. In order to prevent the oxidation of As-III, we introduced several steps including i) a pH 6.0 sample preparation buffer ii) removing oxygen present in the mobile phase by degassing with Argon and iii) use of low temperature (-70 $^{\circ}$ C) for long term storage. The above-mentioned method can be applied to analyze Arsenic species in human urine.

**MP044 PCBs and OH-PCBs in Mothers and Their Children Living in Urban and Rural Communities** R.F. Marek, University of Iowa / Civil & Environmental Engineering, The University of Iowa / College of Engineering; K. Wang, P.S. Thorne, J. DeWall, The University of Iowa / College of Public Health; K.C. Hornbuckle, University of Iowa / Department. of Civil

& Environmental Engineering, IIHR-Hydrosience and Engineering. We have analyzed human blood serum collected since 2008 from adolescent children and their mothers in the urban East Chicago, Indiana area ( $n > 100$ ) and the rural Columbus Junction, Iowa area ( $n > 100$ ) for all 209 PCB congeners and 11 hydroxylated PCBs (OH-PCBs). East Chicago is a heavily-industrialized residential community on the southwestern shore of Lake Michigan. Bisecting the area, and passing within 2 km of two schools, is the Indiana Harbor and Ship Canal from which at least 7 kg PCBs per year volatilize. In contrast, residents of the rural Columbus Junction area have no known PCB exposure from current or past industrial sources. We used highly selective methods to analyze samples for all 209 PCBs as 160 chromatographically-resolved peaks and 11 hydroxylated PCBs. A full suite of quality control measures, including standard reference materials, was applied to optimize and assess the analytical method for our target compounds. Analysis of the first year of serum collection suggests that East Chicago children are enriched in lower molecular weight, more volatile PCBs. There is no statistically significant difference between East Chicago and Columbus Junction sum PCBs or sum OH-PCBs. Interestingly, children have about half the amount of PCBs but about the same amount of OH-PCBs as their mothers. Though sum OH-PCBs correlate with sum PCBs, analysis of individual metabolites and their likely parent congeners offer no clear metabolism pathway preference. Following analysis of a second round of blood sampling one year later, these trends are examined for continuity within the second year of data.

**MP045 Phthalates and Brominated Flame Retardants: Indoor Concentrations, Dermal Wipes and Urine Biomonitoring** S.R. Chaudhuri, University of Toronto / Department of Chemical Engineering and Applied Chemistry, University of Toronto; A. Saini, E. Goosey, University of Toronto; H. Qi, Harbin Institute of Technology; M. Venier, Indiana University / School of Public and Environmental Affairs, Indiana University; M.L. Diamond, University of Toronto / Department of Geography and program in planning, University of Toronto / Department of Geography. As part of a detailed indoor and exposure assessment of 5 individuals and their homes, we measured concentrations of phthalate esters and brominated flame retardants in indoor air, dust, and window films in several rooms per homes, and dermal wipes and urine (the latter only for phthalate metabolites) per individual. Here we report on the relationship among several of the indoor levels and those in dermal wipes. Three consecutive wipes were taken on four consecutive days for each of the five individuals. The wipes were of the left hand, the right hand and forehead. Standard laboratory procedures and QA/QC were followed for sample extractions, clean up and analysis by GC-MS. For phthalates, higher molecular weight di(2-ethylhexyl) phthalate (DEHP) and diisononyl phthalate (DiNP) concentrations were 1 to 2 orders of magnitude higher in indoor dust, window films, and dermal wipes compared to lower molecular weight phthalates. Levels of DEHP and DiNP in dust also varied by an order of magnitude between individual homes. DEHP and DiNP concentrations in hand wipes were greater than those of forehead wipes. Metabolites of diethyl phthalate (DEP) and DEHP were found to be the highest in participant urine samples. For brominated flame retardants (BFRs), concentrations in indoor dust samples were highest for ethylhexyl-tetrabromobenzene (TBB), bis(2-ethylhexyl) tetrabromophthalate (TBPH), and tris-dichlorophenyl phosphate (TDCPP). DecaBDE replacements brominated trimethylphenylindane (OBIND) and decabromodiphenylethane (DBDPE) were also present but at lower concentrations and frequency of detection. The concentrations of BFRs in dermal wipes followed these patterns.

**MP046 QuEChERS sample preparation followed by UPLC-MS/MS analysis of DOSS in egg and blood tissue collected from birds impacted by Deepwater Horizon** A. Yeudakimau, University of Connecticut / Center of Environmental Sciences and Engineering; A. Provas, University of Connecticut / Center for Environmental Sciences and Engineering; C.R. Perkins, University of Connecticut / Center for Environmental Sciences and Engineering, University of Connecticut / Center for Environmental Sciences and Engineering; J. Stuart, University of Connecticut / Center for Environmental Sciences and Engineering. After the devastating Deepwater Horizon offshore rig explosion in the Gulf of Mexico on April 20<sup>th</sup> 2010, a series of measures were undertaken to minimize the potential for crude oil to spread and impact coastal areas and their associated wildlife. Oil dispersant known as Corexit 9500 was widely used throughout the affected region. Primary components of Corexit 9500 are sorbitan, butanedioic acid, propylene

glycol, and Dioctyl Sulfosuccinate Sodium Salt (DOSS). A quantification method was developed for the determination of DOSS in various types of bird egg and blood tissues. Sample preparation utilized a QuEChERS (Quick, Efficient, Cheap, Effective, Rugged and Safe) extraction technique. A Waters Acquity UPLC system equipped with a tandem mass spectrometer was used for developing a separation method and achieving significantly lower detection limits when compared to alternative methods, including traditional high pressure liquid chromatography. The method provided an excellent selectivity and sensitivity for DOSS with a detection limit as low as 500 pg/mL and with associated analyte recoveries in the range of 90-115%. The extraction efficiency was monitored by adding a surrogate compound, sodium octyl sulfate-d17 (SOS-d17), to every sample with typical recoveries of 60-95%. In summary, this method can provide a rapid and easy preparation and sample analysis for the determination of DOSS in various tissue matrices.

**MP047 Speciation of iodide and iodate using gradient IC-ICP-MS** W. Zou, California Department of Public Health; K. Ting, J. Quinn, California Department of Toxic Substances Control; J. She, California Department of Public Health. MeI is effective in controlling a broad spectrum of soil borne pathogens and has the potential to replace MeBr in soil fumigation. However, MeI is carcinogenic and exhibits moderate to high acute toxicity for inhalation and ingestion. Therefore, the environmental fate of MeI is of great concern. In aqueous environment, MeI either degrades to iodide or to iodate. With oxidation states ranging from -1 to +7, the predominant states of iodine in aqueous systems are -1 (iodide,  $I^-$ ) and +5 (iodate,  $IO_3^-$ ). In reducing environments, aqueous iodine usually occurs as the mobile monovalent anion,  $I^-$ . Under more oxidizing conditions, iodine is present as  $IO_3^-$ . Therefore, it is critical to simultaneously monitor MeI,  $I^-$ , and  $IO_3^-$  levels in aqueous solution. In the present study, a modified Perkin-Elmer IC-ICP-MS system (Series 200 LC pumps and Elan 6100 ICP-MS, plus a Dionex suppressor controller RFC-10) was applied to analyze iodine species. The column was Ionpac AS16 (4x250mm) with AG16 (4x50mm). At a flow rate of 1 mL/min, a gradient of  $H_2O$  and 350 mM NaOH at 0%B-100B% in 15 min was good enough to separate iodate and iodide. A RFC-10 controlled ASRS 300 suppressor worked in external water mode with a voltage of 300 mA. ICP-MS was optimized based on the criteria of highest sensitivity of iodine and rhodium (internal standard), ratio of cerium oxide to cerium less than 3%, ratio of doubly charged barium to barium ions less than 5%. Data of iodine element was acquired at  $m/z$  127 with dwell time of 250 ms in dual detector mode. The results showed that iodate and iodide were well separated and LOD of both species could reach 1 ppb. The above-mentioned method can be easily applied to analyze iodine species in human blood and urine.

**MP048 Studying matrix effects on perchlorate assay in human urine using IC coupled with conductivity detector and ESI-MS/MS** X. Wang, California Department of Public Health; W. Zou, R. Gajek, J. She, California Department of Public Health. Perchlorate interferes with iodine uptake into the thyroid gland and is considered as a contaminant by US EPA, ascertaining the necessity of monitoring perchlorate in human body fluids. The state of the art perchlorate analysis in urine is ion chromatography (IC) coupled with conductivity detector and electrospray ionization (ESI) triple-quadrupole mass spectrometry (MS/MS). Conductivity detector works well with simple sample matrix, but has high backgrounds and broad tailing peaks when large amount of anions like sulfate, chloride, and carbonate are present. ESI-MS/MS improves the sensitivity and specificity compared with conductivity detector, but substances in urine matrix may co-elute with perchlorate and cause ion suppression or ion enhancement in ESI. In order to reduce matrix effects, urine samples are typically diluted before analysis. Although dilution is effective in most cases, it affects the method minimal detection limit (MDL) and minimal reporting limit (MRL). In order to improve MDL and MRL, sample pretreatment and cleanup methods have been investigated by other labs using SPE or cation-exchange resin, at the expense of having more complex steps and lower recovery rate. The purpose of our study was to compare matrix effects using conductivity and ESI-MS/MS detectors, and to find the best approach to compensate or subdue matrix effects in urine perchlorate assay. In our preliminary study, perchlorate was eluted at 11 min using a AS16 column (2x250mm) along with a AG16 guard column (2x50mm) and data was acquired using conductivity detector. We compared results among water samples of different sources (tap water, Milli Q water, HPLC grade water, and LC-MS grade water) spiked with

1 ppm of perchlorate. Interestingly, results show that Milli Q water had lowest background anion peaks. Retention time shift, peak shape, MDL, MRL, calibration curve linear range, accuracy, and precision will be studied in in-house made synthetic urine, anonymously collected in-house pooled urine, and synthetic urine from different vendors at different dilution factors spiked at different perchlorate levels. If necessary, we will investigate different sample cleanup approaches to improve MDL and MRL.

**MP049 Urinary Concentrations of Six Parabens in the Alberta Population** D.A. Birkholz, ALS Laboratory Group / Research and Toxicology, ALS Laboratory Group / North American Centre of Excellence; C. Sandau, Chemistry Matters; S. Genuis, University of Alberta; B. Elmayergi, B. O'Neill, M. Ralitsch, ALS Laboratory Group. Parabens are esters of p-hydroxybenzoic acid which are used as antimicrobial preservatives, in cosmetics, pharmaceuticals, and food and beverage processing. The estrogenic activity of parabens in animals and the presence of these compounds in human breast tissue and urine have raised concern on their impact on human health. An in-line solid phase extraction (SPE) method followed by liquid chromatography-tandem mass spectrometry was validated for the determination of parabens in human urine. One of our main findings on the use of protein precipitation methods greatly impact reported paraben concentrations in urine. Fifty-nine samples of urine were received from two medical researchers. Geometric means were determined and compared with the appropriate National Health and Nutrition Examination Survey (NHANES) data. Geometric means were determined for methyl paraben (MP), ethyl paraben (EP), propyl paraben (PP), butyl paraben (BP), isobutyl paraben (IBP) and benzyl paraben (BzP). For the entire population set aged 12 – 67 geometric means were 24.0 (MP), 13.2 (EP), 6.9 (PP), 0.72 (BP), 0.70 (IBP) and 0.36 (BzP) ng/mL. These values are generally lower than those reported by NHANES for appropriate ethnic group comparison from the 2009-2011 data set for MP, EP, PP and BP (n = 826). The observed range of values in our study are as follows: 0.74 – 666 (MP), 3.9 – 247 (EP), 1.2 – 496 (PP), 0.35 – 9.7 (BP), 0.35 – 9.8 (IBP), and 0.35 – 0.69 (BzP). Geometric means observed for females (n = 41) aged 20 – 67 were: 26.7 (MP), 13.8 (EP), 7.1 (PP), 0.81 (BP), 0.80 (IBP) and 0.35 (BzP). These are generally lower than those reported by NHANES. The ranges for females was 0.74 – 666 (MP), 4.5 – 247 (EP), 1.2 – 331 (PP), 0.35 – 9.7 (BP), 0.35 – 9.8 (IBP) and 0.35 – 0.37 (BzP). A great deal of interest has arisen in Canada concerning the human body burdens of parabens, especially in women of child bearing age and in pregnant women. As a result, Health Canada, Statistics Canada and our laboratory will conduct a much larger study. Furthermore, our research team is very interested in looking at circulating blood levels to determine whether medical intervention is required to eliminate and/or reduce human body burdens of environmentally relevant chemicals.

**MP050 Comparison of IC-MS, HILIC LC-MS, and RP LC-MS of Perchlorate Analysis in Human Urine** W. Zou, X. Wang, R. Gajek, J. She, California Department of Public Health. Perchlorates are often produced by natural processes, but can also be produced artificially as a component of solid rocket fuel, or used on spacecraft and submarines as emergency oxygen supply. Unfortunately, perchlorate interferes with iodine uptake into the thyroid gland. In January 2008, California's Department of Toxic Substances Control stated that perchlorate is a threat to human health and water resources. In February, 2011, US Environmental Protection Agency (EPA) stated that perchlorate is a contaminant. Therefore, monitoring perchlorate in human body fluids is critical to protect public from potential adverse effects. In the present study, with IC-MS, HILIC LC-MS, and RP LC-MS, we wanted to see which platform was better for perchlorate analysis in human urine. A triple quadrupole MS/MS mass spectrometer (API-5000, Sciex) was coupled either with an IC system (ICS-2000, Dionex) or an LC system (LC-20, Shimadzu). On the IC, an anion exchange column (AS-20, 250 x 2 mm, Dionex) protected by a guard column (AG-20, 50 x 2 mm, Dionex) was used together with an ion suppressor (ASRS-300, Dionex). On the LC, either an HILIC column (Excel 2 CN, 150 x 2.1 mm, ACE) or a modified RP column (Excel 2 C18-PFP, 150 x 2.1 mm, ACE) with suitable guard column was used. Unlabeled perchlorate ( $\text{HClO}_4$ ) was monitored in negative ESI mode using MRM transition of m/z 99 → m/z 83, m/z 101 → m/z 85, and labeled internal standard ( $\text{HClO}_4^{18}$ ) was acquired using m/z 107 → m/z 89. Compound specific and source parameters were optimized to maximize the sensitivity of the assay. Initial Demonstration of Capability (IDC) for each assay will be conducted immediately after the optimization

process. The method with highest sensitivity and lowest matrix effects will be chosen for routine analysis of perchlorate in human urine.

**MP051 Genotoxic and cytotoxic damage produced by mercury on blood cells of the common carp (*Cyprinus carpio*)** M. Galar-Martinez, National School of Biological Sciences, IPN / Laboratory of Aquatic Toxicology, Department of Pharmacy; J. Nunez-Betancourt, National School of Biological Sciences, IPN; S. Garcia-Medina, National School of Biological Sciences, IPN. / Laboratory of Aquatic Toxicology, Department of Pharmacy; L. Gomez-Oliván, School of Chemistry, Autonomous University of Mexico State.. Mercury is one of the most important heavy metals in the aquatic ecosystems, since it is not removed by natural processes, can be incorporated into the food chain due to bioaccumulation processes and can produce serious toxic effects on diverse aquatic species. In fish, for example, has been shown that this metal produces disorders in sensorial, food, reproductive and swimming behavior. However, regarding the genotoxic and cytotoxic damage, there is little information and such studies are essential to identify the mechanisms by which it operates. The aim of this study was to evaluate the cytotoxic and genotoxic effects of mercury in blood of common carp (*Cyprinus carpio*). In order to reach this aim, test organisms were exposed to different sublethal concentrations of the metal (0.001 mg / L and 0.01 mg / L) for 12, 24, 48, 72 and 96 h. After the exposure time, blood samples were obtained and the following biomarkers were evaluated: DNA damage using the micronucleus assay and apoptosis by the technique of in situ labeling of fragmented DNA (TUNEL). The results showed that mercury produced a marked induction of micronuclei frequency and apoptosis of blood cells in both test concentrations at all exposure times, in both cases peaking at 48 h, then decline, although always above the control. These results demonstrate the genotoxicity and cytotoxicity caused by mercury and the need for further toxicological studies of this metal.

**MP052 Short-term molecular-level effects of silver nanoparticle exposure on the earthworm, *Eisenia fetida*** O.V. Tsyusko, University of Kentucky / Department of Plant & Soil Sciences; S. Hardas, University of Kentucky / Department of Chemistry; W.A. Shoults-Wilson, Roosevelt University / Department of Biological, Chemical, and Physical Sciences; C. Starnes, University of Kentucky / Biostatistics, Epidemiology, and Research Design; G. Joice, University of Kentucky / Plant and Soil Sciences; D.A. Butterfield, University of Kentucky / Department of Chemistry; J. Unrine, University of Kentucky / Plant and Soil Sciences. Short-term changes in levels of expression of nine stress response genes and oxidative damage of proteins were examined in earthworms, *Eisenia fetida*, exposed to polyvinylpyrrolidone (PVP) coated silver nanoparticles (Ag-NP) and  $\text{AgNO}_3$  in natural soils. The worms were exposed at nominal Ag concentration of 100 and 500 mg  $\text{kg}^{-1}$  for 0, 1, 3, and 7 days. The responses varied significantly among days with seven out of nine analyzed genes having day as the most significant variable determining changes in gene expression. Among the days, the third day showed the highest number of significant changes in levels of gene expression and protein carbonyls relative to controls. Gene expression patterns for Ag-NPs and  $\text{AgNO}_3$  were similar, suggesting that ions are primarily responsible for the observed responses. Significant correlations of decreased gene expression with increased Ag soil concentration were observed for CAT and HSP70 on day three and for MT on day seven suggesting that genetic responses of these genes are determined by Ag soil concentration independent of the NP size and from whether the worms were exposed to ions or particles. Significant increases in the levels of protein carbonyls on day three were observed for all treatments indicating that *E. fetida* experienced oxidative stress three days after exposure to both particles and ions. Decreased expression and activity of CAT, one of the enzymes responsible for detoxification of highly reactive oxygen species  $\text{H}_2\text{O}_2$ , was also observed on day three. Decreases in CAT may lead to accumulation of  $\text{H}_2\text{O}_2$ , consistent with the increased protein carbonyls on day three. The results from this study suggest that Ag ions are primarily responsible for Ag NP toxicity in *E. fetida*. However, given that < 15% of Ag in the NPs was oxidized in these soils, dissolution of Ag-NPs is likely to occur after or during their uptake.

**MP053 Effect of Cd (II) and Pb (II) on Vetiver gene expression of a putative Voltage-Dependent  $\text{Ca}^{2+}$  Channel, TPC1** M. Rodriguez Hernandez, Universidad Autonoma de San Luis Potosi / Faculty of Chemistry; I. Bonifaz Arredondo, Instituto Potosino de Investigación Científica y Tecnológica A.C.; M. Alfaro De la Torre, J. Flores Flores, Universidad

Autonoma de San Luis Potosi / Faculty of Chemistry. There is a considerable interest in the development of low-cost, effective, affordable and environmentally friendly solutions to remediate sites contaminated with heavy metals. Phytoremediation is an interesting technology for this purpose. From the biotechnological point of view, the ability to remove metals by the plants can be improved by inducing their tolerance to the pollutants. Thus, the strategies followed by the plants for the metals uptake, the translocation and compartmentalization, need to be understood. The plant *Vetiveria zizanioides* has been used for soil and water remediation and it is a potential candidate species for the absorption of a wide range of heavy metals from metal-contaminated soils and water. However, the uptake mechanisms that this plant used to accumulate metals are still not very well known. This work is focused in the removal of divalent metals (Cd and Pb) by studying the transport mechanisms of those metals in *V. zizanioides*. We analyzed the uptake mechanism of Cd and Pb by the plant root through the transport mechanism of  $\text{Ca}^{2+}$ . Young plants ( $n=3$  per treatment) of equal size were grown hydroponically and amended with 0 – 15  $\text{mgL}^{-1}$  of each heavy metal individually for 10 days. The grown index as well as total chlorophyll of plants exposed to the heavy metals was not significant to controls. Moreover, a  $\text{Ca}^{2+}$ -permeable channel gene *VzTPC1* encoding a putative membrane protein was cloned from *V. zizanioides*. Our investigation revealed that the overexpression of *VzTPC1* induced by Cd in the nutrient solution was similar to the plants growing in a solution with calcium; whilst the gene expression of *VzTPC1* in plants exposed to Pb was only slightly correlated with the concentrations of the ion solution.

**MP054 Sex-specific gene expression in early life stage fathead minnows (*Pimephales promelas*) throughout development and after exposure to synthetic hormones** J.K. Leet, Purdue University / Forestry and Natural Resources; J.J. Amberg, United States Geological Sciences / Upper Midwest Environmental Sciences Center; A.W. Olmstead, Bayer CropScience / Mid-Continent Ecology Division, Bayer CropScience / Environmental Toxicology and Risk Assessment; G.T. Ankley, US EPA / Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, U.S. EPA / National Health and Environmental Effects Research Laboratory; L.S. Lee, Purdue University / Dept. of Agronomy Crop, Soil & Environmental Sciences, Purdue University / Dept. of Soil, Crop & Environmental Sciences; M.S. Sepulveda, Purdue University / Forestry & Natural Resources and School of Civil Engineering, Purdue University / Forestry & Natural Resources &. There is evidence that exposure to endocrine disrupting chemicals (EDCs) during early life stages can alter sex differentiation in fishes. Fathead minnows (*Pimephales promelas*) are commonly used as a model fish species in endocrine disruption studies. However, limited knowledge exists on molecular pathways associated with sex differentiation in early life stages of this species. Changes in the expression of genes important in sex differentiation could be useful in evaluating the effects of EDCs on gonadal development and sex differentiation. Until this point no study has characterized the sex-specific baseline expression of genes in developing fathead minnows. Using a sex-linked DNA marker to verify gender, we evaluated the expression of genes involved in gonad development and sex differentiation (*dmrt1*, *cyp19a*, *cyp17*, *star*, *esr1*, *ar*) in developing fathead minnows (10 – 45 days post hatch; dph) to establish this baseline data. Expression of all genes remained relatively constant in males except for *cyp17*, which increased to almost 20 fold by 45 dph. Gene expression patterns in females varied more than those in the males, but generally expression increased 10 to 20 fold by 45 dph. Since these genes have been linked with sex differentiation, we hypothesize expression of these genes will be altered in a sex-specific manner when fathead minnows are exposed to androgens, estrogens, or mixtures of EDCs during this same life-stage. Preliminary results show a significant increase in *cyp19a* expression in males exposed to 1.5 ng/L 17 $\alpha$ -ethinylestradiol (a potent synthetic estrogen) between 10 and 20 dph, but no significant increase in expression was observed in females. Evaluation of these molecular markers in combination with gender identification is being used in developing tools to efficiently evaluate sex-specific responses in early life stage fish exposed to EDCs. These tools will help us better understand the mechanisms regulating sex differentiation in fathead minnows and how EDCs may alter these processes.

**MP055 Comparison of genotoxic potential and related mechanisms of various bisphenols using DNA-repair-deficient chicken DT40 cell lines** S. Lee, Seoul National University / School of Public Health, Seoul

National University; K. Choi, Seoul National University / School of Public Health. Bisphenol A is a common ingredient of polycarbonate and epoxy resins which have been widely used in plastic food containers, medical devices and toys. Over 2.2 million tons of BPA was produced worldwide as of 2009. BPA has been detected in various food items and human serum up to few hundreds ng/L, and suspected for adverse health effects such as reproduction damages, developmental changes, genotoxicity and carcinogenesis. Because of such concerns, more alternative bisphenols are expected to be used. In the present study, we investigated the genotoxicity potential and mechanisms of BPA and alternative bisphenols such as Bisphenol AF, bisphenol AP, bisphenol B, bisphenol F, bisphenol M, bisphenol P, bisphenol S and bisphenol Z using genetically modified chicken DT40 cell. Responses of a panel of isogenic DT40 mutants, each defective in one of the major DNA damage repair mechanisms, which include base excision repair (*Pol $\beta$ <sup>-/-</sup>*), nucleotide excision repair (*XPA<sup>-/-</sup>*), homologous recombination (*Rad54<sup>-/-</sup>*), non-homologous end-joining (*Ku70<sup>-/-</sup>*), and translesion DNA synthesis (*REV3<sup>-/-</sup>*) were evaluated after exposure to each of bisphenols. The cell viabilities of each mutants and the wild-type were measured and only the noncytotoxic doses that resulted in < 80% decrease of cell viability in wild-type cells were evaluated for genotoxicity. BPP showed greatest genotoxic potential than the other bisphenols. The *Rad54<sup>-/-</sup>* mutant cell showed hypersensitivity to all the test bisphenols, suggesting that the genotoxicity of bisphenols involves DNA damages which can be repaired by homologous recombination. Bisphenols may cause double strand breaks that can be repaired by homologous recombination. The results of cell viability were compared with those of chromosomal aberration assay in the same mutant cell.

**MP056 Microarray analysis in the ovary of Queen conch (*Strombus gigas*) reveals reproduction and stress are impacted in environments with high tributyltin** R. Kan, C. Titley-O'Neal, University of New Brunswick; D. Spade, Y. Zhang, University of Florida; C.J. Martyniuk, University of New Brunswick / Dept. of Biology/Canadian Rivers Institute, University of New Brunswick / Biology; N. Denslow, University of Florida; B. MacDonald, University of New Brunswick. The Queen conch (*Strombus gigas*) is a threatened species due to overharvest throughout much of its range prior to the 1980s. Conch populations are declining or stagnant despite harvest protections due to anthropogenic impacts that include pollution from boating activities. In the British Virgin Islands (BVI), individuals from local populations have exhibited imposex, a condition in which there is a superimposition of male organs (penis and or vas deferens) in gonochoristic female gastropods. Studies in the BVI suggest that tributyltin (TBT), a compound used as an antifouling paint, is correlated with an increased incidence of imposex. However, the direct mechanisms leading to imposex are not well understood. The present study utilized an 8 x 15K Queen conch microarray to measure the response of the ovarian transcriptome in conch inhabiting polluted environments with high TBT in the BVI. The polluted sites, Road Harbour (RH) and Trellis Bay (TB), are harbours with high boating activity while the reference sites, Guana Island (GI) and Anegada (AN), are areas with low boating activity. At RH and TB, there were 754 and 898 probes differentially expressed in the ovary from the control (GI) site ( $P$ -value 0.05,  $E$ -value <  $10^{-4}$ ). There were few transcripts (< 10%) that were affected at both sites, suggesting that there are additional environmental factors influencing gene expression patterns. When considering both RH and TB together in comparison to GI, functional enrichment showed that the biological processes and molecular functions of calcium ion binding, immune response, and negative regulation of cell proliferation were over represented in the polluted sites. Sub-network enrichment analysis revealed that transcripts involved in the biological processes of general metabolism, immune, lipid metabolism, and stress were affected in polluted environments. The disruption of lipid metabolism may provide some insight into the induction of imposex due to the activation of the retinoic X receptor by TBT. Furthermore, stress appeared to be prevalent in Queen conch collected from RH rather than those collected from TB. This may correspond to the higher TBT load at RH. Our study shows that multiple Queen conch pathways are affected by an environment that experiences heavy boating activity in the BVI. However, a limitation is to directly link changes at the transcriptomics level to high TBT levels in the harbour.

**MP057 Analysis of oil and dispersants adverse effects on the sheepshead minnows** N. Vinas, Mississippi State University; K.J. Kroll, University of Florida / Physiological Sciences; L. Escalon, US Army Engineer Research

and Development; T. Habib, BTS; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology, University of Florida / Dept. of Physiological Sciences &. The Deep Water Horizon oil spill resulted in the release of over 200 million gallons of crude oil into the waters of the Gulf of Mexico. More than 2 million gallons of the dispersants Corexit EC9500A and Corexit EC9527A were applied either to surface waters or to deep water in order to disperse the oil in an attempt to accelerate oil degradation. Crude oil hydrocarbons and surfactants have been shown to cause structural damage in the gill, the major route of pollutant uptake in aquatic organisms affecting gas exchange processes and limiting oxygen transfer, facts that could lead the organisms to experience hypoxic conditions. Using an ecologically relevant species, the sheepshead minnow (*Cyprinodon variegatus*, SHM), we have shown that exposures to mixtures were more toxic than the dispersant and oil individually. In this experiment, male SHM were exposed for four days to water-accommodated fractions (WAF) of oil (0.5 ppm), Corexit EC9500A (0.05 ppm), Corexit EC9527A (0.05 ppm), and mixtures of oil and each one of the dispersants (0.5ppm oil/0.05 ppm dispersant) in our laboratory. Mixtures of dispersants and oil were designed to mimic proportions used in the Gulf during the spill. Exposure to just 3 ppm of Corexit EC9527A resulted in 100% mortality. A mixture of 0.5 ppm Corexit 9527/ 5 ppm oil also resulted in 100% mortality. We analyzed gene expression changes in the liver and testis of exposed SHM using a commercially available 15,000-gene microarray (EcoArray, Alachua, FL). In the liver, Corexit EC9500A and oil were the least toxic compounds, while both mixtures and Corexit EC9527A were similar in toxicity and had the most effects. Interestingly, although Corexit EC9500A is considered to be much less toxic than Corexit EC9527A, our results show that when combined with the WAF their toxicity is similar. Furthermore, 76% of the differentially expressed genes were common between the two mixtures, indicating the high similarity in toxicity of both Corexits when mixed with the oil. This common response was related to pathways such as oxidative stress, hypoxia, cardiac hypertrophy, liver proliferation, and dopamine receptor signaling. Many of these effects are in accordance with previously described effects such as hypoxia, cardiovascular abnormalities, cardiac dysfunctions or neurotoxicity. These observations suggest that dispersants and oil could pose a greater threat to the marine ecosystem than previously suggested.

**MP058 Chemical flame-retardant toxicity and accumulation in *Daphnia magna*** L.D. Scanlan, U.C. Berkeley / Molecular Toxicology, U.C. Berkeley / graduate student; K. Dailey, U.C. Berkeley; K. Douglas, H. Stapleton, Duke University; C. Vulpe, University of California, Berkeley / Nutritional Sciences and Toxicology. Chemical flame-retardants (FR) are commonly used in furniture foam and fabric, building insulation and electronics casings. These chemicals are not covalently bound to the items in which they are used, so they leach into the environment where there is potential for toxicity. Firemaster550® (FM550) is a chemical formulation used as a replacement for penta-brominated diphenyl ether (penta-BDE), which was banned from use because of toxicity, persistence and accumulation. FM550 components have been detected in many different kinds of animals including sea mammals and in indoor house dust. In this work, we first determined the acute 48-hour LC<sub>50</sub> of FM550, its components, and penta- and octa-BDE on *Daphnia magna*, an eco-indicator used in water quality assessment. We then performed gene expression microarray assays to determine differential expression in daphnids exposed to each FR. We also analyzed *Daphnia magna* exposed to two concentrations of FM550 to determine if the chemicals accumulated in their tissues. We found that each FR caused a unique expression pattern in the daphnids. Penta-BDE was the most toxic FR, while octa-BDE was the least. Furthermore, daphnids accumulated FM550 after a 48-hour aqueous exposure to 48.6 µg/L. These results may indicate that *Daphnia* has the potential to bioaccumulate FM550 in aquatic ecosystems. Results also indicate that hydrophobic compounds effect *Daphnia* in unique ways, as is evident from the chemicals' different gene expression profiles. Further work includes chronic toxicity assays, an analysis of the toxicity of Bis(2-ethylhexyl) phthalate, a plasticizer with similar structure to one of FM550's brominated components, and effects on the lipidome of exposed *Daphnia*.

**MP059 Evaluation of the Micronucleus Formation After Exposure to Environmentally Relevant Concentrations of Atrazine Herbicide** R.G. Borelho, University of Sao Paulo / Ecotoxicology; S.H. Monteiro, L.A. Maranhão, P. Alves, G. Moura Andrade, V. Tornisielo, Center for Nuclear

Energy in Agriculture/University of Sao Paulo. Atrazine is one of the most used herbicide in the cultivation of sugar cane in the region of Piracicaba River (São Paulo, Brazil) which probably can be contaminated by this molecule. The goal of this work was to monitor this herbicide in the surface water in six points of this water course during one year through Liquid Chromatography Tandem Triple Quadrupole Mass Spectrometry (LS-MS/MS) and to exposure the concentrations found to the fish *Danio rerio* to verify the micronucleus formation. First of all a rapid method was developed and validated for determination of atrazine in surface waters. The method consists in filtering the water in 0.45 µm filter followed by injection into Liquid Chromatography Tandem Triple Quadrupole Mass Spectrometer (LC-MS/MS). The transitions monitored were: 216.0/103.9 and 216.0/173.9. The limits of detection and quantification (LOD and LOQ) were 0.07 µg·L<sup>-1</sup> and 0.10 µg·L<sup>-1</sup> respectively. During the sampling period were found concentrations of atrazine between 0.11 to 1.92 µg·L<sup>-1</sup> that is below of the Brazilian environmental legislation that is 2 µg·L<sup>-1</sup>. Thus, *D. rerio* were exposed to 1.0; 1.5 and 2.0 µg·L<sup>-1</sup> of this product plus control group (maintenance water) for 4 days in beakers (2L) with aeration system. Each treatment consisted of 2 replicates with 7 organisms in each. During the test no feed was provided for the fish and the test solutions were not renewed. After the exposition period six animals (n = 6) of each treatment were anesthetized and had its tail sectioned to obtain blood. Blood was dripped on microscopic slides and fixed in methanol for 10 minutes and then stained with Giemsa 5%. For each animal was counted 1000 cells that were observed in microscope and photographed in case of appearance of micronucleus and erythrocytic nuclear abnormalities. Micronuclei formation and erythrocytic nuclear abnormalities were observed in all concentrations (p < 0.05) and in the lower concentrations respectively. We concluded that Environmentally relevant concentrations of atrazine showed be mutagenic and genotoxic to *D. rerio* and probably lower concentrations can have the same effect since they are present in the water. Thus, new test should be done to confirm this information.

**MP060 Gene expression profile, lipid peroxidation and oxidative DNA damage in carp fish following exposure to hypoxic and subsequent recovery conditions** S.A. Mustafa, University of Plymouth / Biomedical and Biological Sciences. S A Mustafa, S J Davies, A N Jha School of Biological Sciences, University of Plymouth, UK Email: sanaa.mustafa@plymouth.ac.uk In fish a complex set of physiological and biochemical strategies are employed to cope with environmental stress including hypoxic stress, underlying mechanism of which could be expression of certain key genes. In order to probe the hypotheses that hypoxia induces oxidative stress and this stress could be manifested in varieties of way, *Cyprinus carpio*, a model fish species, were chronically exposed to hypoxic condition (1.8±0.6 mg l<sup>-1</sup>) for 21 days and subsequently allowed to recover under normoxic condition for 7 days. At the end of these exposure periods maximising the use of biological samples and adopting an integrated approach several endpoints were evaluated at different level of biological organisation. These included determination of (a) expression of hypoxia inducible factor 1 (HIF-1α) gene, DNA repair genes (xrcc1 and ogg1) using RT-PCR in liver samples (b) oxidative DNA damage in erythrocytes (using modified Comet assay employing bacterial enzymes: Fpg and Endo-III), (c) lipid peroxidation in liver samples by measuring the MDA production using the 2-thiobarbituric acid (TBARS test) (d) histopathological changes in gills. The results suggested that the expression levels of HIF-1α in response to hypoxia were significantly higher compared to concurrent normoxic controls, which reverted to control values within 7days exposure to normoxic condition (P < 0.05). The expression of xrcc1 and ogg1 were significantly increased under both hypoxic and recovery conditions. Interestingly, the highest rate of oxidative DNA damage occurred when the fish were kept under hypoxic conditions followed by a rapid increase of the oxygen concentration (recovery period for 7 days) compared to fish maintained under normoxic condition as concurrent controls. Hypoxic groups showed significantly increased values for TBARS levels (by ~ 2 fold) compared to both normoxic and recovery groups. Histopathological changes revealed damage in gill tissue under both hypoxia and recovery stages. Taken together, the results suggest that exposure to hypoxia resulted in the induction of biological damage at different levels of biological organisation.

**MP061 Differential gene expression in rainbow trout (*Oncorhynchus mykiss*) exposed to Randle Reef sediment** J.P. Sherry, T. Neheli, Environment Canada / Water Science & Technology Directorate; D.E. Crump, Environment Canada / National Wildlife Research Centre, Environment

Canada / Canadian Wildlife Service; S.W. Kennedy, Environment Canada, University of Ottawa / Department of Biology, University of Ottawa / Department of Biology, Environment Canada / National Wildlife Research Centre, Environment Canada. Hamilton Harbour was designated an Area of Concern (AOC) by the International Joint Commission in 1985. For that reason, there is an ongoing Remedial Action Plan (RAP) to restore the harbour's beneficial uses. Sediment in the Randle Reef (RR) area of Hamilton Harbour is highly contaminated with polycyclic aromatic hydrocarbons (PAHs) and heavy metals. We report the use of Fluorescent RNA Arbitrarily Primed Polymerase Chain Reaction (FRAP-PCR) to develop a molecular fingerprint in juvenile rainbow trout that were exposed to RR sediment. FRAP-PCR enabled us to identify 42 unique genes that were differentially expressed in livers of fish exposed in the laboratory to RR sediment compared to fish exposed to Lake Ontario water. A 20-gene subset, all of which were confirmed by qPCR, was selected as a fingerprint for use in the diagnosis of exposure to RR contaminants. CYP1A and Vtg both of which are known to change expression upon exposure to PAHs were up-regulated by exposure to RR sediment. Pathways analysis showed that exposure to RR sediment altered the expression of genes within multiple categories including cell adhesion, cell morphogenesis, DNA synthesis, and immune response. Pathways analysis also enabled us to explore links between the modulated transcripts and potential health effects. In the next phase we propose to use the diagnostic fingerprint to track the efficacy and progress of the proposed remediation of RR from the perspective of fish in the adjacent waters.

**MP062 Toxicogenomic approach to determine contaminant exposure using Hornyhead Turbot (*Pleuronichthys verticalis*)** D.E. Vidal-Dorsch, S.M. Bay, Southern California Coastal Water Research Project; M.C. Brown-Augustine, University of California- Berkeley / Department of Nutritional Science and Toxicology; C. Vulpe, University of California, Berkeley / Nutritional Sciences and Toxicology. Previous work in our laboratories has demonstrated that gene microarrays from model and non-model aquatic organisms (fathead minnows, *Pimephales promelas*, the amphipod, *Eohaustorius estuaris*, and the water crustacean, *Daphnia magna*) produce gene-exposure profiles related to specific chemical classes or environmental chemical mixtures. New monitoring tools that perform rapid screening of contaminant effects in aquatic ecosystems need to be developed and validated before they can be incorporated into regional assessments of environmental quality. We are currently developing additional tools using the marine flatfish hornyhead turbot (*Pleuronichthys verticalis*), an indigenous benthic species from southern California. To investigate exposure effects, we are producing a high-density microarray with sequences obtained using Next-Generation techniques. This array will be used to generate gene expression profiles after laboratory exposures to estradiol, ammonia, cadmium, and effluents (secondary treated and primary treated). In addition, we will obtain gene profiles from fish collected in areas near municipal wastewater discharges and reference sites. Our data will assess the usefulness of a biomonitoring indicator using hornyhead turbot (*Pleuronichthys verticalis*) transcriptomic data from a microarray.

**MP063 Modulatory effects of marine pollutants on whole cytochrome P450 (CYP) genes in the marine medaka, *Oryzias melastigma*** J. Lee, Hanyang University / Dept of Chemistry, Hanyang University Graduate School / Dept of Chemistry; B. Kim, J. Rhee, Hanyang University. The cytochrome P450 superfamily is a large and diverse group of enzymes. P450 gene expression, protein levels and P450 mediated metabolism of xenobiotics are induced by PAHs in diverse aquatic species. Thus, regulation of P450 enzyme activity may play a central role in the adaptation of aquatic animals to environmental pollutants. To understand the effects and fates of marine pollutants, we identified the cytochrome P450 (CYP) gene superfamily in the marine medaka, *Oryzias melastigma*. We searched for CYP genes in local genome databases for the marine medaka which were constructed and sequenced by Next Generation Sequencing (NGS) technologies. Finally, we investigated functional 70 CYP genes in *Oryzias melastigma*. To determine the placements of CYP genes, we performed the phylogenetic analysis with those of diverse organisms using maximum likelihood and Bayesian method. The same clade of CYP genes were separated and clustered into the well-known vertebrate CYP clans, CYP 2, 3, 4, and mitochondrial clans, respectively. We analyzed the specific expression patterns of CYP transcripts in developmental and different sexual stages. Expression patterns of CYP transcripts were also analyzed by real-time RT-PCR after exposure to marine pollutants (e.g. benzo[a]pyrene and water-accommodated fraction (WAF) of

crude oil). Differentially modulated expression patterns of CYP transcripts suggest that these CYPs would be involved in defenses and detoxification mechanisms against marine pollutants. Overall, this is the first report to characterize the whole CYP gene superfamily expressed in the marine medaka, *Oryzias melastigma*. This study would be helpful to expand the knowledge on their innate roles in xenobiotic metabolism and physiology of aquatic species.

**MP064 Mitochondrial DNA as a target of environmental toxicants** J.N Meyer, Duke University / Nicholas School of the Environment; M.C. Leung, Duke University / Nicholas School of the Environment, Duke University / graduate student; J. Rooney, A. Ji, I. Ryde, I. Ryde, Duke University; A.S. Bess, Duke University / Nicholas School of the Environment. Mitochondrial DNA (mtDNA) has received less attention than nuclear DNA (nDNA) as a target for genotoxins, but a growing body of evidence suggests that mtDNA damage may be important both for health and as a biomarker for exposure. I will briefly review mtDNA biology and what is known about mtDNA environmental genotoxicity, and then present recent research on the fate and effects of persistent mtDNA damage. mtDNA is more sensitive than nuclear DNA to many common genotoxins, and lacks some repair pathways that are present in the nucleus. In particular, helix-distorting adducts formed after exposure to environmentally important genotoxins such as ultraviolet C (UVC) radiation and some polycyclic aromatic hydrocarbons and mycotoxins are repaired in the nuclear genome by nucleotide excision repair. However, nucleotide excision repair does not occur in the mitochondria, so that the fate of such DNA damage in the mitochondrial genome is unknown. The effects of such persistent damage are also unknown; we hypothesized that the effects of such damage would be particularly important after early life stage exposure since mtDNA copy number is lowest at that time. Using the nematode model *Caenorhabditis elegans*, we found that UVC-induced photodimers result in lower levels of mtDNA-encoded mRNAs, decreased ATP levels, decreased oxygen consumption, larval developmental arrest, and neurodegeneration. Furthermore, UVC-induced mtDNA damage is slowly removed in a process dependent at least in part on mitochondrial fusion, fission and autophagy. Mutations in mitochondrial fusion and autophagy genes exacerbate the larval arrest, suggesting a potent gene-environment interaction in which the effects of mtDNA damage caused by environmental agents are exacerbated by decreased mitochondrial fusion and autophagy.

**MP065 Effect of Anthropogenic Contamination on Genetic Diversity in Mediterranean Mussels from the Strait of Istanbul** C. Theodorakis, Southern Illinois University Edwardsville / Department of Biological Sciences and Environmental Sciences Program, Southern Illinois University Edwardsville / Environmental Sciences, Southern Illinois University / Environmental Sciences; K. Schramm, GSF Helmholtz Zentrum / Institute of Ecological Chemistry; O. Okay, Istanbul Technical University; M. Meyer, Southern Illinois University Edwardsville / Biological Sciences. The objective of this study was to determine the effects of urban contamination on genetic diversity of Mediterranean mussels (*Mytilus galloprovincialis*) from the Strait of Istanbul, Turkey. Mussels were collected from two reference sites and five other sites with varying degrees of contamination within a 50 km stretch of shoreline in or near Istanbul. Sections of the cyclooxygenase subunit III (COX III) gene and the D-loop were PCR-amplified from mitochondrial DNA and sequenced. Sequences were analyzed by examining genetic diversity within and among sites (nucleotide and haplotype diversity indices, Nei's genetic distance), phylogeographic patterns (minimum spanning trees, Mantel tests), partitioning of genetic diversity (AMOVA), asymmetric migration patterns, and spatial structuring (Bayesian analysis). Genetic diversity of the D-loop was represented by both nucleotide substitutions and complex insertion/deletion patterns. Both loci revealed two major clades, one of which was significantly distinct from any other published sequences from individuals of this species collected in the Mediterranean. Both loci also revealed fine-grained genetic structuring and genetic differentiation among sites. Finally, both loci revealed that the genetic diversity of the contaminated sites was greater than that of the reference sites, which may have been due to mutations or alterations in gene flow. These findings are significant because it 1) provides further evidence that anthropogenic disturbance can increase genetic diversity of impacted populations, 2) suggest a unique evolutionary history for one of the major clades, 3) demonstrates that fine-grained genetic structuring may occur over short distances in marine species with pelagic larvae, and 4) it is one of the first studies that demonstrates

possible anthropogenic impacts on genetic diversity in a marine species with a pelagic dispersal stage.

**MP066 Acute toxicity of Iranian Heavy crude oil to the Rockfish (*Sebastes schlegeli*); feeding disrupts the hepatodetoxification and immune systems** H. Kim, Oil and POPs Research Group, Korea Ocean Research and Development Institute, Korea; Y. Che, R. Addison, W. Shim, J. Jung, Oil and POPs Research Group, Korea Ocean Research and Development Institute. Oil spilled into marine environments induces the hepatodetoxification system and disrupts immune function in fish (Reynaud and Deschaux, 2006). However, the mechanism of toxicity to the immune system has not been fully investigated. Changes in the immune system may affect disease susceptibility in fish (Zelikoff, 1998). In this study, we describe the effects of spilled crude oil from the “*Hebei spirit*” (Iranian Heavy Crude Oil in gelatine capsules) on juvenile rockfish. Effects on multiple hepatodetoxifying enzymes (Cytochrome P4501A and GST) and on the immune responses including interleukin-1 $\beta$  (IL-1 $\beta$ ), granulocyte colony-stimulating factor (G-CSF) and Cathepsin L (Cat. L) were measured in liver, spleen and kidney. From 12 h after treatment, the oil-fed groups had slightly higher concentrations of bile fluorescent metabolites and CYP1A expression than the control group in liver and spleen. Cat. L and G-CSF mRNA also increased significantly in the early stages of exposure (from 12h to 48h after exposure) but then decreased to the levels in the control group, or lower. Therefore, it is suggested that innate immune response of oil-fed fish induced sensitively at initial stage due to the IHCO exposure but several immune-related markers may decrease to less than that of control group after initial stage of response.

**MP068 Development of two small fish species, *Pimephales promelas* and *Cyprinodon variegatus*, as model organisms for immunotoxicity** M.K. Sellin Jeffries, Miami University / Department of Zoology, Miami University; B.A. Arivett, S.E. Fiester, Miami University / Department of Microbiology; D.D. Coffey, L.M. Thornton, Miami University / Department of Zoology; A.W. Smith, Miami University; L.A. Actis, Miami University / Department of Microbiology; J.T. Oris, Miami University / Department of Zoology. To adequately assess the environmental risks associated with exposures to aquatic pollutants, the effects of contaminant exposures on immune function should be considered. To date, only a handful of fish species (e.g., *Oryzias latipes*, *Onchorynchus mykiss*) have been utilized in studies investigating the impacts of toxicant exposures on immune function. The goal of the current study was to develop the fathead minnow (FHM, *Pimephales promelas*) and the sheepshead minnow (SHM, *Cyprinodon variegatus*) as model organisms for assessing immunotoxicity in freshwater and estuarine fish, respectively. There is a paucity of information regarding basic immune function in FHMs and SHMs; therefore, the first objective of this study was to characterize basic aspects of immune function in each species. This was accomplished by measuring 1) leukocyte numbers, 2) differential mRNA expression of immune-related genes in blood, spleen, liver and kidney tissue, 3) serum IgM levels, 4) plasma lysozyme activity and 5) pathogen resistance in adult FHMs and SHMs with no known history of pathogen or contaminant exposure. The second objective of this study was to evaluate the effects of a model immunotoxicant, benzo[a]pyrene (BaP), on immune function in FHMs and SHMs. Fish exposed to BaP were intraperitoneally-injected with 200  $\mu$ g/g body weight BaP, while the vehicle control fish were injected with corn oil. Forty-eight hours after the injections, a subset of fish from each group was sacrificed and tissues were collected for determination of leukocyte numbers, mRNA expression, IgM levels and lysozyme activity. The remaining fish were subjected to a pathogen resistance trial in which the mortality of minnows intraperitoneally-injected with an LD<sub>30-50</sub> dose of bacteria (i.e., *Yersinia ruckeri* for FHMs and *Vibrio anguillarum* for SHMs) was monitored for 10 days following the pathogen exposure. These results of this study demonstrate that both the FHM and SHM are suitable model organisms for use in immunotoxicity studies.

**MP071 PCB-126 exposure lowered antimicrobial peptide secretion in juvenile northern leopard frogs [*Lithobates (Rana) pipiens*]** T.L. Cary, University of WI – Madison / Forest and Wildlife Ecology, University of WI-Madison / Zoology, University of WI-Madison / Forest and Wildlife Ecology; J.D. Pask, Vanderbilt University Medical Center / Pathology, Microbiology and Immunology; L.A. Rollins-Smith, Vanderbilt University Medical Center / Pathology, Microbiology and Immunology, and of Biological Sciences; W.H. Karasov, University of Wisconsin / Zoology, and

of Forest and Wildlife Ecology. Chytridiomycosis, an emerging infectious disease of amphibians caused by the fungus *Batrachochytrium dendrobatidis* (*Bd*), has been implicated in declines of amphibian populations world-wide. In addition to disease, another factor threatening global amphibian populations is environmental contamination. Measures of immune function provide a way to analyze how contaminant exposure may be linked to disease susceptibility. In the case of *Bd*, antimicrobial peptides (AMPs) secreted onto the skin of amphibians are thought to defend against the fungus, thus acting as a first-line innate immune strategy. We hypothesized that larval exposure to PCB-126, an environmentally persistent organic contaminant, would decrease AMPs secreted by *Rana pipiens*. In order to obtain newly metamorphosed froglets carrying a body-burden of PCB-126, tadpoles were fed a diet containing 0.37, 1.2, or 5.0 ng PCB-126/g. A control group was fed the same diet, but without PCB-126 (0.0 ng/g). Post-metamorphic (10.3  $\pm$  1 [S.E.M.] weeks) frogs were injected with amphibian phosphate buffered saline (APBS) or norepinephrine-HCl dissolved in APBS and placed in buffer to collect secreted skin peptides. The buffer was acidified, and the peptides were enriched by passage over C18-Sep-Paks to obtain hydrophobic peptides which include the AMPs. AMPs were quantified using a bradykinin based peptide assay. Additionally, skin peptides were analyzed using matrix-assisted laser desorption time-of-flight mass spectrometry to determine any differences in type of AMPs secreted between control and PCB-treated frogs. Control frogs secreted 593  $\pm$  101  $\mu$ g/g body weight (BW) ( $n$  = 10) skin peptides, while frogs exposed to 0.37, 1.2, or 5.0 ng PCB-126/g had 336  $\pm$  43 ( $n$  = 11), 378  $\pm$  62 ( $n$  = 10), and 365  $\pm$  56 ( $n$  = 10)  $\mu$ g/g BW skin peptides, respectively. However, this decrease was not statistically significant (1-way ANOVA,  $F_{3,37}$  = 2.47,  $p$  = 0.0769). Additionally, the suite of AMPs secreted by frogs in all treatment groups was similar, indicating that the type of AMP secreted was not affected by PCB exposure. If there is a minimum threshold of AMPs necessary to be protective of *Bd* infection in juvenile *R. pipiens*, lowered AMP levels due to contaminant exposure may make froglets more susceptible to *Bd*. Supported by UW Sea Grant Institute (grant number NA16RG2257, project number R/EH-2).

**MP072 The immunologic effects of waterborne oil sands-derived naphthenic acids on rainbow trout** L. Leclair, / Environmental Sciences; N.S. Hogan, University of Saskatchewan / Toxicology Centre; B. Koellner, Friedrich Loeffler Institute; G.Z. MacDonald, Canadian Rivers Institute, University of Prince Edward Island; M.R. Van den Heuvel, Canadian Rivers Institute, University of Prince Edward Island. Naphthenic acids are a major organic constituent in waters influenced by oil sands contamination. With increased diseases in fishes being associated with oil-sands influenced waters, there is interest surrounding the potential of naphthenic acids as an immunotoxicant. The lack of availability of naphthenic acid standards representative of that found oil sands required the extraction of naphthenic acids from 17-year-old tailings waters. High resolution mass spectrometry indicated that the extracted naphthenic acids were at least 91% representative of classical naphthenic acid structures. The median lethal threshold of the extracted naphthenic acids was 15 mg/L. For immune experiments, rainbow trout were exposed to 0, 1, and 8 mg/L naphthenic acids in a flow through system in two separate trials. After 7 d of exposure, a portion of the rainbow trout were sampled for immune parameters. To assess the immunologic response blood, spleen, gill and head kidney samples were taken at the end of the exposure and the constituent leukocytes, T-lymphocytes, B-lymphocytes, thrombocytes and myeloid cells were counted and typed via flow cytometry analysis using fluorescent antibodies specific for those cell types. Total cell counts were done on each tissue using flow cytometry in conjunction with a fluorescent dye, DiOC6. The remainder of the trout in each experiment were injected with inactivated *Aeromonas salmonicida* and held in clean water for 21 d and subject to similar lymphatic cell evaluation in addition to evaluation of antibody production by ELISA. Naphthenic acid responses were compared to a positive control, benzo[a]pyrene, a known immune suppressor. Naphthenic acids had no significant impacts on total leukocytes, any of the four leukocyte types, or on erythrocytes in blood. There were significant decreases in total leukocytes, thrombocytes and B-cells in spleen, but only as compared to the low dose, which was elevated over the control. Unlike the PAH benzo[a]pyrene, that profoundly depletes splenic and blood B-leukocytes, naphthenic acids appear to show a more complex response of stimulation and depression, and thus do not likely act by the same mechanism.

**MP073 Timing of Thymocyte Cell Death Induction and Receptor Usage by DES and Methoxychlor Metabolite, HPTE, during embryonic exposure** C. Broussard, The University of La Verne, University of La Verne / Biology, University of La Verne / Professor of Biology; A. Lim, University of La Verne / Biology; Z. Muscato, C. Zambrano, S. Moeller, University of La Verne; L. Leung Liu, The University of La Verne, University of La Verne. A number of chemicals prevalent in the environment have been identified as estrogenic endocrine disrupting chemicals (estrogenic EDCs). Studies have shown that estrogenic EDCs not only alter the reproductive system, the brain, and behavior, but may also alter immune responsiveness. Previously, we investigated the effects of two estrogenic EDCs, diethylstilbestrol (DES) and hydroxyphenyl-trichloroethane (HPTE), on embryonic thymocyte development and found that both appear to induce cell death and alteration of differentiation. The assumption has been that estrogenic EDCs, eg. BPA, DES, nonylphenol, and pesticides like methoxychlor and its metabolite HPTE, utilize estrogen receptors to mediate their effects. In order to determine whether and which estrogen receptors DES and HPTE may use, we conducted several experiments. First, we did a time course of treatment to determine how quickly DES and HPTE induced death in developing embryonic thymocytes. Rapid induction of apoptosis would suggest a receptor-initiated signaling cascade, whereas slow induction would imply a transcriptionally mediated pathway. Second, we used an inhibitor of the classical estrogen receptor alpha and, in separate experiments, an inhibitor of GPR30, a nonclassical estrogen receptor, to block any interactions DES or HPTE might have with ER alpha or GPR30, respectively. The rescue of apoptosis and alteration of embryonic thymocyte differentiation by one or both of the inhibitors would indicate which receptor was primarily responsible for the estrogenic EDCs adverse effects. Third we stimulated embryonic thymocytes after exposure to estrogenic EDCs in FTTC, to determine if thymocytes matured in this environment were functional. We present the findings of these experiments and propose a mechanism for estrogenic EDC action in differentiating embryonic thymocytes. This material is based in part upon work supported by the National Institute of Environmental Health and Safety (NIEHS) under Grant No. 1R15ES017345-01. Any opinions, findings and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the NIEHS.

**MP074 Evaluation of the Ecotoxicological Effects of Dexamethasone** J.L. Ribas, I.C. Guiloski, Federal University of Paraná / Pharmacology; G.L. Galvan, Federal University of Paraná / Genetic; E.M. Reynaldo, Hospital da Cruz Vermelha Brasileira filial do Paraná / Research Center; M.M. Cestari, Federal University of Paraná / Genetic; A. Zampronio, H.C. Silva de Assis, Federal University of Paraná / Pharmacology. Steroid hormones have been found in water bodies. In this study, toxic effects of an environmental water contaminant dexamethasone (DEX) were evaluated. Male Swiss mice received water containing DEX (0.03-3.0µg/L) for 14 days as the only source of drinking water. Control group received only water. Mice were then killed and biochemical (aspartate aminotransferase [AST], alanine aminotransferase [ALT], total protein [PT], albumin [ALB], globulin [GLOB], creatinine [CREAT], sodium [Na], potassium [K], calcium [Ca] and creatine phosphokinase [CPK]), hematological (Erythrocyte, hemoglobin, hematocrit, leukocyte and platelet) and immunological biomarkers (cell migration induced by carrageenin [Cg] and NO production induced by lipopolysaccharide [LPS] at 1 to 10000ng/mL in macrophages) were carried out. Additionally, total weight, abdominal fat and adrenal weight were determined. One Way ANOVA followed by Bonferroni's post hoc test was applied. The 3.0µg/L DEX-treated group showed an increase in abdominal fat compared to the control group. The adrenal weight had a significant increase in all the treated groups. Both AST and ALT increased significantly at 3.0µg/L DEX-treated group, as well as GLOB and K. CPK increased in all concentrations of DEX tested. Other biochemical parameters did not show statistically significant differences among the groups. In relation to hematological biomarkers, DEX, at lower concentrations (0.03-0.3µg/L), reduced the number of leukocytes while at a higher concentration (3µg/L) this number was increased. The number of resident peritoneal cells did not differ between the test and control groups, but there was a significant reduction in the cell migration elicited by Cg in the all DEX-treated groups due to a significant decrease in the migration of polymorphonuclear cells. Basal NO synthesis by macrophages from DEX-treated animals was significantly lower when compared to the control group. LPS-stimulated NO production was reduced in macrophages from 3µg/L DEX-treated mice compared

to control macrophages, independently of the concentration of LPS used to stimulate the cells. The results suggest that a constant exposure of organisms to dexamethasone present in water can lead to potential toxic effects, including biochemical, hematological and immunological changes, showing that more attention must be given to the proper disposal of pharmaceutical products in water.

**MP075 The Effects of Diethylstilbestrol on Maturation and Differentiation of Sex Specific Embryonic C57BL/6 Thymocytes in Organ Culture** C. Zambrano, University of La Verne / Department of Biology; C. Broussard, The University of La Verne, University of La Verne / Biology, University of La Verne / Professor of Biology. The endocrine system consists of a network of hormone producing glands. Hormones are released in low doses and serve as chemical messengers that regulate many of the body's functions, including the immune system. Endocrine disrupting chemicals (EDCs) are substances, which interfere with the natural occurring endocrine system of the body. These chemicals display hormone like properties or interfere with hormone activity, which may disrupt the development of the immune system. It has been demonstrated in studies of neonatal and adult systems that sex is also a variable in the effects of EDCs. One such EDC is diethylstilbestrol (DES), a synthetic estrogen that serves as a model for other EDCs. DES was once prescribed during pregnancy to prevent complications and was later discovered to cause endocrine disruption. It has been reported that females exposed to DES *in utero* may have an increased risk of developing a rare form of vaginal cancer at a young age. Reproductive tract abnormalities have been reported in both females and males of second and third generation offspring of DES mothers. Along with reproductive effects, there is evidence that developmental exposure to DES can alter the functioning of the immune system. Previous studies shown that DES impacts developing thymocytes, yet no studies have examined how DES effects on thymocyte development differ in male and female embryos. The aim of this study was to determine whether DES effects on the different subpopulations of developing embryonic T cells differ based on sex of the embryo. PCR-amplification of a Y chromosome gene was used in sex identification. An *ex vivo* assay was used to examine the initial development of T cells and an *in vitro* assay with phytohemagglutinin stimulation examined mature T cells. Thymii were extracted from C57BL/6 mice embryos at 16 to 18 days of gestation. Our results indicate a decrease in T cell viability of both sexes in a dose dependent manner, and effects on the different subpopulations were also observed. These findings suggest that DES affects normal development and survival rate of both male and female embryonic T cells. This material is based upon work supported by the National Institute of Environmental Health and Safety (NIEHS) under Grant No. 1R15ES017345-01. Any opinions, findings and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the NIEHS.

**MP076 BIMS: A database of baseline physical, chemical, and ecological conditions in the Gulf of Mexico prior to the Deepwater Horizon accident** A. Fogg, M. Henning, M. Meaders, J. Nicolette, ENVIRON International Corporation. In Natural Resource Damage Assessment, accurate characterization of an ecosystem's baseline conditions is critical to the accurate quantification of injury. Baseline is the condition of the natural resources and services that would have existed had an incident not occurred. It is not possible to accurately quantify natural resource injuries from the Deepwater Horizon release in the Gulf of Mexico without a thorough understanding of baseline conditions. It is also important to capture long-term trends associated with physical, chemical, and biological stressors affecting baseline conditions. Adequately characterizing baseline conditions of the Gulf of Mexico is uniquely challenging, given the large geographic scale, diversity of natural resources and the services they provide, and immense volume and diversity of data available. Further complicating matters is the fact that baseline conditions are not static; conditions may cycle seasonally or may decline or improve over time for reasons completely unrelated to the release. We are developing a Baseline Information Management System (BIMS) that is robust and flexible enough to meet these challenges. We describe this innovative system, the types of data included in BIMS, and the anticipated final product. BIMS is a secure web-based system that currently hosts over 13,000 data sources, including over 1,600 map layers, 11,000 reports and articles, and 550 Excel and Access data tables. Baseline data on natural resources in the Gulf of Mexico includes information for invertebrates, fish, reptiles, birds, and mammals, as well as habitat data. Surface

water, sediment, and biological tissue data are included to characterize the baseline chemistry and toxicity. Physical, chemical, and biological stressor data includes (but is not limited to) information on petroleum releases, non-petroleum releases, hypoxic zones, harmful algal blooms, erosion, coastal development, shoreline modification, and extreme weather conditions. BIMS is a compilation of publicly available government monitoring data, peer-reviewed literature, geospatial data, and interpreted, transcribed, and standardized data. BIMS has fully-linked and traceable information, intuitive searching and displays, and full map creation and data export functions. Even though BIMS is still under development, it is proving to be a useful tool for understanding the baseline conditions of the Gulf of Mexico prior to the Deepwater Horizon accident.

**MP077 Tracking the disappearance of oil from Gulf Coast marshes following the MC-252 Deepwater Horizon Incident** G. Harmon, Senior Project Scientist / Ecology / Cardno ENTRIX, Cardno Entrix / Senior Project Scientist / Ecology; A. Koonjebharay, Cardno Entrix. Data collected during the Summer 2010, Fall 2010, Spring 2011 and Fall 2011 at fixed sites throughout the Gulf of Mexico were used to track the disappearance of oil from Gulf coast marshes. Natural processes account for most of the oil removal although 14 of the 202 sites monitored were treated to facilitate these natural processes. These data were collected during cooperative Natural Resource Damage Assessment studies conducted by gulf state Trustees, the National Oceanic and Atmospheric Administration, and BP. Assessment sites were randomly selected from among more than two thousand Pre-Assessment survey points that were established in Summer 2010. The selected injury sites represent varying degrees of oiling and a variety of marsh habitats (herbaceous, Phragmites, back barrier, and mangroves). There are 164 sites being monitored in Louisiana, 16 sites in Alabama, and 22 sites in Mississippi. Observations were made of oiling on plant stems and on the soil surface. Observations made during the Fall 2011 assessments indicate that oil was still visible on less than 20% of the originally oiled sites. The majority of the sites where oil was visible in Fall 2011 were sites that had been initially classified as heavily oiled. In addition to the decrease in the percentage of sites that show oiling, we will also show evidence that the amount of oil on these sites has decreased significantly by Fall 2011.

**MP078 Polycyclic aromatic hydrocarbon concentrations in neuston and plankton samples from the coastal waters off Pensacola and Fort Myers, FL** I. Campbell, K. Workinger, Florida Gulf Coast University; D. Rumbold, Florida Gulf Coast University / Associate Prof of Marine Science, Florida Gulf Coast University / Professor of Marine Science; A. Loh, Florida Gulf Coast University. The 2010 British Petroleum Macondo-1 blowout released an estimated 4.93 million barrels of crude into the northern Gulf of Mexico. Despite cleanup efforts, oil slicks near the Macondo well have been reported as recently as March 2012. Polycyclic aromatic hydrocarbons (PAHs) are a major component of oil. Neuston (from surface tows) and plankton (from oblique tows beginning at mid-depth) samples were collected using a 150-mm mesh net off the coast of Fort Myers Beach and Pensacola Beach, FL. Samples were collected at three sites along these two transects from 10 km to 40 km offshore between February 2011 to March 2012. Polycyclic aromatic hydrocarbons were extracted using microwave extraction and quantified via gas chromatography mass spectrometry. Concentrations of PAHs in neuston and plankton samples ranged from less than 2 ng/g to greater than 50 ng/g. Concentrations of PAHs were lower from sampling sites within 16km of shore. Results from this study will be utilized in a comprehensive integrated study on the potential residual effects from the blowout that includes *ex situ* bioassays and chemical assays of water samples collected concurrently with these neuston/plankton samples.

**MP079 Impacts of Hurricane Isaac and Tropical Strom Lee on Mobilizing Deepwater Horizon Oil Spill Residues along Alabama's Beaches** P. Clement, Auburn University / Department of Civil Engineering; J. Hayworth, V. Mulabagal, F. Yin, G. John, Auburn University. In June, 2010, crude oil from the Deepwater Horizon (DH) incident began washing ashore along Alabama and Florida coastlines. Alabama's sandy beaches were heavily inundated by emulsified oil which survived all emergency actions during the 150 mile journey from the DH well to Alabama's shoreline. Close to the shoreline, an unknown amount of emulsified oil interacted with suspended particulates and submerged, forming relatively stable submerged oil mats (SOMs). Emerging research suggests that although the lighter petroleum components in the submerged oil could have weathered rapidly while the oil

was floating over open waters, the heavier components, such as high molecular weight polycyclic aromatic hydrocarbons (PAHs), could have resisted weathering processes. Therefore, the fate of PAHs sequestered in SOMs remains uncertain. In this study, we examine various environmental issues related to SOMs using both observational and chemical characterization data. Field data was collected immediately after several high energy weather events, which included Tropical Strom Lee and Hurricane Isaac that impacted the Gulf Shores region in September of 2011 and 2012, respectively. Our observational data show that the level of tar ball activity associated with SOMs continues to exceed the expected background level by several orders of magnitude. Our chemical characterization data show that the concentration levels of several hazardous PAHs in SOM and tar ball samples collected after Tropical Strom Lee and Hurricane Isaac are almost identical to the levels observed in the oil emulsions that arrived on Alabama's beaches back in June, 2010. These results indicate that an unknown amount of submerged oil still remain trapped near Alabama's beaches; also, several high molecular weight PAHs trapped in these submerged oil material are relatively recalcitrant. More studies are needed to better assess the potential long-term hazards posed by these partially weathered oil residues to Alabama's near-shore environments and the associated ecosystem.

**MP080 PAH concentrations and bioassays of sea-surface microlayer and subsurface water collected from the Gulf of Mexico off Pensacola and Ft. Myers, FL** A. Loh, I. Campbell, Florida Gulf Coast University; J. Guymarch, S. Le Floch, CEDRE; K. Workinger, D. Grant, P. Barreto, J. Barreto, Florida Gulf Coast University; D. Rumbold, Florida Gulf Coast University / Associate Prof of Marine Science, Florida Gulf Coast University / Professor of Marine Science. Polycyclic aromatic hydrocarbons (PAHs) are a major component of crude oil. Despite cleanup efforts, oil slicks near the 2010 British Petroleum Macondo-1 well have been reported as recently as March 2012. We will present PAH concentrations in water samples collected from the sea-surface microlayer (SSML), subsurface water (0.5m) and from mid-depth along two transects out to 40 km offshore of Pensacola and Fort Myers, Florida between February 2011 and March 2012. At each of three stations along the transects, up to 2 liters of SSML was collected using a radio-controlled autonomous sampler with a rotating Teflon drum. Subsurface water (from 0.5m and mid-depth) was collected using a peristaltic pump from the sampler or a GoFlo (closed – open – closed) bottle. All water samples were then analyzed for PAHs using the Stir Bar Sorptive Extraction (SBSE or Twister™) technology and thermal desorption gas chromatography mass spectrometry. Not surprisingly due to their ubiquitous nature, PAHs were detected in several samples. However, data have not yet been compared to the Macondo oil chromatograms and, thus, the source of the detected PAHs remains uncertain. Additionally, all collected water samples were screened for toxicity using a battery of *ex situ* bioassays consisting of bacterial luminescence (*Vibrio fischeri*), urchin development (*Lytechinus variegates*) and survival of adult copepods (*Acartia tonsa*). Several of the samples, particularly samples of SSML were found to be toxic. Results from this study will be utilized in a comprehensive integrated study on the potential residual effects from the blowout that includes chemical assays, enzyme induction assays and morphological assessment of neuston and plankton samples collected concurrently with these water samples.

**MP081 The Deepwater Horizon Oil Spill: Interlaboratory Comparison Exercises and Certification of Standard Reference Material 2779 Gulf of Mexico Crude Oil** J.R. Kucklick, National Institute of Standards and Technology (NIST) / Analytical Chemistry Division, National Institute of Standards & Technology / Hollings Marine Laboratory; M. Schantz, B. Benner, National Institute of Standards and Technology. The Deepwater Horizon (DWH) oil spill began on April 10, 2010 and continued four months releasing approximately 5 million barrels of oil that impacted about 500 miles of Gulf of Mexico shoreline. Assessing the spill's impact would require a massive effort by local, state, and federal agencies as well as private companies. A major challenge to responding to the spill was a need to understand the quality and comparability of data for oil-related compounds being generated by dozens of laboratories involved in the damage assessment. To assist with the damage assessment from the DWH spill, the National Institute of Standards and Technology (NIST) in collaboration with the National Oceanic and Atmospheric Administration (NOAA) conducted four interlaboratory measurement exercises for parent polycyclic aromatic hydrocarbons (PAHs), alkyl PAHs and oil marker compounds in sediment, mussel tissue, oil, and an exercise for PAHs in whole blood and

plasma. For each exercise, participants were requested to provide data on a reference sample, typically a Standard Reference Material (SRM) if available, and an unknown sample. This resulted in approximately 100 data sets for about 90 target compounds. The exercises provided important information on lab comparability of PAH measurements and on the scope of PAH-related compounds that can be measured by different laboratories. Data from laboratories participating in the oil exercise was also an important contribution to the certification of Standard Reference Material (SRM) 2779 Gulf of Mexico Crude Oil. This reference material greatly increases the number of values for PAH-related compounds relative to other NIST crude oil SRM. SRM 2779 has certified values for 20 individual PAHs and reference values for additional PAHs, alkyl PAH groups, hopanes and steranes.

**MP082 Sediment, Tissue, and Weathered-Oil Sample Holding Times for Oil Spill Monitoring** D. Shea, North Carolina State University / Department of Biology; W. Thorsen, K. O'Neal, P. Lazaro, North Carolina State University.

It has been over two years since the Deepwater Horizon (DWH) incident in the Gulf of Mexico where hundreds of thousands of samples were collected, but many were not analyzed within published maximum holding times (MHT) and even today there are samples of interest that have yet to be analyzed. The establishment of MHTs usually is driven by shorter-term durations that are typical of most environmental monitoring. However, the DWH incident is atypical in that the enormous number of samples made it impractical to analyze all samples of interest within published MHTs. To provide data to help assess the integrity of PAH data from samples held beyond the published MHTs, we reviewed the literature and historical data from our laboratory on the stability of PAHs and hopane in sediment, tissue and weathered oil when stored frozen at -20 C and -80 C. Analyses were conducted over an 8-year period for the following samples. 1) Weathered oil samples, oiled sediment, and oiled mussels from Prince William Sound, Alaska following the *Exxon Valdez* Oil Spill. 2) Oysters and passive sampling devices (PSDs) exposed in the laboratory to a mixture of crude oil and creosote. All samples were extracted, fractionated, and analyzed by GC/MS according to methods described previously. Our results at -20 C indicate that after 4 years, for weathered oil, losses were observed for parent naphthalene, C1-naphthalene, and parent fluorene at close to 25%, with no further loss at 8 years, and with no statistically significant loss of other PAHs or hopane. PAH decreases were somewhat greater in sediment fortified with PAH in the laboratory compared to sediment oiled in the field. Bivalves generally had less depletion of PAH compared to sediment and mostly just parent naphthalene. PSDs had somewhat greater PAH loss than sediment. At -80 C, there was a consistent, but statistically insignificant lower rate of PAH loss. These data are consistent with samples we have analyzed more recently over the past 2 years from the DWH incident. We conclude that the proper storage of oil, sediment, and tissue for at least up to 8 years at -20 C results in only small loss of the most volatile PAH and that storage at -80 C is not necessary. Furthermore, our results provide strong evidence that oil, sediment, and tissue samples collected following the DWH incident and properly stored should remain valid for at least 8 years.

**MP083 A Novel Approach for Estimating PAH Concentrations in Bioassays with Oil** C. Greer, Queen's University / Biology; P.V. Hodson, Queen's University / School of Environmental Studies; R.S. Brown, Queen's University / Department of Chemistry.

Toxicity tests often generate large numbers of samples that require chemical analysis to quantify the concentration of oil to which the organisms are exposed. Currently, the preferred approach is to quantify total polycyclic aromatic hydrocarbons (TPAH) by gas chromatography-mass spectrometry (GC-MS). However, GC-MS is very costly and time consuming, and typical budgets cannot accommodate a thorough analysis of all water samples. Fluorescence spectrophotometry is an alternative method that compares the magnitude of fluorescence of a sample to a standard curve of known concentrations of whole oil, to estimate the concentration of oil in the sample through detection of the fluorescent compounds. Although fluorescence is faster and more economical than GC-MS, it does not directly measure dissolved PAH. Our objective was to estimate TPAH by correlating GC-MS and fluorescence data. We developed a fluorescence standard curve from dilutions of the stock solution used for dosing exposure tanks and analyzed TPAH in the same stock solution by GC-MS to convert the standard curve to TPAH. Fluorescence analysis of individual toxicity test solutions provided an estimate of TPAH in test solutions, and the accuracy of these estimated PAH concentrations was assessed by a limited number of GC-MS analyses of the test solutions.

With some modifications, this strategy of combining a limited number of GC-MS analyses with more thorough fluorescence analyses provided a faster and more economical way to describe exposure conditions of toxicity tests.

**MP084 Overestimation of PAH Bioavailability When Using Passive Sampling Devices in Oil Spills** D. Shea, North Carolina State University / Department of Biology; D. Forestier, W. Thorsen, K. O'Neal, P. Lazaro, North Carolina State University.

The use of passive sampling devices (PSDs) to measure bioavailable PAH exposure resulting from spilled crude oil has been criticized due to the potential for oil to adhere to the surface of the PSD. If this oil is not completely removed prior to analysis, the PAH in the oil would be measured along with the PAH absorbed in the PSD yielding a total PAH concentration in excess of that considered dissolved or bioavailable. This would be analogous to measuring PAH in water containing oil droplets, mussels, etc. To determine whether the presence of oil adversely affects the performance of the PSD, we compared the accumulation of PAHs in four types of PSDs to that in mussels under conditions with varying amounts of fresh and weathered crude oil. The PSD types included: semi-permeable membrane devices (SPMDs), polyethylene (PE), polydimethylsiloxane (PDMS) and polyoxymethylene (POM). We found that all four types of PSDs can greatly overestimate the bioavailability of PAHs to mussels in the presence of oil, with POM having the least bias. Under the conditions used in our laboratory exposures, the physical contact of oil with the PSD increases accumulation up to 1000-fold while exposure of mussels to the same oil conditions results in only a 3-fold increase in PAH. In heavily oiled exposures, PSDs are highly enriched in total PAH compared to mussels and the relative abundance of PAHs in the PSD matches that of the source oil. Furthermore, nearly all of the PSDs that had this PAH enrichment also contained hopane – a highly water insoluble biomarker of the source oil – that should not accumulate in the PSD through the dissolved phase. Conversely, hopane was not detected in any of the PSDs that did not show this PAH enrichment. In water accommodated fraction (WAF) exposures where source oil was not present, the PSDs were not enriched in PAH compared to mussels and the relative abundance of PAHs in the PSDs matches that expected from accumulation via dissolved phase. This work demonstrates that SPMDs and other PSDs can be an inappropriate means of estimating bioavailable PAHs in the presence of crude oil and that detailed PAH analysis and the measurement of sterane and/or hopane source-oil biomarkers is critical to determining whether the PSDs provide valid data on the dissolved or bioavailable PAH in water resulting from spilled oil.

**MP085 Utilizing Comprehensive Methodologies to Examine Chemical Contaminants Including Oxygenated PAHs (OPAHs) in Gulf of Mexico Complex Mixtures** S.G. O'Connell, Oregon State University / Environmental and Molecular Toxicology; T. Haigh, Oregon State University / Environmental and Molecular Toxicology Dept; S.E. Allan, / Environmental and Molecular Toxicology, Oregon State University / Graduate Researcher; G. Wilson, Oregon State University / Environmental and Molecular Toxicology Dept; K.A. Anderson, Oregon State University / Environmental & Molecular Toxicology, Oregon State University / Dept. of Environmental & Molecular Toxicology.

Passive samplers are deployed to examine bioavailable fractions of contaminants in a variety of matrices including air, water, and sediments. New deployment devices and materials have been developed in the last decade to sample contaminants with wide ranges of physiochemical properties, including non-polar and polar organic compounds. In this research, passive sampling devices (PSDs) consisting of lipid-free polyethylene tubing were used in four locations in the Gulf of Mexico beginning in May of 2010, prior to shoreline oiling of the Deepwater Horizon Oil Spill. Further field efforts were continued in Florida, Mississippi, Alabama, and Louisiana to capture events during and after visible oil was present at a few of these locations through May, 2011. Extracts from these passive sampling devices were used to characterize PAHs spatially and temporally in previous work, but subsequent analyses of these samples have resulted in the quantitation of non-target emerging contaminants like oxygenated polycyclic aromatic hydrocarbons (OPAHs) through liquid and gas chromatography mass spectrometry (LCMS, GCMS, respectively). OPAHs are characterized in recent publications as an emerging class of contaminants with environmental concentrations and toxicities similar to PAH analogues, and by using parallel and complementary OPAH methods, we were able to target 24 OPAH compounds. Additionally, after full scan analyses of these extracts in both chromatographic systems, unknown peaks several orders of magnitude greater than some PAH or any OPAH compounds were

identified as sulfonated hydrocarbon chains. These compounds are typically used as detergent surfactants, and were identified through mass selection techniques using both LC-MS/MS quadrupole and time-of-flight (TOF) analyses. Additional screening of 1200 analytes using GC-MS Automated Mass Spectral Deconvolution and Identification System (AMDIS) revealed several other unique compounds. Current efforts are ongoing to identify as many compounds that may be toxicologically relevant in these PSD extracts from the Gulf of Mexico.

**MP086 Preparation and characterization of oil-water dispersions by pressurized flow injection (PFI) of oil into a continuous turbulent flow generator** B. Hansen, SINTEF Materials & Chemistry / Marine Environmental Technology; P. Gardinali, Florida International University / Department of Chemistry and Biochemistry; B.A. Stubblefield, Oregon State University, Oregon State University / Environmental and Molecular Toxicology; G.M. Rand, Florida International University / Ecotoxicology & Risk Assessment; O.X. Pelz, BP / Gulf Coast Restoration Organization, BP Gulf Coast Restoration Organization / GCRO, BP / GCRO; T. Nordtug, SINTEF Materials and Chemistry / Marine Environmental Technology. Preparation of oil water dispersions (OWDs) as exposure media for toxicological testing is usually accomplished by subjecting mixtures of oil and water to a defined amount of energy such as controlled agitation in an aspirator bottle or mixing by agitating the water with pumps or propellers. Most of these systems are static and the resulting oil concentration and droplet size distribution is highly dependent on the oil properties and also the geometry of the generator systems. As an alternative to these methods a system for generating defined OWDs in flow systems was developed. A recent report on a pressurized fluid injection (PFI) droplet generator (Nordtug et al, 2011) introduced a simple design to systematically deliver oil into a turbulent but controlled water stream. The method is based on continuous generation of oil dispersion with defined oil droplet size distribution and oil concentration by adjusting the oil:water ratio and the energy input (turbulence). The present study presents an inter-laboratory comparison of the capability of the PFI-generator to produce OWDs with different degrees of weathering. Droplet density, droplet size distribution and chemical analyses will be used to characterize the OWDs. The stability of the solutions will also be determined by following the formation and degradation of the OWDs by fluorescence microscopy, particle counting and 3D fluorescence spectroscopy. A protocol describing the operational conditions of the PFI-generator with respect to the creation of exposure media matching predicted or observed droplet size distributions during the DWH incident will be provided.

**MP087 Optical characterization of oil-water dispersions by fluorescence spectroscopy and microscopy: getting the answer in real time** K. Sandoval, Florida International University / Department of Chemistry & Biochemistry; I. Ley, A. Fernandez, Florida International University / Southeast Environmental Research Center (SERC); P.R. Gardinali, Florida International University / Department of Chemistry & Biochemistry and SERC. Oil is undoubtedly a complex mixture of hundreds of chemicals many of which are insoluble or slightly soluble in water. When crude oil reaches the sea surface it may form slicks that could be dispersed naturally by wave action, evaporated, dissolved, biodegraded or chemically dispersed. Droplet formation is an important factor controlling the environmental behavior of spilled oil since it's linked to processes like biodegradation, dissolution, organism uptake, and transport. Despite the fact that formation of oil-water dispersions are common during releases of crude oil and derivatives, the toxicological effects of oil in the environment are largely associated with the dissolved fractions of the oil. Due to natural turbulence from a release in a deepwater location and application of dispersants at the sea floor, droplet formation was an important process during the DWH release. This work describes a combination of fluorescence-based techniques to characterize oil water dispersions (OWDs) generated in laboratory experiments by providing droplet sizes, densities, concentrations, and bulk analysis of petroleum hydrocarbons in real time. OWDs were prepared by traditional techniques using aspirator bottles. Dispersions were created at different loading rates with different energy regimes (No-vortex, high-energy) and using chemical dispersants. A Horiba Yobin Fluoromax 4 spectrofluorometer was used to generate three dimensional excitation emission matrices (3DEEMs) directly from the samples. Two regions in the spectrum were used to assess dissolved components (Ex 280nm/Em335nm) vs. droplets (Ex345nm/Em440nm). Droplets were measured and counted by using an Olympus

IX-71 epifluorescence microscope. Unlike suspended solids or microorganisms, oil droplets fluoresced when excited with blue-violet radiation (330-385nm). The microscope was calibrated using fluorescent polystyrene beads at three sizes between 1 and 7µm. Results indicated that no-vortex WAF preparations produced stable, droplet free solutions. High-energy methods introduced large amounts of microdroplets of a wide range of sizes but the dispersions were highly dynamic and unstable. In contrast, chemically enhanced WAFs created under low energy condition produced more homogeneous and more stable OWDs suitable for toxicological testing. Filtration did drastically reduce the number of droplets from all OWDs; however, oil breakthrough was observed when the operational conditions were not carefully controlled.

**MP088 The contribution of oil droplets to the uptake and toxicity of oil dispersions to copepods** B. Hansen, SINTEF Materials & Chemistry / Marine Environmental Technology; D. Altin, BioTrix; A.J. Olsen, Norwegian University of Science and Technology; I.B. Overjordet, SINTEF – Materials & Chemistry; G. Rand, Florida International University; W. Stubblefield, Oregon State University; P. Gardinali, Florida International University; O.X. Pelz, BP / Gulf Coast Restoration Organization, BP Gulf Coast Restoration Organization / GCRO, BP / GCRO; T. Nordtug, SINTEF – Materials & Chemistry. The objective of this study was to investigate the potential contribution of oil droplets to adverse biological responses and uptake of oil components in filter-feeding boreal copepods (*Calanus finmarchicus*) exposed to naturally dispersed oil. In order to estimate the relative contribution of oil droplets versus the water soluble components (WSF), copepods were exposed to unfiltered (droplets) and filtered (WSF) dispersions at three different concentrations. Differences between the two parallel treatments in terms of body burden and acute toxicity were compared. Three different oils with different physical-chemical properties (paraffinic, naphthenic and naphthenic/waxy heavy end) were used in identical experiments. The copepods were exposed to 0.4, 2 and 10 mg oil/L nominally for 4 days, and controls were treated only with natural sea water. The concentrations used are for the lower concentrations within environmentally realistic concentrations, whereas the high concentration may be realistic in certain areas following dispersant treatment of surface spills or following a sea floor blow-out. Oil droplet concentrations and size ranges were analyzed daily through particle counting. Fluorescence microscopy was used to assess both the presence of oil droplets and algal material in the copepod's guts. While overall low copepod mortality was observed throughout, contribution of oil droplets to body burden increased with increasing dispersion concentrations. However, a large part of the oil body burden appears to be associated with the copepod surface, intestine and filtering apparatus and a substantial fraction of the ingested oil droplets was excreted through fecal pellets.

**MP089 Physical and chemical characterization of oil-water mixtures as toxicity exposure media: assessing composition, stability, and droplet formation** K. Sandoval, Florida International University / Department of Chemistry & Biochemistry; A. Fernandez, I. Ley, A. Smith, B. Echols, Florida International University / Southeast Environmental Research Center (SERC); G.M. Rand, Florida International University / Department of Earth & Environment and SERC; P.R. Gardinali, Florida International University / Department of Chemistry & Biochemistry and SERC. Assessing the exposure of biological endpoints to oil is usually accomplished by preparing oil-water mixtures of different chemical and physical compositions. Oil water dispersions (OWDs), water accommodated fractions (WAFs) and chemically enhanced water accommodated fractions (CEWAFs) are the three most common ones. Generally, water-soluble components are responsible for the bulk of oil toxicity so that WAFs are the best representation of typical exposure scenarios. Wave action and turbulent flow conditions add energy to environmental systems. The potential for oil droplet formation under these high-energy scenarios is usually assessed by OWDs prepared with different degrees of agitation. Dispersants are also employed in response to oil releases. The effects of dispersed droplets of entrained oil are evaluated from CEWAFs. All these scenarios depend on two key assumptions: WAFs have only "truly dissolved" hydrocarbons and OWDs, and CEWAFs are physically and chemically stable so that they can be used for toxicological testing. This study describes a series of physical and chemical procedures used to characterize the composition and stability of WAFs/OWDs and CEWAFs from the time of preparation through their use in exposure chambers. Epi-fluorescence microscopy was used to assess the presence or absence of oil droplets down to 1µm. Excitation/emission in the violet- blue region

permitted distinguishing entrained oil from non-fluorescent particles. Size calibration using dyed polystyrene beads allowed both average droplet sizes and droplet size distributions to be measured in each solution. Fluorescence spectroscopy was used to assess dissolved and entrained oil components using 3DEEMs. Results indicate that preparation of WAFs at low energy conditions (no-vortex) at a 1:1000 OWR produce droplet free-solutions. OWD droplet size distributions are energy, loading rate and oil-type dependent. Self-dispersions of oil are much more dynamic and unstable than CEWAFs (1:20 DOR). Inter- and intra-laboratory tests showed that low energy WAF preparations were analytically consistent. CEWAF preparations did introduce larger amounts of all oils tested in the dispersions but concentrations were more variable than for WAF preparations. Serial dilutions yielded reproducible and predictable concentrations. These findings point out the importance of conducting a comprehensive physical and chemical characterization of the exposure media in support of toxicological testing.

**MP090 Assessment of chemistry and acute toxicity of weathered MC252 oils: Are mass-based LC50s alone indicative of effect of weathering on toxicity?** L. Faksness, SINTEF / Marine Environmental Technology; B.H. Hansen, SINTEF Materials and Chemistry; D. Altin, BioTrix; T. Nordtug, SINTEF Materials and Chemistry; O. Pelz, BP GCRO. The water accommodated fractions (WAFs) of fresh (i.e. source oil) and weathered MC252 oils have been studied with special emphasis on chemistry and acute biological effects (algae growth (*Skeletonema costatum*) and copepod mortality (*Acartia tonsa*)). Low-energy WAFs were prepared following the CROSERF guidelines using an oil-to-water ratio of 1 to 10000 (100 mg oil/L water). The WAFs have been prepared from fresh and artificially weathered MC252 oil residues from 150 °C+ (representing surfacing oil) to 300°C+ (representing 3 to 5 days on sea). In addition, WAFs were generated from artificially weathered MC252 oil supplied by NOAA and two naturally weathered oil samples collected in the Gulf after the Deepwater Horizon well accident. The field samples were slick oil collected on July 19, 2010, by the USCGC Juniper and from the CTC barge. WAF is of special interest because components dissolved from an oil slick or from dispersed oil droplets are known to be bioavailable to marine organisms and therefore have a potential for causing toxic effects. On each WAF, measurements of volatile organic compounds (VOCs) and semi-volatile organic compounds (SVOCs, e.g. PAHs and total petroleum hydrocarbons) were obtained. The chemistry of the WAFs indicates that weathering preferentially removes the lighter, more volatile compounds and, in general, reduces the overall concentration of dissolved oil constituents in the WAF. The 100% WAFs were diluted and used in toxicity tests. Acute toxicity can be presented as specific toxicity, expressed from EC50 or LC50 values and normalized to mass-based concentration data, or relative toxicity, expressed as EC50 and LC50 values computed from %WAF. Relative toxicity indicated that weathering decreases toxicity since a higher %WAF was needed to produce toxic effects from weathered oils. The two methods of presenting the toxicity data show that toxicity depends on the specific composition of the WAF, and not just on the total WAF concentration or the weathering state of the oil.

MP091 Toxicity of MC252 oil to copepods and early-life stages of a sea urchin and finfish K. Workinger, Florida Gulf Coast University; D. Rumbold, Florida Gulf Coast University / Associate Prof of Marine Science, Florida Gulf Coast University / Professor of Marine Science; A. Loh, Florida Gulf Coast University. We evaluated the sensitivities of three different *ex situ* screening bioassays for detecting residual toxicity from the Deepwater Horizon blowout by conducting 24-hour static toxicity tests of chemically-enhanced (using COREXIT 9500) water accommodated fraction (CE-WAF) of artificially weathered MC252 oil (Source oil B). Preliminary assessment of the data indicate the 24-hr lethal concentration (LC50) for 50% of exposed adult copepods, *Acartia tonsa*, was much more sensitive than the 24-hr effective concentration (EC50) for abnormal development of exposed urchin (*Lytechinus variegatus*) embryos (i.e., resulting in abnormal development in 50% exposed). Toxicity tests utilizing development of redfish (*Sciaenops ocellatus*) were found to have a sensitivity similar to the urchins. In agreement with the published literature, skeletal deformations (e.g., lordosis and scoliosis) were the most obvious sub-lethal defect in the fish embryos following a 24-hr exposure (beginning within 5 hours of spawning). The 24-hr lethal concentration (LC50) for 50% of the exposed redfish eggs was 10x higher.

MP092 Effects of Deepwater Horizon oil exposures on the swimming performance and cardiac development of juvenile mahi (Coryphaena hippurus) E. Mager, University of Miami / Rosenstiel School of Marine and Atmospheric Science, University of Miami, RSMAS / Division of Marine Biology & Fisheries; A. Esbaugh, University of Miami, RSMAS / Rosenstiel School of Marine and Atmospheric Science, University of Texas – Austin, Marine Science Institute / Post-Doctoral Fellow; J. Stieglitz, R. Hoenig, D. Benetti, M. Grosell, University of Miami, RSMAS. Mahi (*Coryphaena hippurus*) were exposed to oils collected from the Gulf of Mexico following the 2010 Deepwater Horizon (DWH) spill to assess potential impacts on swimming performance. Two types of experiments were performed to examine both acute and chronic effects in juvenile mahi following a brief exposure to oil: (1) 48 h static exposures initiated with freshly fertilized eggs, followed by normal rearing for ~30–40 d under control flow-through conditions and (2) 24 h exposures to ~30–40 d old juveniles. All oil exposures were performed using dilutions of Water Accommodated Fractions (WAFs). To assess swimming performance, fish were subjected to an incremental velocity test using a miniature Blazka-style variable speed respirometer to obtain measures of critical aerobic swim speed ( $U_{crit}$ ) and aerobic scope. All fish were starved at least 24 h prior to swimming. Additionally, a subsample of larvae were collected immediately following the 48 h exposures to examine cardiac development as determined by *in vivo* microscopic analyses of cardiac edema and heart angle. The effects to swimming performance as well as cardiac development in mahi exposed during the embryonic/larval stage will be reported.

MP093 PAH metabolites in bile and enzymatic biomarkers in livers of reef fish from the northern Gulf of Mexico after the Deepwater Horizon Oil Spill L. Allen, D. Johnson, NOAA Environmental Cooperative Science Center, Florida A&M University; W. Patterson, J. Tarnecki, University of West Florida / Dept of Biology; C. Jagoe, NOAA Environmental Cooperative Science Center, Florida A&M University. The Deepwater Horizon Oil spill released almost 5 million barrels of crude oil into the Gulf of Mexico in 2010. Crude oil contains toxic components including polycyclic aromatic hydrocarbons (PAHs) that may harm aquatic organisms. Fish metabolize PAHs and excrete the metabolites via bile, where they can be detected fluorimetrically. Cytochrome p450 induction, which is involved in the biotransformation and excretion of PAHs, can be measured as activity of 7-ethoxyresorufin o-deethylase (EROD) in liver. We collected over 500 fish from multiple offshore locations in the Gulf of Mexico off Alabama and Florida in 2010–2011, during and after the oil spill, and measured bile metabolites and liver enzyme activities. Species included *Lutjanus campechanus* (red snapper), *Balistes caprisus* (grey triggerfish), *Pagrus pagrus* (red porgy), and *Seriola dumerili* (greater amberjack). Bile fluorescence was measured at excitation/emission wavelengths of 290/335, 341/383 and 380/430 nm to detect metabolites of 2, 4 and 5 ring PAHs, respectively, and standardized to billiverdin and protein concentrations. Most fish had bile fluorescence signals consistent with naphthol, indicative of oil exposure. Bile fluorescence decreased over the sampling period, suggesting that PAH exposure declined after the oil release ended. EROD activities were generally highest in fish collected near the well site, and differed among species and locations. Additional enzyme assays (for glutathione-S-transferase, a phase 2 detoxification enzyme, and superoxide dismutase, involved in antioxidant defenses) are underway to further characterize oil exposure and biochemical responses in these fish.

MP094 Impact of the Deepwater Horizon oil spill on the eastern oyster, *Crassostrea virginica* spermatozoa cellular alterations and fertilization success L. Donaghy, J. Vignier, B. Denkert, J. Devine, L. Haynes, Florida Gulf Coast University; P. Soudant, University of Brest – CNRS; F.E. Chu, Virginia Institute of Marine Science; J.M. Morris, M.W. Carney, J. Lipton, D. Cacula, Stratus Consulting, Inc.; A. Volery, Florida Gulf Coast University / Marine and Ecological Sciences, Vester Marine Field Station. In April 2010, the Deepwater Horizon (DWH) oil spill released 780,000m<sup>3</sup> of crude oil in the Gulf of Mexico, and a chemical dispersant, Corexit 9500A and 9527, was used to dissipate oil slicks at the wellhead and on the surface. The eastern oyster, *Crassostrea virginica*, is an economically and ecologically important species which propagates along the Gulf of Mexico. The oil spill occurred at the beginning of its spawning season. Exposure of gametes to toxicants in spawning animals such as *C. virginica*, potentially may lead to decreased fertilization success. Most studies use fertilization success as the assay end point. However, various defects of gametes can alter fertilization.

Using flow cytometry, we aimed at understanding the cellular modifications occurring in exposed sperm. Our results showed that oil from surface-collected DWH oil as well as dispersant impacted intracellular mechanisms. Although viability was not decreased, mitochondrial activity and associated ROS production were inhibited in a dose-dependent way. Inhibited mitochondrial metabolism would decrease the energy production needed for sperm motility. Furthermore, acrosomal integrity, which is primordial for fusion between sperm and egg, was also altered. This might also be responsible for decreased fertilization. Flow cytometry provided new insights on the intracellular damages occurring in sperm during hydrocarbons and dispersant exposures, potentially leading to unsuccessful fertilization.

**MP095 Evaluation of toxicity of Deepwater Horizon oil and dispersant on gametes of the oyster *Crassostrea virginica*: embryogenesis and larval development** J. Vignier, Florida Gulf Coast University / Marine and Ecological Sciences; B. Denkert, J. Devine, L. Donaghy, L. Haynes, Florida Gulf Coast University; P. Soudant, University of Brest – CNRS; J.M. Morris, M.W. Carney, J. Lipton, D. Cacela, Stratus Consulting, Inc.; F.E. Chu, Virginia Institute of Marine Science; A. Voley, Florida Gulf Coast University / Marine and Ecological Sciences, Vester Marine Field Station. The accidental explosion of the MC252 drilling rig off the coast of Louisiana on April 20, 2010, released 4.9 million barrels of crude oil in the Gulf of Mexico, and some 3 million liters of chemical dispersants, Corexit 9500A and 9527, were used directly at the well head and on surface to break oil slicks. This was the largest oil spill in US history after the Exxon Valdez. The eastern oyster, *Crassostrea virginica*, is an ecologically and economically important species along the Gulf of Mexico, representing about \$67 million (2009). The oil spill occurred during the spawning season of *C. virginica*; therefore the exposure of gametes to contaminant might be potentially toxic and decrease fertilization success and impact embryonic and larval development. The aim of this study was to examine the effects of acute exposure to surface-collected Deepwater Horizon oil, dispersant alone (Corexit 9500A) and dispersed oil on gametes (eggs and sperm) of oysters. Fertilization success, embryo development, larval growth and survival were assessed at different time points (1h, 24h, and 96h). Lethal and sub lethal concentration ranges were also determined. Our results showed that dispersant only and oil and dispersant combined significantly impacted fertilization rates, developmental success, viability of the larvae and growth in a dose-dependent way. Oil alone significantly decreased the fertilization success in a dose-dependent manner, and highly altered larval development and subsequent survival.

**MP096 Effect of artificially weathered oil from Deepwater Horizon oil spill and dispersants on the early life stages of oysters** J.M. Devine, J. Vignier, B. Denkert, L. Donaghy, L. Haynes, Florida Gulf Coast University; P. Soudant, University of Brest – CNRS; F.E. Chu, Virginia Institute of Marine Science; J.M. Morris, M.W. Carney, J. Lipton, D. Cacela, Stratus Consulting, Inc.; A. Voley, Florida Gulf Coast University / Marine and Ecological Sciences, Vester Marine Field Station. The estuaries and coastal areas of the Gulf of Mexico are ecologically and economically important serving the recreational and commercial needs of the population. Critical habitats such as oyster reefs in addition to serving ecological roles of biofiltration, wave mitigation and enhancement of water quality, also serve as refuge for recreationally and commercially important fishery species. In addition, oysters are also commercially important. The purpose of this study was to determine the toxicity of Deepwater Horizon oil and dispersant to eastern oysters *Crassostrea virginica*. The effects of the water accommodated fractions (WAFs) of artificially weathered source oil, Corexit9500 and oil-dispersant mixtures were examined on early life stages of *Crassostrea virginica*. Hatchery spawned oysters from an unexposed region of the Gulf of Mexico allowed for collection and exposure of oysters at each of the following life stages; gametes, embryos, D larvae, and early spat. End points such as survival, larval development, and developmental abnormality were examined. Results suggest a dose-dependent response to oil, dispersant and oil-dispersant mixtures by early life stages of oysters.

**MP097 Biological Responses of the Eastern Oyster *Crassostrea virginica* Exposed to Deepwater Horizon Oil and Dispersants via Dietary Pathways** A. Voley, Florida Gulf Coast University / Marine and Ecological Sciences, Vester Marine Field Station; L. Haynes, N. Martin, L. Castret, A. Griffith, L. Donaghy, Florida Gulf Coast University; P. Soudant, University of Brest – CNRS; F.E. Chu, Virginia Institute of Marine Science; J.M.

Morris, M.W. Carney, J. Lipton, D. Cacela, Stratus Consulting, Inc; B. Denkert, J. Devine, Florida Gulf Coast University. Following the British Petroleum oil spill in the Gulf of Mexico on April 20th, 2010; oil was found washed ashore in coastal areas in the Northern Gulf of Mexico. Oil particles can adsorb onto algae, detritus, and debris that can be ingested by filter feeding organisms such as the Eastern oyster (*Crassostrea virginica*). The benthic, sedentary nature along with the economic importance of oysters renders them particularly suited for the current study on the biological effects of oil (surface-collected Deepwater Horizon oil) that were ingested by oyster via filtration. Adult oysters were exposed to oil adsorbed onto algae cells at three different concentrations and responses of oysters followed over a period of 3 weeks. Disease prevalence and intensity of *Perkinsus marinus*, tissue alterations, immune responses and survival were examined after 2 and 3 weeks. Results suggest that survival was dose dependent and immune responses were affected in oil-exposed oysters. Results related to histopathological alterations and immune responses will be discussed.

**MP098 Signals of continued exposure to crude oil in populations of adult Gulf killifish (*Fundulus grandis*) across Barataria Bay, LA** B.D. Dubansky, Louisiana State University / Department of Biological Sciences, Louisiana State University / graduate student; A. Whitehead, University of California Davis; C.D. Rice, Clemson University / Biological Sciences; F. Galvez, Louisiana State University / Dept. of Biological Sciences. Following the Deepwater Horizon oil spill in April 2010, fish were sampled from pre-oiled sites along the coastal marsh of Louisiana, Mississippi, and Alabama to obtain baseline data on the health status of Gulf killifish (*Fundulus grandis*). The six sites were identified and sampled based on predictions of crude oil landfall, though only one site, Grand Terre Island in Louisiana, actually received significant oiling. Genomic and physiological data obtained from *in situ* sampling of killifish from these sites [Whitehead et al. 2011 (PNAS)] identified Grand Terre Island as an outlier, coincident with the oiling of this site and the greater Barataria Bay estuary. Fourteen additional sites in Barataria Bay, Louisiana receiving varying degrees of oiling were subsequently identified, and adult killifish were collected and sampled *in situ* from these sites in November and December of 2010. Using ELISA with liver microsomal fractions, we show that fish sampled from oiled sites had an increase in the expression of cytochrome P450 1A (CYP1A) protein, a sentinel biomarker of exposure to aryl hydrocarbon receptor (AhR)-active polycyclic aromatic hydrocarbons (PAHs). Moreover, the mRNA levels of CYP1A and the AhR repressor (AhRR) in livers were elevated in fish from oiled locations, which correlated with subtle changes in expression of liver CYP1A as examined by immunohistochemistry (IHC). Using IHC, we also found a high concentration of protein expression of CYP1A in the gills, head kidneys, and intestines of fish collected from heavily-oiled sites. Intestinal CYP1A protein expression was the most sensitive indicator of exposure, with increased CYP1A protein occurring generally in the more anterior regions of the intestine, indicating a gastrointestinal route of exposure to AhR-active PAHs. The data obtained from these 14 sites compared to reference sites coincides with the degree of oiling based on the Shoreline Cleanup Assessment Technique (SCAT). Additional sampling efforts in Barataria Bay in August 2011 at select sites also showed a clear signal of continuing exposure to crude oil, with Grande Terre showing a very high transcriptional profile of exposure to AhR-active PAHs.

**MP099 The effect of oil dispersants and salinity on the biodegradation of south Louisiana crude oil and impacts on Gulf killifish *Fundulus grandis*** A. Kuhl, LSU Aquaculture Research Station; J.A. Nyman, Louisiana State University / Renewable Natural Resources; C.C. Green, Louisiana State University / Renewable Natural Resources. Chemical dispersants like COREXIT are an important technology in the remediation of oil spills in the aquatic environment. Further, it has been demonstrated that environmental salinity is an important factor in the effectiveness of the dispersants on the breakdown of crude oil. Thus the purpose of this work is to investigate the effect of a dispersant on the degradation of crude oil and study the effects of varying oil degradation on acute toxicity and a sublethal physiological response in a common estuarine fish at various salinities observed in an estuarine environment. We hypothesize that biodegraded oil in the presence of dispersant will persist longer and have greater toxicity than non-dispersed oil. Laboratory mesocosms were designed with oxic water at salinities of 4, 12, or 18 g/L overlying sediment that has an oxic surface layer and an anoxic subsurface, simulating various estuarine conditions. Mesocosm water was spiked with various combinations of crude oil and of COREXIT 9500 at

the manufactures recommended dilution ratio (1:10). Treatments consist of water mixed with crude oil alone, COREXIT alone, a combined exposure to crude oil and COREXIT, and a control and allowed to biodegrade in mesocosms for 1, 4, and 16 weeks prior to harvesting water for analytical analysis and acute toxicity testing. Acute toxicity was assessed using a 96-hr static-renewal acute toxicity bioassay and juvenile common Gulf killifish (*F. grandis*). Following exposures, fish were harvested and cytosolic and nuclear protein fractions were isolated. Ethoxyresorufin-O-deethylase (EROD) and glutathione-S-transferase (GST) enzyme activity were measured and used as a biomarker of sublethal polyaromatic hydrocarbon (PAH) exposure. Results demonstrate a marked increase in PAH concentrations and resultant acute and sublethal toxicity in dispersed oil versus non-dispersed oil. Additionally, the toxicity of the dispersed oil was detectable at the greatest dilutions and persisted through 16 weeks of biodegradation. Moreover, dispersant alone was acutely toxic at the manufacturers recommended dispersant:oil ratio without activating the AhR response system. This toxicity increased at salinities outside the iso-osmotic conditions. This data indicates that dispersed oil increased the bioavailability of PAH resulting in both greater acute and sublethal toxicity.

**MP100 Acute and Chronic Toxicity of Unweathered and Weathered MC252 Oil to Mysid Shrimp (*Americamysis bahia*) and Tidewater Silversides (*Menidia beryllina*)** M.T BenKinney, Exponent; O.X. Pelz, BP / Gulf Coast Restoration Organization, BP Gulf Coast Restoration Organization / GCRO, BP / GCRO; G.M. Rand, Florida International University / Ecotoxicology & Risk Assessment. A variety of biological studies have been initiated in response to the Deepwater Horizon Mississippi Canyon 252 (MC252) spill to characterize potential effects from fresh and weathered MC252 crude oils. Laboratory tests have been conducted with mysid shrimp (*Americamysis bahia*) and tidewater silversides (*Menidia beryllina*) using a series of field-collected MC252 crude oils (MASS oil, CTC Barge oil, Juniper oil) that represent a continuum from fresh to highly weathered. Test organisms were exposed to water accommodated fractions (WAFs) of the oils prepared under slow stir non-vortex conditions for 20 hours with a 4 hour settling period before decanting. Static acute tests were conducted for 48 hours exposure in closed containers with zero headspace. Serial dilution of the freshly-prepared (100%) WAF using a standardized 1:1000 oil to water ratio was used to prepare the solutions evaluated in the static tests. Chronic tests were conducted with daily renewal of WAFs during the 21 (shrimp) or 28 (fish) day exposures. Three exposure concentrations (0.01, 0.1, and 1.0 g oil/L water) and a laboratory control were evaluated in the chronic tests. Analytical characterization of the test solutions included volatile hydrocarbons, polycyclic aromatic hydrocarbons (PAHs) and alkylated PAHs, and saturated hydrocarbons (SHC- alkanes). Results from the acute and chronic WAFs will be compared among the tests and with the parent oils. Based on the test results, the weathered oils (CTC, Juniper) were significantly less toxic than the fresher MC252 source oil (MASS oil).

**MP101 Macondo crude oil from the Deepwater Horizon oil spill disrupts specific developmental processes during zebrafish embryogenesis** Y. de Soysa, A. Ulrich, Smith College / Department of Biology; T. Friedrich, University of Massachusetts / Department of Molecular and Cellular Biology; D. Pite, Smith College / Department of Chemistry; S. Compton, D. Ok, R. Bernardos, Smith College / Department of Biology; G. Downes, University of Massachusetts / Department of Molecular and Cellular Biology; S. Hsieh, Smith College / Department of Chemistry; R. Stein, M.C. Lagdameo, Smith College / Department of Biology; K. Halvorsen, Smith College / Department of Mathematics; L. Kesich, Smith College; M. Barresi, Smith College / Department of Biology. The Deepwater Horizon disaster was the largest marine oil spill in history, and total vertical exposure of oil to the water column suggests it could impact an enormous diversity of ecosystems. Water soluble components of crude oil and specific hydrocarbons have been shown to cause defects in cardiovascular and craniofacial development in a variety of teleost species, but the developmental origins of these defects are unknown. We tested whether water accumulated fractions (WAF) of the Deepwater Horizon oil could impact specific processes throughout embryonic and larval development in zebrafish. WAF treatments caused defects in craniofacial development and circulatory function similar to previous reports, but we extend these results to show they are likely derived from an earlier defect in neural crest cell development. Moreover, we demonstrate that exposure to WAF also causes deformations in programmed cell death, locomotor behavior, sensory and motor axon

pathfinding, somitogenesis, and muscle patterning. Interestingly, the severity of cell death and muscle phenotypes decreased over several months of analysis, which was correlated with a rapid drop-off in the aromatic and alkane hydrocarbon components of the oil. Whether these teratogenic effects are unique to the oil from the Deepwater Horizon oil spill or generalizable for most crude oil types remains to be determined. This work establishes a model for further investigation into the molecular mechanisms behind crude oil mediated deformations. In addition, due to the high conservation between vertebrates, our work also provides a platform for more focused assessment of the impact that this oil spill has had on the early life stages of native fish species in the Gulf of Mexico and the Atlantic Ocean.

**MP102 Effects of crude oil, dispersants (Corexit 9500 and 9527), and mixtures on sheepshead minnows** K.J. Kroll, University of Florida / Physiological Sciences; A.C. Mehinto, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology; L. Escalon, UA Army Engineer Research and Development Center; N. Garcia-Reyero, Mississippi State University / Institute for Genomics Biocomputing and Biotechnology; N.D. Denslow, University of Florida / Department of Physiological Sciences and Center for Environmental and Human Toxicology, University of Florida / Dept. of Physiological Sciences &c. On April 20, 2010 the Deepwater Horizon oil rig ruptured releasing crude oil into the Gulf of Mexico for 4 months. Oil spill volumes are estimated to be on the order of 4.9 million gallons. In order to breakup the oil, two different dispersants Corexit 9500 and 9527 were used at a ratio of 1:10- 1:50 (dispersant:oil volume) as recommended by the manufacturer. About 1.8 million gallons of the dispersants were reportedly used during the spill. Quantities of the dispersant type used during the spill have not been disclosed. Although research on the effects of crude oil has been studied, the toxicity of the dispersants and their mixtures on different life stages are very limited, especially for Corexit 9527. The objectives of this study were to investigate the effects of crude oil, the two 2 dispersants, and oil/dispersant mixtures on embryo development, homeostasis, and biomarkers of reproduction of sheepshead minnows (*Cyprinodon variegatus*). To simulate weathering, the oil, 2 dispersants, and their mixtures were mixed with artificial seawater in glass carboys for 7 days. The oil was removed using separatory funnels. The resulting water accommodated fraction (WAF) was subsampled and analyzed for PAH (polyaromatic hydrocarbons) and BTEX (benzene, toluene, xylene), and dispersant fingerprinting by GC-MS. In addition, the crude oil sample used for this study was also characterized. The WAF from the Oil/Corexit 9527 mixture contained 2-5 times higher quantities of PAH's and BTEX than the oil/Corexit 9500 mixture and it was more toxic in dose-dependent exposure studies, using doses that we expected to be below the LC<sub>50</sub>. Juvenile sheepshead minnows experienced 100% mortality at Corexit 9527 concentrations >3 ppm, and in an oil/Corexit 9527 mixture (10ppm /1 ppm). There were no mortalities in crude oil WAF.

**MP103 At what molecular weight, if ever, do petroleum hydrocarbons become non-toxic to aquatic life?** D.W. Smith, Conestoga Rovers & Associates. The aquatic toxicity and solubility of many non-aromatic petroleum hydrocarbons (PHC) are opposite functions of molecular weight and carbon number (C#). Toxicity increases with molecular weight whereas solubility decreases. According to current information, PHC toxicity increases more slowly than solubility decreases. Therefore, as molecular weight increases, a point is reached where minimally toxic concentrations exceed the solubility limit, at which point this compound and heavier compounds become non-toxic. This effect is demonstrable with acute toxicity. Acute toxicity for aliphatics above about C9 (nonane) becomes progressively harder to demonstrate without resorting to supersaturation. Almost no chronic bioassays have been conducted for aliphatic, in general, and specifically with compounds heavier than about C9. Chronic toxicity for aliphatics higher than C9 are based on extrapolation of toxicity observed for lighter compounds. These extrapolations predict that the transition point to non-toxic aliphatics occurs as low as C12 (dodecane), whereas other extrapolations suggest that it occurs at around C30. Unfortunately for assessing risk of petroleum spills, this range of uncertainty encompasses the bulk of the mass of many weathered petroleum products, such as jet fuel, diesel and heating oil, and crude oils. My talk reviews the evolving science on this issue. Current evidence suggests that the answer to the title question depends on the exposure period, the species, and the risk assessor's tolerance for uncertainty.

**MP104 Chemical Dispersants Used in the Gulf of Mexico Oil Crisis Response Are Cytotoxic to Human Skin Fibroblasts** J.T. Wise, University of Southern Maine / Wise Laboratory of Environmental and Genetic Toxicology; S.S. Wise, University of Southern Maine / Wise Laboratory of Environmental and Genetic Toxicology, Ocean Alliance; H. Xie, University of Southern Maine / Wise Laboratory of Environmental and Genetic Toxicology; J. Griffith, University of Southern Mississippi / Department of Coastal Sciences; J.P. Wise Sr, University of Southern Maine / Wise Laboratory of Environmental and Genetic Toxicology. Chemical dispersants are chemicals compounds used to aid in the cleanup of crude oil spills. They became a significant public health concern in 2010 due to the BP Deepwater Horizon Oil Crisis when millions of gallons of chemical dispersants specifically Corexit® 9527 and 9500 were used to break up the crude oil. They were applied via aerial spray and deepwater injection. Toxicity of Corexit® to humans is unknown. The primary routes of exposure to these chemical dispersants are inhalation, direct dermal contact and ingestion; therefore, the objective of this study is to determine the cytotoxicity and genotoxicity of these two dispersants (Corexit® 9500 and 9527) in human skin (BJhTERT) and lung (WTHBF-6) fibroblasts. Cells were treated with and without S9 fractions with cofactors, because fibroblast cells may not readily express P450 enzymes necessary to metabolize the chemicals. Corexit® 9500 was cytotoxic to skin cells. Specifically in skin, 50, 250, 350 and 500 ppm 9500 induced 95, 89, 52, and 3 percent relative survival, respectively. S9-mediated metabolism increased toxicity inducing 78, 84, 39 and 2 percent relative survival, respectively. Corexit® 9527 was cytotoxic to skin cells. Specifically in skin, 500, 650, 850 and 1000 ppm 9527 induced 89, 83, 74, and 51 percent relative survival, respectively. S9-mediated metabolism increased toxicity inducing 87, 77, 47 and 35 percent relative survival, respectively. Ongoing and future work will consider the genotoxic effects as well as the effects of dispersed oil.

**MP105 A Novel Derivatization-based LC-MS/MS Method for Quantitative Characterization of Naphthenic Acid Isomer-group Profiles in Soil and Sediment Samples** M. Woudneh, AXYS Analytical Services Ltd; C. Hamilton, Axys Analytical Services / Client Services, Axys Analytical Services Ltd.; G. Wang, J.P. Benskin, J.R. Cosgrove, AXYS Analytical Services Ltd. Naphthenic acids (NAs) are a complex mixture of naturally occurring acyclic carboxylic acids which are found around petroleum deposits. NAs can concentrate during the extraction of bitumen from oil sands and are among the major toxic constituents of water used during this process. Management of NA-contaminated process water poses a major challenge for ensuring environmental sustainability in Alberta's oil sands. To support environmental monitoring efforts, new tools are urgently needed for accurately and reproducibly quantifying NAs in environmental samples. In this work, we developed a novel derivatization-based LC-MS/MS method that is suitable for quantitative characterization of NA isomer-group profiles in ambient soil and sediment samples. The method utilizes liquid-solid extraction with ultrasonic agitation and cleanup using strong anion exchange (SAX) cartridges. Quantification was simplified by optimizing collision-induced dissociation within the mass spectrometer to produce approximately constant response factors among the various isomer groups. To reduce their impact on NA data, ubiquitous fatty acids were chromatographically separated from NA isomer groups. We validated the method using soil samples from northern Alberta and applied principal component analysis to NA isomer signatures to distinguish natural or industry-impacted soils from those from outside Alberta, and also from NA profiles in pristine environments (i.e. far from petroleum deposits).

**MP106 A powerful technique for the analysis of metal complexation by macro-molecules – a case study of storm event distributions** E.R. McKenzie, University of California Davis / Civil and Environmental Engineering; P.G. Green, University of California, Davis; T.M. Young, University of California Davis / Civil and Environmental Engineering. High pressure size exclusion chromatography (SEC) coupled with an online inductively coupled plasma mass spectrometer (ICP-MS) is a powerful tool to assess the size dependence of metal complexation for macro-molecules (< 300 kDa) such as natural organic matter (NOM). This system was applied in the assessment of storm event samples from four land uses: highway, urban, agricultural, and natural. Wastewater effluent and biosolids runoff were also assessed. Al was associated with large macromolecules. Absorbance ( $\lambda=254$  nm) was used to detect organic matter (OM), which was primarily detected with molecular weights 3-6 kDa; Cu, Zn, and Ni were also detected in this

same size range, indicating that they were likely complexed by the OM. Cr, Mn, Co, Ni, and Pb were commonly detected as dissolved constituents (< 100 Da). Only small shift in size associated complexations were observed during the storm. SEC – ICP-MS is a powerful tool for assessing metal complexation; SEC – IPC-MS application to storm event samples revealed both complexed metals (Cu, Zn, and Ni), as well as bioavailable metals (Cr, Mn, Co, Ni, and Pb).

**MP107 A Study on the Importance of Solid-to-Water Ratios to the Absorption and Desorption Rates of PAHs in Polyethylene Passive Samplers** O. Slosser, LMU; R.G. Adams, Loyola Marymount University. Polycyclic aromatic hydrocarbons (PAHs) along with other hydrophobic organic contaminants pose significant environmental and health risks and their quantification in surface waters is important for water quality monitoring. Polyethylene (PE) passive samplers are low-cost and allow for in situ measurement of trace organic contaminants with a simple post-extraction process. In order to estimate the dissolved chemical concentration, the rate of chemical uptake in PE must be measured; however it is impacted by temperature, PE thickness, water-boundary layer thickness, biofilm thickness, and the solid-to-water ratio. In order to estimate the in situ rate of chemical uptake, pre-added performance reference compounds (PRCs) have been used to estimate first-order desorption rates. Assuming that the rates of absorption and desorption for comparable chemicals are the same, these PRC-measured rate constants are then used to estimate the extent to which equilibrium is achieved by the chemicals of interest. In this study desorption and absorption rates for phenanthrene and pyrene will be measured in laboratory experiments in order to assess the validity of the equivalent absorption and desorption rate assumption using the precise chemical measurements afforded by synchronous fluorescence. Additionally, because the ratio of the mass of PE to water impacts the rate of chemical uptake, the rate constants in the field will vary from those measured in the lab. In order to assess the importance of this phenomenon, rate constants for sorption and desorption will be measured in laboratory experiments with varying solid-to-water ratios. Preliminary results show the rates of absorption and desorption for phenanthrene are comparable. Both desorption and absorption curves for phenanthrene in water can be fit with a first order model. Experiments with varying solid-to-water ratios for phenanthrene and pyrene are in progress. Equivalent absorption and desorption rates and corrections for varying solid-to-water ratios are needed in order to correct for disequilibrium in field-deployed passive samplers.

**MP108 Advanced oil fingerprinting using comprehensive two-dimensional gas chromatography in the Hebei Spirit oil spill case** U. Yim, Korea Ocean Research and Development Institute / Oil & POPs Research Group, Korea Ocean Research & Development Institute; S. Ha, W. Shim, Korea Ocean Research & Development Institute. After the *Hebei Spirit* oil spill (HSOS) in December 2007, mixtures of three types of Middle East crude oil (total 12,547 kl) were stranded along 375 km of coastline in Western Korea. The HSOS was the worst oil spill case in Republic of Korea, and there were many forensic issues to be solved. After oil enters into marine environments, two main factors, i.e., mixing with background hydrocarbons and oil weathering, affect its hydrocarbon composition. Similar to other oil spill incidents, there was a lack of background contamination data for the spill sites. Furthermore, the alteration of the chemical composition of the spilled oils by weathering and chemical dispersion was largely unknown. To unravel these relationships, conventional tiered fingerprint approach including gas chromatography (GC) and mass spectrometry (MS) was applied to analyze fingerprint characteristics of spilled oil. Additionally, emerging fingerprinting techniques were also employed for further detail analysis. When there exists complication in oil fingerprinting like the HSOS case, more distinctive oil fingerprinting tools are required. Comprehensive two-dimensional gas chromatography (GCxGC) has the potential to revolutionize forensic oil spill analysis. GCxGC is capable of separating an order of magnitude more compounds from complex mixtures than conventional GC. GCxGC facilitates the understanding of the sources, weathering, and toxicity of unresolved complex mixtures (UCM) hydrocarbons. In HSOS case, GCxGC was promising to comprehensively evaluate the varying degree of mixing effects of the three spill sources and the abiotic and/or biotic effects of weathering. GCxGC facilitated the initial screening of various types of hydrocarbons using group type analysis and the application of isoprenoid compounds like biphytane, methyl hopanoids and benzohopanes with the

help of enhanced separation. We found these compounds had potential to be used as conservative fingerprints in the HSOS case.

**MP109 Analysis of cyclic and linear volatile methylsiloxanes in water environment** Y. Horii, K. Minomo, M. Motegi, K. Nojiri, Center for Environmental Science in Saitama. The determination of siloxanes include cyclic and linear volatile methylsiloxanes (VMS) in environment is important for the evaluation of human and environmental risks. VMS have been widely used in consumer products because VMS have low surface tension, high thermal and chemical stabilities, and believed to be inert. However, VMS are recently identified as priority chemicals for environmental risk assessment due to their persistence in the environment and bioaccumulative potentials. Analysis of VMS in environment is very challenging due to their high volatility and potential sources of background contamination. In this study, we developed a simple method for analysis of cyclic and linear VMS in water samples by using purge and trap extraction off-lined gas chromatograph/mass spectrometer (GC/MS). In chemical analysis, firstly, 500 mL water samples was gently transferred into an 1-L glass gas washing bottle and 100 ng of  $^{13}\text{C}_5$  labeled decamethylcyclotrisiloxane (D5) in acetone was added into the sample as an internal standard. To accelerate volatilization of VMS and prevent forming water, 50 g of sodium chloride was added. The gas washing bottle was purged at the flow rate of 600 mL/min using a vacuum pump. The sample trap, several types of SEP cartridges such as active carbon and XAD2 were tested, was mounted on the outlet of the gas washing bottle. The extraction efficiency in different extraction times and water bath temperatures was evaluated. After purging the samples, the sample trap was dry-purged by pure nitrogen gas for 10 min, then target chemicals were eluted with 5 mL of dichloromethane. The eluant was gently concentrated to 1 mL. Quantification of cyclic VMS include hexamethylcyclotrisiloxane (D3) to dodecamethylcyclotrisiloxane (D6) and linear VMS include octamethylsiloxane (L3) to dodecamethylpentasiloxane (L5) was performed on a GC coupled to high resolution MS or high resolution time-of-flight MS. The presence of VMS in laboratory products and reagents, GC parts, and also ambient air, are the major difficulty in the analysis of VMS. To reduce contamination, blank levels of VMS for all products and reagents used were tested. We selected silicone free or low bleed materials to achieve high precision analysis of VMS in environmental water samples. The optimized method was applied for river water samples collected from Saitama, Japan.

**MP110 Analysis of Gasoline Using Whole-Oil GC-MS Method** M.J. Benotti, Battelle / Analytical and Environmental Chemistry; R. Lizotte, K. McNerney, J. Thorn, Battelle. Analytical methods for the analysis of petroleum products include the analysis of the more volatile components by purge-and-trap gas chromatography mass spectrometry (GC-MS), the larger molecular weight hydrocarbons by GC-MS, and the saturated hydrocarbons (SHCs) by gas chromatography flame ionization detection (GC-FID). An alternative to this approach is analysis using a "whole oil" method, in which the material is directly injected into the GC-MS or GC-FID without sample preparation or dissolution in solvent. While the approach is not suited for the analysis of crude oil or heavy distillates given the additional maintenance associated with residual deposits, it provides a unique tool for the analysis of light to medium distillates and NAPL samples. The benefit of the whole oil GC-FID approach is that it allows for analysis of C3-C44 SHCs providing a more comprehensive fingerprint compared to traditional approaches where the smaller material (

**MP111 Analysis of Pesticides and Polycyclic Aromatic Hydrocarbons in Snow Using Solid Phase Micro-Extraction** C. Walsh, Oregon State University / Chemistry; J.E. Schlau, Oregon State University / Chemistry; S. Simonich, Oregon State University / Depts. of Chemistry and Environmental & Molecular Toxicology. Atmospheric transport of persistent organic pollutants (POPs), and selective removal via snowfall, provides a mechanism for deposition of POPs to remote and/or high-elevation ecosystems, including sites which might otherwise be expected to be pristine. Prior analytical methods for measuring pesticides and PAHs in snow required large (50 kg+) samples and extensive sample preparation, which limited the practical spatial and temporal scale of field studies. An analytical method using Solid Phase Micro-Extraction-GC-MS was developed to measure a wide range of persistent organic pollutants, including organochlorine pesticides (OCPs) and polycyclic aromatic hydrocarbons (PAHs) in melted snow. Field tests on water from Dixon creek in Corvallis, Oregon and snow collected at HJ Andrews Experimental Forest in the Oregon Cascade Range showed the

detection and quantitation of these POPs at trace concentrations (ng/L) in 40 mL sample volumes.

**MP112 Application of Passive Air Samplers to Assess the Vertical Variability of Semi-Volatile Organic Contaminants in the Atmosphere of Hawaii** X. Zhang, University of Toronto Scarborough / Chemistry, University of Toronto / Environmental Sciences; Y. Lei, University of Toronto Scarborough; J. Barnes, Mauna Loa Observatory; F. Wania, University of Toronto Scarborough / Dept. of Physical & Enviro. Science, University of Toronto at Scarborough / Dept. of Physical & Enviro. Science. Many semi-volatile organic chemicals (SVOCs) such as organochlorine pesticides and polybrominated diphenyl ethers (PBDEs) have been ubiquitously detected in the global atmosphere, even in remote regions where such chemicals have never been produced or used. While many studies have focused on SVOCs transported to remote polar and highland regions, few studies have investigated SVOCs undergoing long range transport to remote tropical islands far from emission sources. The global long range atmospheric transport of SVOCs occurs mainly in the free troposphere, where little interaction with the earth surface boundary layers occurs. Investigating the occurrence of SVOCs in the free troposphere is important to understand their long range atmospheric transport. In this study, air from the free troposphere and from the marine boundary layer of the Big Island of Hawaii were sampled at Mauna Loa (19°43'53"N, 155°2'52"W, 3398 m above sea level) and at the east coast of the island (19°32'9"N, 155°34'31"W, sea level, 50 m horizontal distance from the ocean) using flow-through air samplers (FASs). FASs were operated simultaneously at the two sites from April to September, 2011. Polyurethane foam (PUF) plugs used as the sampling medium were replaced every month. Three PUF plugs were installed in each FAS and analyzed separately to assess and correct for break-through. Each month, 3100–7700 m<sup>3</sup> and 300–800 m<sup>3</sup> of air was sampled at the Mauna Loa site and at the coastal site, respectively. Among the PBDEs analyzed in the samples using an Agilent 7000A triple quadrupole GC/MS/MS system, only BDE-47 and -99 were detected frequently over the five months. The concentrations in the marine boundary layer (4.4–24 pg/m<sup>3</sup> BDE-47 and 2.4–88 pg/m<sup>3</sup> BDE-99) were higher than in the free troposphere (0.1–0.4 pg/m<sup>3</sup> BDE-47 and 0.1–0.3 pg/m<sup>3</sup> DE-99) PBDE concentrations measured at the mountain site were lower than what has been reported for other global background sites in the Arctic and on the Tibetan Plateau, suggesting that Mauna Loa may truly represent global background levels for SVOCs. Between the two FAS sampling sites, within a horizontal distance of 50 km, the elevation changes from 0 m to 4000 m above sea levels. Along this large gradient, we also deployed XAD-based passive air samplers to assess the vertical variability of SVOCs.

**MP113 Challenges in real-time detection of trace compounds in the atmospheric matrix: Quantitative detection of alkyl amines using ion chromatography** T.C. VandenBoer, M.Z. Markovic, A. Petroff, J.G. Murphy, University of Toronto / Department of Chemistry. Two methods based on ion chromatography (IC) were developed for the detection of methyl and ethyl alkyl amines (methylamine (MA), ethylamine (EA), dimethylamine (DMA), diethylamine (DEA), trimethylamine (TMA) and triethylamine (TEA)) and  $\text{NH}_3/\text{NH}_4^+$  in online atmospheric gas-particle and size-resolved particulate samples. These compounds have recently been suggested to play an important role in the formation of new respirable particles in the atmosphere, with few quantitative measurements available. The IC methods enable selective and quantitative detection of alkyl amines at ambient atmospheric concentrations (pptv and pg m<sup>-3</sup>) in samples where significant interferences can be expected from  $\text{Na}^+$  and  $\text{NH}_4^+$ . Sample pre-concentration enabled instrumental detection limits on the order of pmol (sub-ng) levels per sample, an improvement of up to 102 over current IC methods. Separation was achieved using gradient elution on Dionex CS12A and CS17 columns. The relative standard deviations in retention times during 3 week continuous (hourly) sampling campaigns ranged from 0.1 – 0.5 % and 0.2 – 5 %, respectively, across a wide dynamic range of atmospheric concentrations. Both methods have high analytical accuracy for the nitrogenous bases ranging from 9.5 – 20 % for  $\text{NH}_3$  and < 5 – 15 % for the amines. The IC methods were interfaced with an Ambient Ion Monitor (AIM), an online gas-particle collection system, and a Micro Orifice Uniform Deposit Impactor (MOUDI). In eight urban and rural MOUDI samples, the mass loading of amines consistently maximized on the stage corresponding to particles with aerodynamic diameters between 320 and 560 nm. The molar ratio of amines to ammonium ( $\text{R}_3\text{NH}^+/\text{NH}_4^+$ ) in fine aerosol ranged between

0.005 and 0.2, and maximized for the smallest particles, implicating amines as important particle precursors in the atmosphere. During AIM-IC campaigns in downtown Toronto and Egbert, ON DMA, TMA + DEA, and TEA were observed to range from below detection limit to 10 pptv in the gas phase. In the particle phase, MAH<sup>+</sup>, DMAH<sup>+</sup> and TMAH<sup>+</sup> + DEAH<sup>+</sup> were observed to range from below detection limit up to 15 ng m<sup>-3</sup>. These results highlight the need for sensitive and selective detection of methyl and ethyl amines in addition to NH<sub>3</sub> in continuous online monitoring strategies.

**MP114 Determination of Haloacetic Acids in Water by GC/ $\mu$ ECD and Strong Anion Exchange SPE** J. Stevens, D. Smith, K. Lynam, Agilent Technologies, Inc. / Chemistries and Supplies Division. The most widely used method for disinfecting water for public consumption is chlorination. During chlorination, oxidizing agents such as hypochlorite can react with any natural organic matter or bromide present in the raw water to form disinfection byproducts (DBPs). Many of these DBPs have classified as possible human carcinogens are regulated by the US Environmental Protection Agency (EPA) under Stage 1 Disinfectants/Disinfection Byproducts Rule. Haloacetic acids (HAAs) make up the second largest group of DBPs, after the trihalomethanes (THMs). There are nine HAAs (HAA9) recommended for monitoring. Five of the acids are grouped and regulated as the sum HAA5, which has an established maximum contaminant level (MCL) of 60 ng/mL. Although no current MCL has been established for the remaining acids, monitoring for all nine Haloacetic acids (HAA9) is encouraged. EPA Method 552.3 is currently used for compliance monitoring of HAA9, along with the chlorinated herbicide dalapon in drinking water. Although liquid-liquid extraction (LLE) is typically used for HAAs analysis, solid-phase extraction (SPE) offers several advantages, including high selectivity, high capacity, reduced solvent use, reduced preparation time, and reduced cost per analysis. Recent studies have shown successful utilization of SPE for HAAs extraction. Because Haloacetic acids are anionic at pH values above their pKa, a strong anion exchanger (SAX) can be used effectively to retain and preconcentrate these analytes. In this application, a silica-based quaternary ammonium strong anion exchanger was used as the SPE sorbent. A dual column GC/ $\mu$ ECD approach provided consistent and sensitive analysis for the derivatized HAAs. The detection limit for most of the HAAs was 0.05-0.05 ng/mL. Analyte recoveries at three fortifications levels (0.2-2, 1-10, 4-40 ng/mL) ranges from 82-116% with relative standard deviations (RSDs) < 3.5%.

**MP115 Determination of Pesticides and Pesticide Degradates in Filtered Water by Direct Aqueous Injection Liquid Chromatography Tandem Mass Spectrometry** M.W. Sandstrom, L.K. Kanagy, C.A. Anderson, U.S. Geological Survey / National Water Quality Laboratory; C.J. Kanagy, U.S. Geological Survey. An analytical method that utilizes liquid chromatography tandem mass spectrometry (LC/MS/MS) was developed for determination of 252 current-use pesticides and pesticide degradates in filtered water samples from streams and ground water. The pesticides represent a broad range of chemical classes including acetanilide and triazine herbicides, fungicides and organophosphate insecticides, and were selected based on criteria such as mass applied to agricultural and urban land, probability of occurrence in streams and ground water, and toxicity to humans or aquatic organisms. One unique aspect of the method is that it includes a large number (136) of pesticide degradates. The method uses direct injection of a filtered 100- $\mu$ L water sample into the LC/MS/MS; no other sample preparation is necessary. During analysis, two injections are used, one in electrospray ionization (ESI) positive mode and one in ESI negative mode, using dynamic multiple reaction monitoring (MRM) conditions, with two MRM transitions for each analyte. The LC and MS/MS instrument parameters were optimized to select conditions that provided the highest sensitivity for the majority of analytes. Recoveries of most of the analytes were from 80 to 120 percent, with standard deviations less than 20 percent over the concentration range of 10 to 5000 ng/L in the water matrices tested (reagent water, 2 streams and a ground water). Method detection limits (MDLs) for most analytes were from 2-50 ng/L in ESI positive mode, while MDLs were about an order of magnitude higher for analytes analyzed by ESI negative mode. Interferences in some stream samples caused low recovery of an internal standard that resulted in high recoveries of some analytes, indicating that careful monitoring of internal standard responses and selection of alternate internal standards is a requirement for accurate quantification. The LC/MS/MS method minimizes sample preparation while increasing sensitivity and accuracy, and is suitable for quantification of a broad range of important

pesticides and pesticide degradates at concentration levels relevant for environmental monitoring studies.

**MP116 Determination of Pharmaceutical Compounds in Great Lakes Top Predator Fish** X. Xia, B. Crimmins, P. Hopke, Clarkson University; J. Pagano, State University of New York at Oswego; M. Milligan, State University of New York at Fredonia; T. Holsen, Clarkson University. The Great Lakes Fish Monitoring Program (GLFMP), administered by the U.S. EPA Great Lakes National Program Office (GLNPO), aims to monitor temporal trends of emerging contaminants in the Great Lakes using top predator fish as biomonitors. Recent work has focused on identifying and quantifying emerging contaminants including pharmaceuticals in lake trout due to their toxicity and potential chronic effects on the aquatic environment. In this study, an ultra-high pressure liquid chromatography-Xevo G2 Qtof mass spectrometry (UPLC-HRMS) method was developed. Reversed-phase separation of pharmaceutical target compounds was achieved using an ACQUITY UPLC<sup>®</sup>HSS T3 column, and aqueous 0.1% (V/V) formic acid and methanol as mobile phases. Sample preparation procedure and analysis method will be discussed. The analytical results including detection limits of different target compounds will be presented.

**MP117 Development and Validation of Complementary LCMS and GCMS Methods to Examine Oxygenated-PAHs (OPAHs) in Environmental Mixtures** S.G. O'Connell, Oregon State University / Environmental and Molecular Toxicology; T. Haigh, G. Wilson, Oregon State University / Environmental and Molecular Toxicology Dept; K.A. Anderson, Oregon State University / Environmental & Molecular Toxicology, Oregon State University / Dept. of Environmental & Molecular Toxicology. Despite the reports of oxygenated polycyclic aromatic hydrocarbons (OPAHs) in publications for over three decades, quantitative analyses of these compounds have only started to make significant advances within the last few years. OPAHs, alternatively labeled oxy-PAHs, have one or more oxygen attached to the aromatic ring structure, and a few of these compounds have been reported as being persistent in the environment, and potentially more toxic than their PAH analogues. OPAHs may be formed from petrogenic or pyrogenic sources, but also through chemical oxidation, photo-oxidation, or biological transformation of un-substituted PAHs. In previous studies, both gas chromatograph (GC) and liquid chromatograph (LC) mass spectroscopy (MS) methods have successfully quantitated OPAHs in environmental samples, but methods often report only a handful of compounds, thus limiting environmental investigations. Using parallel and complementary methods of LC/APCI/MS and GC/EI/MS to analyze a suite of OPAH compounds has not been reported in any literature sources to our knowledge. Utilizing both chromatographic methods provides the identification and quantitation of 24 target OPAHs (log K<sub>ow</sub> 0.2-4.81), with 19 compounds shared between methods, and 3 quantitatively determined by GCMS (Xanthone, Chromone, and Perinaphthenone), and 2 by LCMS (1,6-Benzo[a]pyrenedione, and 7,8-Benzo[a]pyrenedione) in addition to labelled and deuterated standards. All 22 OPAHs in the GCMS method were within 15% accuracy, and had less than 15% relative standard deviations (RSDs), while the LCMS quantitated 19 of 21 non-labelled compounds within 20% accuracy, and less than 15% for RSDs using calibration standards (n=6). Instrumental limits of detection ranged from 0.006-0.528  $\mu$ g/mL using the GCMS, and only 0.010-0.021  $\mu$ g/mL on the LCMS. After method validation, both methods were used to examine OPAHs in complex mixtures from the Portland Harbor Superfund Site, OR. Using passive samplers deployed at this Superfund, several semi-polar organic compounds were identified in the complex extract mixture, including OPAHs. Current work will quantify any additional OPAHs present in the extracts using both complementary methods for a full analysis of 24 OPAH compounds.

**MP118 Development of a Sediment Collection Protocol and Sampling Device for Incremental Sampling in a Mid-Atlantic Tidal Creek and Marsh** J. Barber, U.S. Environmental Protection Agency; M. Ciarlo, EA Engineering, Science, and Technology, Inc., EA Engineering, Science, and Technology; K. Rigney, D. Straume, EA Engineering, Science, and Technology, Inc.. Incremental sampling of sediments presents unique challenges in estuarine environments where a broad range of water depths, sediment types, and habitats may be encountered. An incremental sampling protocol and specialized sampling equipment were developed as part of investigation of sediments in Darby Creek, a tidal estuary located near Philadelphia, PA. The protocol targeted 50 increments of the top 3 inches of sediment in
